AIP Publishing's mission is to advance, promote, and serve the physical sciences for the benefit of humanity. We connect our authors and readers to a living legacy of published science, to peers and institutions across the globe, and to myriad services, tools, and platforms which expand the impact and reach of groundbreaking scientific work.
Learn more at https://pubs.aip.org/aip/apq.

At **ASML** we're changemakers! Our growing team of over 40,000 people and 140 nationalities provides leading chipmakers with the hardware, software and services to mass produce patterns on silicon. We're probably part of the device you're reading this on right now.

Headquartered in Europe's prolific tech hub, the Brainport Eindhoven region in the Netherlands, we have over 60 locations globally and annual net sales of €28 billion in 2024. Want to be part of progress? Visit www.asml.com/careers.

Silver Sponsors

LINBOU Nearfield has been established since 2016, by a group of academic researchers specialized in field-matter interaction. Over the past 9 years, LINBOU has been providing customized electromagnetic and acoustic field scanners that are being used in top institutions, and achieving results in top journals such as Nature, Nature Materials, Nature Physics, etc. The field scanners are capable of visualizing electromagnetic / acoustic field interaction with materials, in either Cartesian coordinates by xyz stage or polar coordinates by rotating stage. Besides research-level scanners, LINBOU also provides teaching-level scanners with teaching experiments. Feel free to contact info@linbou.com for further information.

Learn more at https://www.linbou.com.

Founded in 2003, **PHASICS**, offers state-of-the-art optics metrology and imaging solutions. With over 20 years of expertise, their QuadriWave Lateral Shearing Interferometry (QWLSI) technology delivers ultra-high resolution, sub-nanometric sensitivity, and a wide dynamic range.

PHASICS' Quantitative Phase Microscopy (QPM) solutions support a broad range of applications—from optical metasurface characterization to refractive index variation measurements in bulk materials, and temperature mapping in thermonanoplasmonics.

Learn more at https://www.phasics.com.

The **MetacMed** - Acoustic and mechanical metamaterials for biomedical and energy harvesting applications, project is a European Doctoral Network (DN) funded by the European Commission under the Horizon 2022 Marie Sklodowska-Curie Action (MSCA), Grant Agreement n° 101119738, duration 48 months. MetacMed started on the 1st of March 2024, and will provide world-class interdisciplinary training to 12 Doctoral Candidates (DCs) in the area of acoustic and mechanical metamaterials for biomedical and energy harvesting applications. It consists of a well-balanced consortium that spans four European countries, plus Switzerland and the UK and incorporates academic, research centers and SMEs, interdisciplinary and inter-sectoral aspects of DC skill development.

Please, visit https://www.metacmed.eu for further details about the research program, DCs projects, and application procedures to follow.

Other Partners

Université Paris-Saclay is a research university based in Paris, France. Université Paris-Saclay offers a comprehensive and varied range of Undergraduate, Master's and PhD degrees, renowned internationally thanks to the University's reputation for research excellence and the commitment of its academic staff. The University's constituent faculties, institutes and component institutions all contribute to the curricula with cutting-edge specialized courses in Science and Engineering, Life Sciences and Health, and Social Sciences and Humanities.
Université Paris-Saclay is ranked 1st in France and 12th in the world according to the Academic Ranking of World Universities (ARWU).

AEM - Advanced Electromagnetics is a peer-reviewed, Gold Open Access journal. It covers recent international research results in the general field of Electromagnetic Waves, Antennas and Propagation. Authors of articles published in Advanced Electromagnetics retain the copyright of their articles and are free to reproduce and disseminate their work (under a Creative Commons Attribution License). AEM is widely indexed and has a Scopus CiteScore of 2.9 (2024).

Nanophotonics (De Gruyter) covers recent international research results, specific developments in the field and novel applications. It publishes all article in a Gold Open Access model and belongs to the top journals in the field. Nanophotonics focuses on the interaction of photons with nano-structures, such as carbon nano-tubes, nano metal particles, nano crystals, semiconductor nano dots, photonic crystals, tissue and DNA.

Advanced Devices & Instrumentation is an online-only Open Access journal published in affiliation with Beijing Institute of Aerospace Control Devices (BIACD) and distributed by the American Association for the Advancement of Science (AAAS). Like all partners participating in the Science Partner Journal program, Advanced Devices & Instrumentation is editorially independent from the Science family of journals and BIACD is responsible for all content published in the journal. To learn more about the Science Partner Journal program, visit the SPJ program homepage.

PLENARY SPEAKERS

Robert W. Boyd

University of Ottawa (Canada) & University of Rochester (USA)

Applications of highly nonlinear epsilon-near-zero materials in photonics

Robert W. Boyd received the B.S. degree in physics from the Massachusetts Institute of Technology and the Ph.D. degree in physics in 1977 from the University of California at Berkeley. His Ph.D. thesis was supervised by Charles Townes and involved the use of nonlinear optical techniques in infrared detection for astronomy. Professor Boyd joined the faculty of the Institute of Optics of the University of Rochester in 1977 and in July 2001 he became the M. Parker Givens Professor of Optics. In 2010, he became Professor of Physics and Canada Excellence Research Chair in Quantum Nonlinear Optics at the University of Ottawa. His research interests include studies of nonlinear optical interactions, studies of the nonlinear optical properties of materials, the development of photonic devices including photonic biosensors, and studies of the quantum statistical properties of nonlinear optical interactions. Professor Boyd has written two books, co-edited two anthologies, published over 200 research papers, and has been awarded five patents. He is a fellow of the Optical Society of America and of the American Physical Society and is the past chair of the Division of Laser Science of the American Physical Society.

Applications of highly nonlinear epsilon-near-zero materials in photonics
Optical materials display extremely large nonlinear response in a spectral band around their plasma frequency. This presentation reviews the origin of this behavior and provides examples of such materials and of applications enabled by this response.

Nader Engheta

University of Pennsylvania (USA)

Metastructures That Compute and Optimize

Nader Engheta is the H. Nedwill Ramsey Professor at the University of Pennsylvaniain Philadelphia with affiliations in the Departments of Electrical and Systems Engineering, Physics and Astronomy, Bioengineering, and Materials Science and Engineering. He received his BS degree from the University of Tehran, and his MS and Ph.D. degrees from Caltech. His current research activities span a broad range of areas including optics, metamaterials, electrodynamics, microwaves, photonics, nano-optics, graphene photonics, imaging and sensing inspired by eyes of animal species, microwave and optical antennas, and physics and engineering of fields and waves. He has received several awards for his research including the 2023 Benjamin Franklin Medal in Electrical Engineering, Election to the American Academy of Arts and Sciences (2023), Caltech Distinguished Alumni Award (2023), the 2020 Isaac Newton Medal and Prize from the Institute of Physics (UK), the 2020 Max Born Award from the OPTICA (formerly Optical Society), the 2019 Ellis Island Medal of Honor, the 2018 IEEE Pioneer Award in Nanotechnology, the 2022 Hermann Anton Haus Lecture at MIT, the 2015 SPIE Gold Medal, the 2014 Balthasar van der Pol Gold Medal from the International Union of Radio Science (URSI), the 2017 William Streifer Scientific Achievement Award, the Canadian Academy of Engineeringas an International Fellow the Fellow of US National Academy of Inventors (NAI), the IEEE Electromagnetics Award, the Vannevar Bush Faculty Fellowship Awardfrom DoD, the Wheatstone Lecture in King's College London, 2006 Scientific American Magazine 50 Leaders in Science and Technology, and the Guggenheim Fellowship. He is a Fellow of nine international scientificand technical organizations, i.e., IEEE, OPTICA, APS, MRS, SPIE, URSI, AAAS, IOP and NAI. He has received the honorary doctoral degrees from the Aalto University in Finland in 2016, the University of Stuttgart, Germany in 2016, and Ukraine's National Technical University Kharkov Polytechnic Institute in 2017.

Metastructures That Compute and Optimize

I will present some of the most recent results of our ongoing research projects on nonlocal metasurfaces and metastructures that perform ultrafast analog computation, such as vector-matrix multiplication, matrix inversion, constrained optimization, equation solving, etc. I will also discuss how incoherent light can be used for certain analog computations.

Ortwin Hess

Trinity College Dublin (Ireland)

Nanoplasmonic Quantum Photonics

Ortwin Hess currently holds the Chair Professorship of Quantum Nanophotonics and an SFI Research Professorship in the School of Physics and the CRANN Institute of Trinity College Dublin, The University of Dublin, Ireland. He is Editor-in-Chief of the gold open-access journal APL Quantum. Ortwin is a Fellow of the Institute of Physics (FInstP), a Fellow of Optica (formerly OSA) and a Professorial Fellow of Trinity College Dublin. Previously, Ortwin held the Leverhulme Chair in Metamaterials in the Blackett Laboratory at Imperial College London, UK. From 2003 to 2010 he was a full professor at the University of Surrey (Guildford, UK) and visiting professor at Stanford University, USA, and at the Ludwig-Maximilians University of Munich, Germany. Ortwin obtained the Dr.-rer-nat. (PhD) degree from the Technical University of Berlin, Germany in 1993 and the Habilitation (Dr.-habil.) at the University of Stuttgart, Germany in 1997. Ortwin's research interests bridge quantum nanophotonics with semiconductor and metamaterials physics, laser science and bio-medical photonics. He discovered the 'trapped-rainbow' principle, had the idea of stopped-light lasing and made defining contributions to the fields of spatio-temporal dynamics of semiconductor lasers, ultraslow light in metamaterials, complex quantum dot photonics and photonic crystals and strong coupling in nanoplasmonics. Ortwin pioneered active nanoplasmonics and optical metamaterials with quantum gain for which he has been awarded the Royal Society Rumford Medal.

Nanoplasmonic Quantum Photonics
Nanoplasmonic quantum photonics revolutionizes quantum information technologies by enabling room-temperature quantum operations through extreme nanoscale field confinement and strong photon-emitter coupling. This facilitates ultrafast single-photon emission, multipartite entanglement, near-field coupling, and quantum sensing, enhanced by quantum nanoplasmonic coherent perfect absorption, paving the way for practical quantumdevices operable at ambient conditions.

Stefanie Kroker

Technische Universität Braunschweig (Germany)

Routes for integrated photonics and meta-optics in quantum technologies and precision experiments

Stefanie Kroker studied Physics at Friedrich Schiller University in Jena/Germany and Universidad de Granada/Spain. She did her PhD with the Institute of applied Physics at Friedrich Schiller University in 2014 and became assistant professor at TU Braunschweig and the German national metrology institute, PTB in 2016. In 2020 Stefanie Kroker received the Science Award Lower Saxony and in 2021 she was appointed to a full professorship at TU Braunschweig. She is a member of the German clusters of excellence QuantumFrontiers and PhoenixD. Since 2023 she is associate editor of the journal APL Quantum. Stefanie's research covers nanophotonic and integrated optical systems for applications in sensing, high-precision metrology and quantum technologies. In 2024 she received a Consolidator Grant from the European Research Council.

Routes for integrated photonics and meta-optics in quantum technologies and precision experiments

Integrated photonics and meta-optics enable compact, precise light control, advancing optical metrology in applications like atomic clocks and gravitational wave detectors. This work explores nanophotonic devices for precision experiments and atom chips, focusing on light-matter interactions and the impact of material properties on performance and precision.

Gloria Platero Coello

ICMM-CSIC (Spain)

Robust Edge States in Topological Lattices for Quantum information Transfer

Gloria Platero Coello Gloria Platero is Research Professor at the Materials Science Institute of Madrid, at the CSIC (Spanish Research Council), which is located at the excellence Campus CSIC-UAM (Autonomous University of Madrid). She leads the group at ICMM: “New Platforms and Nanodevices for Quantum Simulation and Quantum Computation” https://wp.icmm.csic.es/npqsic/ and belongs to the University Institute Gregorio Millán on Nanoscience and Industrial Mathematics (Carlos III University of Madrid). She has given over hundred invited, keynote or plenary talks in international conferences and she has been invited to give seminars and to make stays in many research centers all over the world. She has been Mercator Fellow at the University of Regensburg. Supervisor of many PhD students, most of them are working successfully in Academia. She is Fellow or the APS (Quantum Information), and Secretary of the C8 IUPAP Commission on Semiconductor Physics. She will be Chair on January 2025. Her research belongs to the field of Quantum Nanotechnologies. She investigates the theory of spin qubits in quantum dot arrays, their manipulation and the transfer of quantum information in these systems, for quantum computation purposes. She also investigates hybrid systems: superconducting cavities coupled to qubits, where photons are the flying qubits. Time periodic driven systems is one of her main topics of research. She investigates as well, in different platforms as photonic crystals, the role of topological edge states for the transfer of quantum information.

Robust Edge States in Topological Lattices for Quantum information Transfer
This talk will deal with the transfer of quantum information using protected topological edge states. I will discuss the long-range transfer in a dimer chain, a 1D topological insulator, and in the Creutz-Ladder lattice and the role of topological domain walls to speed up the particle transfer.

Eli Yablonovitch

IUC Berkeley (USA)

What I Wish I Had Known, as I Searched for the First 3d Photonic Bandgap

Eli Yablonovitch is a Professor of Electrical Engineering and Computer Sciences at UC Berkeley, where he holds the James & Katherine Lau Chair in Engineering. He is the Director of the NSF Center for Energy Efficient Electronics Science (E3S), a multi-University Center headquartered at Berkeley.
Prof. Yablonovitch introduced the idea that strained semiconductor lasers could have superior performance due to reduced valence band (hole) effective mass. With almost every human interaction with the internet, optical telecommunication occurs by strained semiconductor lasers. He is regarded as a Father of the Photonic BandGap concept, and he coined the term "Photonic Crystal". The geometrical structure of the first experimentally realized Photonic bandgap, is sometimes called “Yablonovite”. In his photovoltaic research, Yablonovitch introduced the 4(n squared) (“Yablonovitch Limit”) light-trapping factor that is in worldwide use, for almost all commercial solar panels. His mantra that "a great solar cell also needs to be a great LED”, is the basis of the world record solar cells: single-junction 29.1% efficiency; dual-junction 31.5%; quadruple-junction 38.8% efficiency; all at 1 sun. His startup company Ethertronics Inc., has shipped over 2 billion cellphone antennas.
Prof. Yablonovitch is elected as a Member of the National Academy of Engineering, the National Academy of Sciences, the American Academy of Arts & Sciences, and is a Foreign Member of the Royal Society of London. He has been awarded the Buckley Prize of the American Physical Society, the Isaac Newton Medal of the UK Institute of Physics, the Rank Prize (UK), the Harvey Prize (Israel), the IEEE Photonics Award, the IET Mountbatten Medal (UK), the Julius Springer Prize (Germany), the R.W. Wood Prize, the W. Streifer Scientific Achievement Award, and the Adolf Lomb Medal. He also has an honorary Ph.D. from the Royal Institute of Technology, Stockholm, & the Hong Kong Univ. of Science & Technology, and is honorary Professor at Nanjing University.

What I Wish I Had Known, as I Searched for the First 3d Photonic Bandgap
The first 3-dimensional Photonic Bandgap was found by Edison-ian search, trial-and-error, guided by physical intuition. The 4-year search was beset by pseudo-gaps, and required deep physical insights to find the right geometry (diamond unit cell in a face-centered-cubic lattice). Nonetheless, there do exist mathematical techniques for 3d geometry optimization that could have led to the right structure more quickly.

KEYNOTE SPEAKERS

Andrea Alù

City University of New York (USA)

Space-time metamaterials

Andrea Alù is a Distinguished Professor at the City University of New York (CUNY), the Founding Director of the Photonics Initiative at the CUNY Advanced Science Research Center, and the Einstein Professor of Physics at the CUNY Graduate Center. He received his Laurea (2001) and PhD (2007) from the University of Roma Tre, Italy, and, after a postdoc at the University of Pennsylvania, he joined the faculty of the University of Texas at Austin in 2009, where he was the Temple Foundation Endowed Professor until Jan. 2018. Dr. Alù is a Fellow of the National Academy of Inventors (NAI), the American Association for the Advancement of Science (AAAS), the Institute of Electrical and Electronic Engineers (IEEE), the Materials Research Society (MRS), Optica, the International Society for Optics and Photonics (SPIE) and the American Physical Society (APS). He is the President of Metamorphose, a Highly Cited Researcher since 2017, a Simons Investigator in Physics, the director of the Simons Collaboration on Extreme Wave Phenomena Based on Symmetries, and the Editor in Chief of Optical Materials Express. He has received several scientific awards, including the NSF Alan T. Waterman award, the Blavatnik National Award for Physical Sciences and Engineering, the IEEE Kiyo Tomiyasu Award, the ICO Prize in Optics, the OSA Adolph Lomb Medal, and the URSI Issac Koga Gold Medal.

Space-time metamaterials
In this talk, I will discuss my group's recent work in the area of space-time metamaterials, with an emphasis on the use of abrupt time switching and spatio-temporal modulation patterns for efficient frequency translation and energy manipulation.

Harry Atwater

California Institute of Technology (USA)

Active Metastructures – Tailoring Space-Time and Breaking Reciprocity

Harry Atwater is the Otis Booth Leadership Chair of the Division of Engineering and Applied Science, and the Howard Hughes Professor of Applied Physics and Materials Science at the California Institute of Technology. Atwater's scientific effort focuses on nanophotonic light-matter interactions. His work spans fundamental nanophotonic phenomena and applications, including active wavefront shaping of light using metasurfaces, optical propulsion of lightsails, quantum and 2D nanophotonics as well as solar energy conversion, on earth and in space.

Atwater was an early pioneer in nanophotonics and plasmonics and gave a name to the field of plasmonics in 2001. He is Chair of the LightSail Committee for the Breakthrough Starshot program. Currently Atwater is also the Director for the Liquid Sunlight Alliance (LiSA), a Department of Energy Hub program for solar fuels, and was also the founding Editor in Chief of the journal ACS Photonics. Atwater is a Member of the US National Academy of Engineering, a Fellow of APS, MRS, SPIE and Optica, a Web of Science Highly Cited Researcher from 2014-2023, and is recipient of numerous awards, including the 2021 von Hippel Award of the Materials Research Society.

Active Metastructures – Tailoring Space-Time and Breaking Reciprocity
In this talk, I will discuss approaches to spatiotemporal wavefront control in active metastructures that can modify energy and momentum states of light, break reciprocity via space-time modulation, and break Kirchhoff's radiation law via action of external or internal magnetic fields.

Renaud Bachelot

Université de Technologie of Troyes (France) & Nanyang Technological University (Singapore)

Hybrid plasmonic nanosystems based on weak and strong coupling

Renaud Bachelot is a full professor of physics at the University of Technology of Troyes (UTT) that he joined in 1996 after graduate studies and PhD at the University of Paris-Cité and ESPCI graduate school (Paris, University PSL). His area of expertise includes nano-optics, nanophotonics, near-field optics, local light/polymer interaction, scanning probe microscopy, nano-optoelectronics and hybrid nanoplasmonics. He recently joined the CINTRA Lab (CNRS/NTU/CINTRA) as an Adjunct Senior Research Scientist. At UTT, R. Bachelot is the director of the Graduate School "Nanooptics & Nanophotonics" (nano-phot.utt.fr) including both master and PhD programs. From 2011 to 2019, RB has been the director of the Light, nanomaterials nanotechnologies CNRS Laboratory involving more than 100 people (l2n.utt.fr). His national and international influence includes current and past activities and positions such as (e.g.) adjunct professor at the LuMin Laboratory (University of Paris-Saclay), Board Member of the Faculty of Physics of Sorbonne University, elected board member of the French Society of Physics, condensed matter section division, adjunct-professor of the Shanghai University (since 2019, "1000-talents" award since 2020), invited scholar in Argonne National Laboratory, USA, and chair of the NFO-15 international conference that took place in August 2018 in Troyes, France. RB has (co)supervised 24 PhD students and is the co-author of more than 130 peer-reviewed articles (H=46, cf. google scholar), 10 book chapters and 5 patents.

Hybrid plasmonic nanosystems based on weak and strong coupling
Hybrid plasmonic nanosystems based on weak or strong coupling are discussed in terms of controlling the spatial distribution, and associated symmetry, of the active medium in the vicinity of the metallic nanocavities.

Guillaume Baffou

Institut Fresnel - CNRS (France)

Wavefront microscopy for nanophotonics

Guillaume Baffou is a CNRS researcher at the Institut Fresnel in Marseille, France. He graduated from the Ecole Normale Superieure de Cachan (now ENS Paris-Saclay) and earned his Ph.D. in Nanoscience from Paris XI University in 2007. Following his doctorate, he undertook a postdoctoral fellowship at ICFO, Barcelona, where he worked on plasmonics and related photothermal effects under the supervision of Prof. Romain Quidant. In 2010, he joined the CNRS and the Institut Fresnel. His contributions to research at the intersection of optics, thermodynamics, and small-scale biology have earned him several honors, including the CNRS Bronze Medal in 2015. In 2018, he was awarded an ERC Consolidator Grant. Most recently, during the 2023–2024 academic year, he spent a year at Columbia University in New York on a Fulbright grant, collaborating with Prof. Rafael Yuste's team.

Wavefront microscopy for nanophotonics
Cross-grating wavefront microscopy (CGM) consists of the association of a 4-wave diffraction grating and a camera separated by millimeter distance. We show how CGM can be used to measure the optical properties of nanoparticles, 2D material a metasurfaces, such as the complex optical polarizability, conductivity, refractive indices, and cross-sections.

Konstantin Bliokh

Donostia International Physics Center (Spain)

Chiral Vortices, Skyrmions, Möbius Strips: From Nanooptics to Ocean Waves

Konstantin Bliokh received the MSc and PhD degrees in physics from the Kharkov National University (Ukraine) in 1998 and 2001, respectively. After that, he worked as a research scientist at the Institute of Radio Astronomy (Ukraine, 2001–2009). He was a post-doctoral fellow at Bar-Ilan University (Israel, 2003–2005), a visiting research scientist at Technion–Israel Institute of Technology (Israel, 2007), a Linkage International research fellow at the Australian National University (Australia, 2008–2009), a Marie Curie research fellow at the National University of Ireland (Ireland, 2009–2011), an associate professor at the Australian National University (Australia, 2015–2019), and a senior research scientist at RIKEN (Japan, 2011–2024). Starting from 2024, he is an Ikerbasque Professor at the Donostia International Physics Center (Spain). His ongoing research areas include: complex wave systems, geometric phases, spin-orbit interactions, wave momentum and angular momentum, wave vortices, wave-matter interactions, etc. He has co-authored more than 130 scientific papers, reviews, and book chapters.

Vortices, Skyrmions, Möbius Strips: From Nanooptics to Ocean Waves
I will present recent theoretical and experimental results on: (i) subwavelength high-intensity vortices around 'holes' in 2D wave systems: from polaritons to ocean waves, (ii) Bessel-type vortices, displacement-field skyrmions, and polarization Möbius strips in sound and water waves, and (iii) manipulation of floating particles using topologically structured water waves.

Alexandra Boltasseva

Purdue University (USA)

Quasi-2D Materials: From Tailorable Photonics to New Physics

Alexandra Boltasseva is a Ron and Dotty Garvin Tonjes Distinguished Professor of Electrical and Computer Engineering with courtesy appointment in Materials Engineering at Purdue University. She received her PhD in electrical engineering at Technical University of Denmark, DTU in 2004. Boltasseva specializes in nanophotonics, quantum photonics, and optical materials. She is the 2023 recipient of the R.W. Wood Prize (Optica, formerly Optical Society of America), 2022 Guggenheim Fellow, 2018 Blavatnik National Award for Young Scientists Finalist and received the 2013 Institute for Electrical and Electronics Engineers (IEEE) Photonics Society Young Investigator Award, 2013 Materials Research Society (MRS) Outstanding Young Investigator Award, the 2011 MIT Technology Review Top Young Innovator (TR35), the 2009 Young Researcher Award in Advanced Optical Technologies from the University of Erlangen-Nuremberg, Germany, and the Young Elite-Researcher Award from the Danish Council for Independent Research (2008). She is a Fellow of the National Academy of Inventors (NAI), MRS, IEEE, Optica, and SPIE. She served on MRS Board of Directors and is former Editor-in-Chief for Optical Materials Express journal.

Quasi-2D Materials: From Tailorable Photonics to New Physics
We discuss the designer-like characteristics of MXenes, achievable with the choice of transition metal and control of stoichiometry, remarkable tailorability of properties of TD materials with the thickness, and ultra-fast TCOs response. We also explore new device concepts for flat optics/metasurfaces.

Kai Chang

Zhejiang University (China)

Exotic Exciton Phases in Two-Dimensional Quantum Materials

Kai Chang is a chair professor at the School of Physics, Zhejiang University. His research focuses on semiconductor physics and device physics, topological quantum matter and spintronics for decades. He has published more than 200 SCI papers including Nature sub-journals, PRL and other SCI papers. He won the second-class prize of the National Natural Science Award in 2004, and was awarded the 2013 Chinese Physical Society Huang Kun Solid State Physics and Semiconductor Physical Science Award. In 2019, he was elected as an academician of the Chinese Academy of Sciences. He is currently a member of the C8 Committee on Semiconductor Physics of the International Union of Pure and Applied Physics (IUPAP).

Exotic Exciton Phases in Two-Dimensional Quantum Materials
Exciton insulator phases has attracted intensive interests in 2D systems. We demonstrate the existence of topological exciton in InAs/GaSb quantum wells resilient to intense in-plane magnetic fields, identify conventional and novel topological exciton density waves in van der Waals systems, and propose light-engineered exciton supersolidity in heterostructures.

Zhigang Chen

Nankai University (China)

Empowering Topological Photonics for OAM Manipulation

Zhigang Chen is currently a Chair Professor at Nankai University, a recipient of China's National Overseas High-Level Talent Program, and a Chief Scientist of a National Key R&D Program. His research interests include nonlinear optics, topological photonics, and optical trapping and manipulation. Dr. Chen is a Fellow of both Optica and the American Physical Society (APS). He has served as an editor or editorial board member for several journals, including Light: Science & Applications, Laser & Photonics Reviews, Optics Letters, Science Bulletin, and Advances in Physics: X. He has also chaired numerous international conferences, including CLEO-Fundamental Science and the Nonlinear Optics Topical Meeting.

Empowering Topological Photonics for OAM Manipulation
In this talk, we present a few demonstrated examples of topology-driven photonic applications based on the simplest topological model. Building on these foundations, we introduce our design and implementation of more advanced photonic structures that enable robust optical vortex transport and effective manipulation of orbital angular momentum (OAM).

Karin Everschor-Sitte

University of Duisburg-Essen (Germany)

Rethinking Linking - Topology in Magnetism, and Plasmonics

Karin Everschor-Sitte is a professor of Theoretical Physics at the University of Duisburg-Essen in Germany. Her main scientific research fields are the complex fundamental physics of topological magnetic textures and spintronics-based unconventional computing. After completing her PhD at the University of Cologne in 2012, Karin Everschor-Sitte worked as a postdoc at the Technical University Munich and then received a DAAD postdoctoral fellowship to conduct research at the University of Texas at Austin. Followed by a period as a postdoc, she led an Emmy Noether group at the Johannes Gutenberg University Mainz, from 2016 to 2021. In 2018, she received the Hertha-Sponer-Prize, and in 2024, she was honored as the Wohlfarth Lecturer.

Rethinking Linking - Topology in Magnetism, and Plasmonics
Topology in physics explores robust, fault-tolerant states of matter aiming at practical applications. Similar topological structures arise in magnetism, optics, and plasmonics despite differing physics. A challenge is understanding them when traditional mathematical topological frameworks are not necessarily applicable. Linking and geometry offer intuitive ways to describe these complex textures.

Vivian Ferry

University of Minnesota (USA)

Computational Models of Light Management in Photovoltaics and LEDs

Vivian Ferry is an Associate Professor in the Department of Chemical Engineering and Materials Science at the University of Minnesota. Prior to joining Minnesota, she was a Postdoctoral Fellow at Lawrence Berkeley National Laboratory working with Prof. A. Paul Alivisatos , and she received her PhD in Chemistry from the California Institute of Technology working with Prof. Harry A. Atwater. Her work in nano-optics and optical materials has resulted in more than 50 journal publications. Her research includes fundamentals of optical materials and applications, including chiral materials, phase-change materials, luminescent materials and composites, large-area fabrication of nanostructures, and applications to energy, sensing, and optoelectronic devices. She is the recipient of an NSF CAREER award, an Air Force Office of Scientific Research Young Investigator Award, the Marion Milligan Mason Award for Women in the Chemical Sciences, the SPIE Early Career Achievement Award, and was named as one of Technology Review's 35 Innovators under 35.

Computational Models of Light Management in Photovoltaics and LEDs
This talk will discuss the computational models for light management strategies in photovoltaics, including systems that integrate luminescent solar concentrators in greenhouses and reduce the temperature of outdoor panels.

Mark C. Hersam

Northwestern University (USA)

Chemically Functionalized 2D Materials for Quantum Photonic Science and Technology

Mark C. Hersam is the Walter P. Murphy Professor of Materials Science and Engineering, Director of the Materials Research Center, and Chair of the Materials Science and Engineering Department at Northwestern University. He also holds faculty appointments in the Departments of Chemistry, Applied Physics, Medicine, and Electrical Engineering. He earned a B.S. in Electrical Engineering from the University of Illinois at Urbana-Champaign (UIUC) in 1996, M.Phil. in Physics from the University of Cambridge (UK) in 1997, and Ph.D. in Electrical Engineering from UIUC in 2000. His research interests include nanoelectronic materials, additive manufacturing, scanning probe microscopy, renewable energy, sensors, neuromorphic computing, and quantum information science. Dr. Hersam has received several honors including the Presidential Early Career Award for Scientists and Engineers, TMS Robert Lansing Hardy Award, MRS Mid-Career Researcher Award, AVS Medard Welch Award, U.S. Science Envoy, MacArthur Fellowship, and eight Teacher of the Year Awards. Dr. Hersam has been repeatedly named a Clarivate Analytics Highly Cited Researcher with over 700 peer-reviewed publications that have been cited more than 78,000 times. An elected member of the American Academy of Arts and Sciences, National Academy of Engineering, and National Academy of Inventors with over 170 issued and pending patents, Dr. Hersam has founded two companies, NanoIntegris and Volexion, which are suppliers of nanoelectronic and battery materials, respectively. Dr. Hersam is a Fellow of MRS, ACS, ECS, AVS, APS, AAAS, SPIE, and IEEE, and also serves as an Executive Editor of ACS Nano.

Chemically Functionalized 2D Materials for Quantum Photonic Science and Technology
Chemical functionalization allows tailoring of the properties of 2D materials and the degree of coupling across heterointerfaces. In this talk, the prospects of 2D materials for quantum photonic science and technology will be discussed with a focus on how chemical functionalization can enhance quantum emission in 2D transition metal dichalcogenides.

Maria Kafesaki

University of Crete & FORTH (Greece)

Empowering chiral metamaterials with gain materials

Maria Kafesaki is Professor in the Dept. of Materials Science and Engineering of the University of Crete and Adjunct Researcher at the Institute of Electronic Structure and Laser (IESL) of Foundation for Research and Technology Hellas (FORTH). She obtained her Ph.D. from the Physics Department of the University of Crete, Greece. She has worked as post-doctoral researcher in CSIC in Madrid, Spain, and in IESL of FORTH. Her current research is on the area of electromagnetic wave propagation in periodic and random media, with emphasis on metamaterials, where she has large theoretical and computational experience. She has more than 140 publications in refereed journals and more than 80 invited talks at international conferences/schools and Institutions. She has participated in many European projects as well as in the organization of many international conferences and schools. She is Fellow of Optica.

Empowering chiral metamaterials with gain materials
We will review our recent works on chiral metamaterials involving gain materials and on chiral metamaterials combining gain and loss. Special attention will be given to parity-time symmetric chiral metamaterials and to chiral metamaterials for circularly polarized laser emission.

Alexander V. Kildishev

Purdue University (USA)

Beyond the Voigt lineshapes: Efficient statistics-convolved approximants in the time domain

Alexander V. Kildishev works on theory and numerical modeling for nanophotonics. He has had several breakthrough results on negative refractive index metamaterials, optical artificial magnetic structures, loss compensation in metamaterials, plasmonic nanolasers, optical metasurfaces, optical cloaks, and hyperlenses. His current interests also cover the AI-driven inverse design of metadevices in optics and acoustics. He has been included on the Highly Cited Researchers List for the years of 2018, 2022, and 2023 in Web of Science (WOS), which recognizes world-class researchers selected for their exceptional research performance with multiple highly cited papers that rank in the top 1% by citations in the cross-field category. Prof. Kildishev is a Fellow of Optica (OSA).

Beyond the Voigt lineshapes: Efficient statistics-convolved approximants in the time domain
We present a minimax-based approach for efficient time-domain modeling of optical responses from materials with disorder. The utility of our approach, generally applicable to symmetric and non-symmetric disorder statistics, is demonstrated by the non-classical oscillator, relaxation, and conductivity models, achieving the shortest possible numerical stencil for a given controlled accuracy.

Philippe Lalanne

Institut d'Optique - CNRS (France)

Tailoring the visual appearance with correlated-disorder metasurfaces

Philippe Lalanne currently works as a CNRS Research Scientist in Bordeaux. He is an expert in nanoscale electrodynamics. Over the course of his career, he has introduced novel modal theories, established general principles for designing high-Q microcavities, clarified the role of plasmons in the extraordinary optical transmissions, and demonstrated the first high-NA optical metalenses using high-index nanostructures during the late 1990s. Presently, his research interest focuses on the non-Hermitian interaction of light with nanoresonators and disordered optical metasurfaces. From 2018 to 2022, he held the role of Director for the GDR Ondes that gathers the French community working on electromagnetic waves. He received several distinctions, including the prestigious 2023 ERC Advanced grant. He is a fellow of IOP, SPIE and OPTICA.

Tailoring the visual appearance with correlated-disorder metasurfaces
We will review our current effort to model the resonance of individual resonators and collections of them with various theories, including quasinormal modes expansion and multiple scattering.

Howard Lee

UC Irvine (USA)

Functional "Meta"-Optical Fibers for Advanced Imaging and Endoscopy

Howard Lee is currently an Associate Professor in the Department of Physics and Astronomy at UC Irvine. Before joining UCI in 2020, he was an Associated Professor in the Department of Physics at Baylor University and IQSE Fellow and visiting professor in the Institute for Quantum Science and Engineering (IQSE) at TexasA&M. He was a Postdoctoral Fellow at the Caltech, working with Prof. Harry Atwater in active plasmonics/metasurfaces. He received his PhD in Physics from the Max Planck Institute for the Science of Light in Germany in 2012 under the supervision of Prof. Philip Russell. His work on nano-optics, plasmonics/metasurfaces, and fiber optics has led to 50 journal publications in various journals, such as Science, Nano Letters, Advanced Materials, as well as 100 invited talks and 180 conference papers. Dr. Lee is a recipient of a 2025 IEEE Photonics Society Distinguished Lecturer, a 2024 SPIE Fellow, a 2023 Finalist of Moore Inventor Fellow, a 2023 UCI Beall Innovation Award in Physical Sciences, a 2022 Finalist of Moore Inventor Fellow, a 2021 iCANX Young Scientist Awarcd, a 2021 Finalist of Rising Stars of Light, 2020 SPIE Rising Researcher, a 2019 DARPA Director's Fellowship, a 2019 IEEE OGC Young Scientist Award, a 2018 NSF CAREER Award, a 2017 DARPA Young Faculty Award, a 2018 OSA Ambassador, and a 2017 APS Robert S. Hyer Award. He has strong passion in promoting optical sciences and physics to students and the general public, and in serving for the professional communities. He organized more than 25 technical sessions in nanophotonics/metasurfaces in international conferences (Optica, META, PQE, MRS, IEEE) and serves as Lead Symposium Organizer for plasmonic/metasurface symposiums at 2019-2025 MRS Fall Meeting and 2020-2025 MRS Spring Meeting (organized > 2000 presentations).

Functional "Meta"-Optical Fibers for Advanced Imaging and Endoscopy
In this talk, I will review the various material platforms (metallic, dielectric, and compound structures) and geometric platforms which have been utilized in "meta"-fiber devices to date. I will present our recent development of "Meta"-optical fiber, an advanced optical fiber integrated with emerging metasurface concepts. I will present the development of ultrathin optical metalens which is cascaded on the facet of optical fiber that enables advanced optical functions via wavefront shaping such as light focusing.

Konstantinos Makris

University of Crete - FORTH (Greece)

Non-normality, Pseudospectra and Exponential sensitivity

Konstantinos Makris is Associate Professor in the Department of Physics, of the University of Crete and Affiliated Researcher at the Institute of Electronic Structure and Laser (IESL) of Foundation for Research and Technology Hellas (FORTH). He obtained his PhD in Theoretical Photonics from the School of Optics and Photonics (CREOL-FCPE) at the University of Central Florida, Orlando (USA) in 2008. From 2008 until 2010 he was a postdoctoral researcher at Ecole Polytechnique Federale de Lausanne (EPFL), Switzerland. During 2011 he was Lecturer at Institute for Theoretical Physics of Vienna University of Technology (TU-Wien), Austria. From 2012 until 2015 he was a Marie Curie fellow between Princeton University, USA and TU-Wien, Austria. His current research interests lie on non-Hermitian physics, nonlinear optics, photonics lattices and wave propagation in complex media. He has more than 100 publications in refereed journals and more than 60 invited talks-colloquia at international conferences/schools and Institutions. In 2022 he was awarded an ERC consolidator grant related to open disorder systems. He was also elected as a 2023 Fellow of OPTICA (former OSA).

Non-normality, Pseudospectra and Exponential sensitivity
In the context of non-Hermitian photonics, we present recent results regarding non-normal optical waveguides. We investigate photonic lattices with gain/loss, as well as, asymmetric couplings and study their spectral and dynamical response based on pseudospectra theory. The recent notions of exponential sensitivity, and power eigenchannels will be also discussed.

Marco Miniaci

IEMN-CNRS (France)

Bioinspired metamaterials

Marco Miniaci is a permanent researcher at the French National Scientific Research Centre (CNRS) appointed at the Institute of Electronics, Microelectronics and Nanotechnology (IEMN) of Villeneuve D'Ascq, in France. His research interests cover theoretical, numerical, and experimental aspects of wave propagation and structural mechanics of phononic crystals and elastic metamaterials. Marco Miniaci currently is the principal investigator of the ERC StG « POSEIDON » (dealing with bioinspired metamaterials, topological protection and underwater acoustics), coordinator of the MAGNIFIC HORIZON-CL4-2022-RESILIENCE-01-10 (dealing with materials for a next generation of (nano-)opto-eòectro-mechanical systems), and participate into the MetAcMed HORIZON-MSCA-2022-DN-01 (dealing with acoustic and mechanical metamaterials for biomedical and energy harvesting applications).

Bioinspired metamaterials

Sir John Pendry

Imperial College London (UK)

Talk 1. Quantum Aspects of Light Propagation in Time-Varying Media

Talk 2. Modulating Optical Properties in Time Using Plasmonic Resonances

John Pendry has worked at the Blackett Laboratory, Imperial College London, since 1981. His research at Imperial College reflects his broad interests in physics but has recently concentrated on optics and electromagnetism in general. In collaboration with scientists at The Marconi Company he designed a series of 'metamaterials' whose properties owed more to their micro-structure than to the constituent materials. The metamaterial concept caught on and now is a major topic not only of research activity, but also of application to 5G and 6G network technology, MRI, satellite communications and much else, though popular interest has concentrated on his design for a cloak of invisibility.

Talk 1. Quantum Aspects of Light Propagation in Time-Varying Media
Recent experiments demonstrate ultra-fast modulation of refractive indices opening up the field of space-time modulation. Breaking time invariance presents new challenges to theory with the removal of conservation of energy/frequency. New conservation laws are emerging which deepen our understanding of these systems.

Talk 2. Modulating Optical Properties in Time Using Plasmonic Resonances
Plasmonic effects in Indium Tin Oxide enable rapid switching of transparency which can be exploited to modulate THz radiation on a fs time scale.

Kaushik Senguptav

Princeton University (USA)

AI to Discover and Synthesize Sub-terahertz Chips beyond Human Intuition

Kaushik Sengupta received his Ph.D. in Electrical Engineering from Caltech in 2012. Dr. Sengupta joined the Department of Electrical and Computer Engineering at Princeton University, Princeton, NJ, as a Faculty Member in 2013, where he is currently a Professor. His research interests include novel chip-scale architectures for intelligent sensing and communication for a wide range of emerging applications.
Dr. Sengupta is an IEEE Fellow. He received the DARPA Young Faculty Award in 2018, the Bell Labs Prize in 2017, the Young Investigator Program Award from the ONR in 2017, the 2015 Microwave Prize, and multiple best paper awards in IEEE IMS and RFIC. He served as a Distinguished Lecturer for the IEEE Solid-State Circuits Society from 2019 to 2020 and for the IEEE Microwave Theory and Technology Society from 2021 to 2023. He is a recipient of the 2021 IEEE Microwave Theory and Technology Outstanding Young Engineer Award and the 2022 IEEE Solid-state Circuits New Frontier Award. He currently serves as the co-chair of the IEEE Solid-state Directions Sub-committee and as a technical advisor for the wireless start-up company, GuRu, based in Pasadena, CA. His group received IEEE Journal of Solid-State Circuits Best Paper of the Year in 2023.

AI to Discover and Synthesize Sub-terahertz Chips beyond Human Intuition
Traditionally, chip-scale high-frequency system design has been in the domain of the experts. We demonstrate here for the first time how AI can not only allow design times that are orders of magnitude faster, but also unearth new sub-THz chip architectures that are beyond human intuition.

Vladimir M. Shalaev

Purdue University (UK)

Silicon Quantum Photonics

Vladimir M. Shalaev, Scientific Director for Nanophotonics at Birck Nanotechnology Center and Distinguished Professor of Electrical and Computer Engineering at Purdue University, specializes in nanophotonics, plasmonics, optical metamaterials and quantum photonics. Prof. Shalaev has received several awards for his research, including the APS Frank Isakson Prize for Optical Effects in Solids, the Optica (formerly, Optical Society of America) Max Born Award for his pioneering contributions to the field of optical metamaterials, the Willis E. Lamb Award for Laser Science and Quantum Optics, IEEE Photonics Society William Streifer Scientific Achievement Award, Rolf Landauer medal of the ETOPIM (Electrical, Transport and Optical Properties of Inhomogeneous Media) International Association, the UNESCO Medal for the development of nanosciences and nanotechnologies, and the OSA and SPIE Goodman Book Writing Award. Prof. Shalaev is recognized as a Highly Cited Researcher in physics by the Web of Science Group for 7 consecutive years, in 2017-2023. He is a Fellow of the IEEE, APS, SPIE, MRS and Optica.

Silicon Quantum Photonics
We discuss scalable quantum photonics circuitry based on room-temperature single-photon emitters in silicon nitride that we recently discovered in this technologically important material platform. We also consider integration of SiN single-photon emitters with waveguides as well as the quantum emission enhancement through integration with resonant cavities and plasmonic nanostructures.

Marin Soljačić

MIT (USA)

Certain intersections of AI and Photonics

Marin Soljačić is a Professor of Physics at MIT. He is a founder of a few companies, including WiTricity Corporation (2007) and Lightelligence (2017). His main research interests are in artificial intelligence as well as electromagnetic phenomena, focusing on nanophotonics, non-linear optics, and wireless power transfer. He is a co-author of more than 300 scientific articles, more than 100 issued US patents, and he has been invited to give more than 100 invited talks at conferences and universities around the world. He is a recipient of the Adolph Lomb medal from the Optical Society of America (2005), and the TR35 award of the Technology Review magazine (2006). In 2008, he was awarded a MacArthur fellowship "genius" grant. He is an international member of the Croatian Academy of Engineering since 2009. In 2011 he became a Young Global Leader (YGL) of the World Economic Forum. In 2014, he was awarded Blavatnik National Award, as well as Invented Here! (Boston Patent Law Association). In 2017, he was awarded "The Order of the Croatian Daystar, with the image of Ruđer Bošković", the Croatian President's top medal for Science. In 2017, the Croatian President also awarded him with "The Order of the Croatian Interlace" medal. He was a Highly Cited Researcher according to WoS for 2019, 2020, 2021, 2022 & 2023. In 2023, he was awarded Max Born award of Optica.

Certain intersections of AI and Photonics
This talk will explore how photonics can enhance AI hardware and how AI can accelerate photonics research. Topics will include large language models for scientific discovery and robotics for photonics experiments, highlighting key opportunities and challenges at this intersection.

Clivia M. Sotomayor Torres

Iberian Nanotechnology Laboratory - INL (Portugal)

Spectral Frequency Response of Hypersonic Phonons in a Non-Trivial Topological Waveguide

Clivia M. Sotomayor Torres obtained her PhD in Physics in 1984 from the University of Manchester, UK. She held tenured academic appointments at Saint Andrews and Glasgow universities in the UK, at Wuppertal University in Germany and was a research professor at the National university of Ireland University College Cork (Tyndall National Institute). From 2007 to 2023 she was an ICREA research professor and group leader of the Phononic and Photonic Nanostructures group at the ICN2 in Spain. Clivia received awards from the Royal Society of Edinburgh, the Nuffield Foundation and an Amelia Earhart Fellowship from ZONTA International (USA). She carries out research in the science and engineering of phononic nanostructures, nanophotonics and thermal transport. In 2020 she was elected to the Academia Europaea. She is holder of an European Research Council advanced grant investigating phonon transport in topological waveguides. Since September 2023 she is the Director General of the International Iberian Nanotechnology Laboratory (INL) in Braga, Portugal, where she has set up a new research group.

Spectral Frequency Response of Hypersonic Phonons in a Non-Trivial Topological Waveguide
The spectral frequency response of a hypersonic phononic wave propagating along a non-trivial topological waveguide is obtained by laser Doppler vibrometry. The guided mode at 2.115 GHz is shown to propagate with minimal loss..

Vincent Tourna

Laboratory of Acoustics - CNRS, Le Mans University (France)

Transition waves in multistable mechanical metamaterials

Vincent Tournat currently holds a Research Professor position at CNRS and conducts research in the field of nonlinear waves and acoustics at the Laboratory of Acoustics at Le Mans University in France. VT graduated with a major in solid state physics, acoustics & wave physics and defended his PhD thesis on nonlinear acoustics in granular materials in 2003. He then spent the year 2004 as a postdoc at Hokkaido University, Japan, working on laser picosecond ultrasonics, prior to starting at CNRS. During his first years at CNRS, he established two research groups on acoustics of granular media and laser ultrasonics, then participated in developing two other areas of research in his department, ultrasonic non-destructive testing, and acoustic metamaterials. For the last decade, his research focuses on nonlinear waves in flexible mechanical metamaterials. From 2007 to 2022, VT led the "Acoustics and Mechanics of Materials" research team of more than 50 people. His research achievements have been awarded prizes on several occasions, including the CNRS Bronze Medal in 2010 and the Silver Whistle early career award by the International Commission on Ultrasonics (ICU) in 2013. Until 2024, he has been the director of the Institut d'Acoustique - Graduate School (http://iags.univ-lemans.fr) created in 2017 and awarded the national label "Graduate School" (a selection of few Institutes comprising high impact research laboratories, departments, as well as recognized master, engineering and doctoral curriculae). VT has been regularly invited for research visits in Japan, Chile, Spain, USA and he is a visiting research Professor at Harvard University since September 2022. https://perso.univ-lemans.fr/ vtournat/

Transition waves in multistable mechanical metamaterials
I will highlight the fundamentals and a selection of recent results on transition waves triggering, propagation, and discuss some of their potential applications. In general, these reconfiguration fronts obey nonlinear reaction-diffusion equations and show specific properties not necessarily found in other waves supported by periodic and/or nonlinear media.

Seokho Yun

Samsung Advanced Institute of Technology - SAIT (Korea)

AI-Driven Photonics: From Metaphotonics to Silicon Photonics Integration

Seokho Yun is the Vice President of Technology at the Samsung Advanced Institute of Technology (SAIT), where he leads the Photonics Research Team, advancing research and development in meta-photonics and silicon photonics. His expertise lies in meta-photonics and silicon photonics, with a strong focus on enhancing device performance, enabling miniaturization, and pioneering innovative functionalities. He earned his Ph.D. in Electrical Engineering from Pennsylvania State University and conducted postdoctoral research at the Materials Research Science & Engineering Center, specializing in metamaterials and plasmonics applications.
Since joining Samsung Electronics in 2012, he has played a key role in leading meta-photonics sensor projects. Under his leadership, in February 2025, his team successfully commercialized the world's first image sensor integrating meta-photonic color-routing nanostructures. As the demand for high-speed data processing continues to accelerate in the AI era, he is spearheading the development of next-generation ultra-high-speed optical interconnect technologies based on silicon photonics. Additionally, he is driving research on the convergence of silicon photonics and meta-photonics, shaping the future of photonics innovation.

AI-Driven Photonics: From Metaphotonics to Silicon Photonics Integration
As we enter the AI era, photonics is evolving beyond boundaries. This keynote explores advances in metaphotonics and silicon photonics—enabling next-generation image sensors, LiDAR, micro-LED displays, and optical interconnects. Their convergence opens new pathways to compact, power-efficient, and high-performance devices that elevate the capabilities of future optical systems.

Nikolay Zheludev

University of Southampton (UK)

Photonic Metamaterial Time Crystals and Timetronics

Nikolay Zheludev 's research interest are in nanophotonics and metamaterials. He is the Deputy Director of the Optoelectronics Research Centre in Southampton University, UK. Prof. Zheludev is elected as a Fellow of the Royal Society (UK) and Member of the USA National Academy of Engineering. He is a Fellow of the European Physical Society (EPS), the Optical Society (OSA) and the Institute of Physics (London). He has been awarded the Michael Faraday Gold Medal, Thomas Young Medal and President of Singapore Science and Technology Award.

Photonic Metamaterial Time Crystals and Timetronics
We discuss recent developments in understanding functionalities and developing applications of time crystals - a new state of matter, a many-body interacting system that exhibits a spontaneous mobilization transition to the robust state of oscillation, breaking time translation symmetry under an infinitely small change of the external driving force.

TUTORIAL

Prof. Andrea Alù

City University of New York (USA)

Wednesday 23th July
14:00 - 15:00 — Torremolinos

Nonlocal metasurfaces

Andrea Alù is a Distinguished Professor at the City University of New York (CUNY), the Founding Director of the Photonics Initiative at the CUNY Advanced Science Research Center, and the Einstein Professor of Physics at the CUNY Graduate Center. He received his Laurea (2001) and PhD (2007) from the University of Roma Tre, Italy, and, after a postdoc at the University of Pennsylvania, he joined the faculty of the University of Texas at Austin in 2009, where he was the Temple Foundation Endowed Professor until Jan. 2018. Dr. Alù is a Fellow of the National Academy of Inventors (NAI), the American Association for the Advancement of Science (AAAS), the Institute of Electrical and Electronic Engineers (IEEE), the Materials Research Society (MRS), Optica, the International Society for Optics and Photonics (SPIE) and the American Physical Society (APS). He is the President of Metamorphose, a Highly Cited Researcher since 2017, a Simons Investigator in Physics, the director of the Simons Collaboration on Extreme Wave Phenomena Based on Symmetries, and the Editor in Chief of Optical Materials Express. He has received several scientific awards, including the NSF Alan T. Waterman award, the Blavatnik National Award for Physical Sciences and Engineering, the IEEE Kiyo Tomiyasu Award, the ICO Prize in Optics, the OSA Adolph Lomb Medal, and the URSI Issac Koga Gold Medal.

Nonlocal metasurfaces
The use of engineered nonlocal responses in metasurfaces has been recently unveiled as a paradigm for extreme wave control, enabling rational control over space, time, frequency and momentum of the incoming signals, as well as analog-based image processing and computing. Several recent demonstrations of metasurfaces performing edge-detection and image-processing using engineered spatial nonlocality have shown a path towards ultrafast, efficient, massively parallel analog image processing based on passive devices, which holds the promise for being extended towards general analog computing platforms. Space-time nonlocal metasurfaces performing the space- and time-derivatives of the incoming signal were also envisioned by tailoring their frequency and momentum dispersion. In this tutorial, I will discuss the basics of nonlocality engineering in metasurfaces and their various implementations and opportunities for this field of research, showcasing compact meta-structures with reconfigurable properties that can perform mathematical operations, solve compact mathematical problems and address the issues of reprogrammability and cascaded responses. I will discuss how these findings may open exciting opportunities for applications in imaging, automotive vehicles, sensing and computing, and serve as a pre-processing tool for simplifying complex computing architectures.

The tutorial is free and open to all META conference attendees.

GUIDELINES FOR PRESENTERS

Oral Presentations

Each session room is equipped with a stationary computer connected to a LCD projector. Presenters must load their presentation files in advance onto the session computer. Technician personnel will be available to assist you.

Scheduled time slots for oral presentations are 15 mn for regular, 20 mn for invited presentations, 30 mn for keynote talks and 35 mn for plenary talks, including questions and discussions. Presenters are required to report to their session room and to their session Chair at least 15 minutes prior to the start of their session.

The session chair must be present in the session room at least 15 minutes before the start of the session and must strictly observe the starting time and time limit of each paper.

Poster Presentations

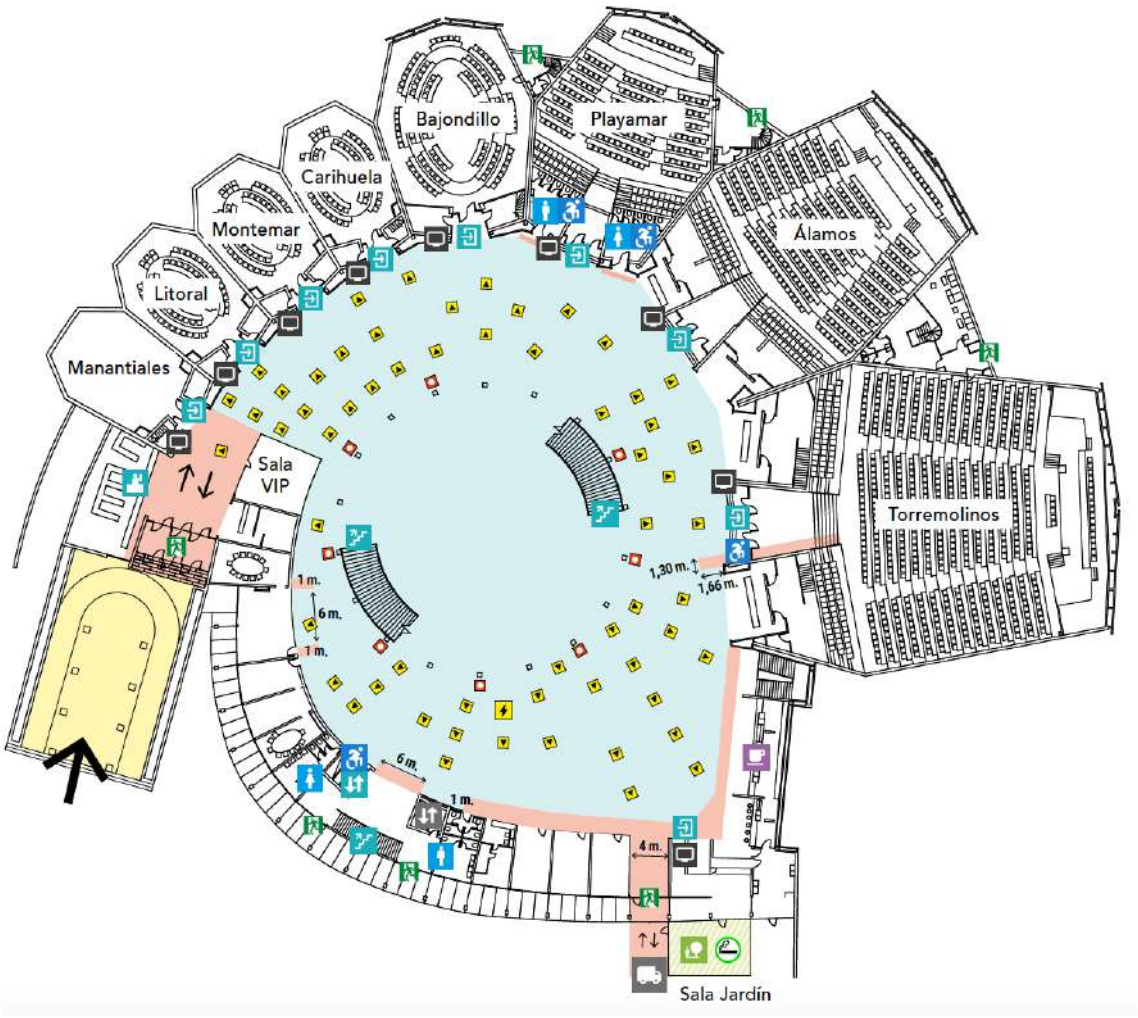
Presenters are requested to stand by their posters during their session. One poster board, A0 size (118.9 x 84.1 cm), in portrait orientation, will be available for each poster. Pins or thumbtacks are provided to mount your posters on the board. All presenters are required to mount their papers 30mn before the session and remove them at the end of their sessions. Posters must prepared using the standard AES poster template (available on the conference website).

USEFUL INFORMATION

Venue

META 2025 will be held at
Palacio de Congresos y Exposiciones de la Costa del Sol
3 Calle Mexico, 29620 Torremolinos (Spain)

https://palacio-congresos.es



Opened in October 1970, the Palacio de Congresos y Exposiciones de Torremolinos (Congress and Exhibition Centre) was the result of a project designed in 1967 by the architects Rafael de la Hoz and Gerardo Olivares James. The building, which became the state heritage property in 1971.

The complex is built on an estate of 70,000 square meters, of which 18,000 square meters are gardens. Situated in a privileged location in the municipality of Torremolinos and located in the upper area of the town on a hill overlooking the sea, the Congress Center is an icon of Malaga's coastal landscape.

The building is arranged in a circular format around which the various auditoriums, meeting rooms, administrative offices and annexed buildings are distributed. The central hall is presided over by its most iconic visual symbol, an emblem of convention and business tourism in Spain: a large translucent dome with an unprecedented crystal lamp hanging from the center of the exposed radial roof, falling like drops in a waterfall spilling over the center of the composition.

Getting to Venue

Getting to Torremolinos from Malaga Airport

Torremolinos is around 8km away from Malaga international airport. You can go from the airport to the city center by taxi, by train or by bus.

Taxi

The airport has a well-signposted taxi rank outside the arrivals area of Terminal T3. Make sure that the taxi driver has started the taximeter at the beginning of the journey (minimum fare). We recommend requesting a receipt for any complaint or claim.

Train

The new suburban train station in the new Terminal T3 building links the airport with Torremolinos city centre and other cities like Benalmadena and Fuengirola in one direction, and it links Malaga city center in the other direction.

The train station is situated underground and accessed via escalators. It is well signposted and can be reached via the square outside arrivals or outside departures. Before the station entry barriers you will see several self-service tickets machines on your right where you can buy your tickets.

The first train to Torremolinos leaves the airport at 05:32, leaving every 20-30 minutes until the last train at 23.42. Line: C1. Estimated travel time: 10 minutes.

Bus

You will find the bus stop straight in front of you outside the arrivals area of Terminal T3 on the side of the road where there are a couple of shelters with seats. You will also see a ticket office in the left hand corner of the arrivals forecourt where you should purchase your tickets for the journey. Line: Torremolinos-Benalmadena-Airport. Estimated travel time: 30 minutes.

Getting to Torremolinos from Malaga train station

There are two train stations in the centre of Malaga : Maria Zambrano and Centro Alameda. Maria Zambrano station provides high-speed (AVE) and long-distance links to many Spanish cities like Barcelona, Cordoba, Madrid, Santiago de Compostela, Seville, etc, as well as local and regional routes.

You can take Line C1 from any of the two stations to reach Torremolinos. The estimated travel time is 20 minutes. You can check the timetables on the website of the national rail company RENFE.

Getting to Torremolinos from Malaga bus station

Malaga bus station is located at the street "Paseo de los Tilos" very near Maria Zambrano train station. So it will be very easy to take a bus or a train from this station. You can take bus line Malaga-Torremolinos. Estimated travel time: 20 minutes.

Plenary presentations

Applications Of Highly Nonlinear Epsilon-near-zero Materials In Photonics (pp. 90)
Robert Boyd

Nanoplasmonic Quantum Photonics (pp. 91)
Ortwin Hess

Robust Edge States in Topological Lattices for Quantum information Transfer (pp. 93)
J. Zurita, C. E. Creffield, Gloria Platero Coello

Routes for Integrated Photonics and Meta-Optics in Quantum Technologies and Precision Experiments (pp. 94)
Stefanie Kroker, M. Gaedtke, S. Häfner, L. Shelling Neto, S. Sauer, M. Schittenhelm, A. Sorokina, N. Wagner

Metastructures That Compute and Optimize (pp. 95)
Nader Engheta

What I Wish I Had Known, as I Searched for the First 3d Photonic Bandgap (pp. 96)
Eli Yablonovitch

Keynote presentations

Modulating Optical Properties In Time Using Plasmonic Resonances (pp. 99)
John Pendry

Quantum Aspects Of Light Propagation In Time-varying Media (pp. 100)
John Pendry

Chemically Functionalized 2D Materials for Quantum Photonic Science and Technology (pp. 101)
Mark Hersam

Empowering chiral metamaterials with gain materials (pp. 102)
Ioannis Katsantonis, Anna Tasolamprou, Maria Kafesaki

Photonic Metamaterial Time Crystals And Timetronics (pp. 104)
Nikolay Zheludev

Computational Models Of Light Management In Photovoltaics And Leds (pp. 105)
Vivian Ferry

Rethinking Linking - Topology In Magnetism, And Plasmonics (pp. 106)
Maria Azhar, Ross Knapman, Philipp Gessler, Alexander Neuhaus, Pascal Dreher, Frank Meyer zu Heringdorf, Karin Everschor-Sitte

Space-time Metamaterials (pp. 108)
Andrea Alu

Wavefront Microscopy For Nanophotonics (pp. 109)
Guillaume Baffou

Vortices, Skyrmions, Möbius Strips: From Nanooptics To Ocean Waves (pp. 111)
Konstantin Bliokh

Hybrid Plasmonic Nanosystems Based On Weak And Strong Coupling (pp. 113)
Minyu Chen, Yuqing Zhao, Sylvie Marguet, Safi Jradi, Ali Issa, Anne Laure Baudrion, Jerome Plain, Christophe Couteau, Cuong Dang, Alexander Govorov, Renaud Bachelot

Certain Intersections Of Ai And Photonics (pp. 115)
Marin Soljacic

Spectral Frequency Response Of Hypersonic Phonons In A Non-Trivial Topological Waveguide (pp. 116)

O. R. Ranjbar-Naeini, O. Florez, M. D. Koijam, B. Djafari-Rouhani, Y. Pennec, T. Makkonen, O.M.E. Ylivaara, S. Pourjamal, J. Ahopelto, Clivia M. Sotomayor Torres

AI To Discover And Synthesize Sub-Terahertz Chips Beyond Human Intuition (pp. 118)
Kaushik Sengupta

Tailoring The Visual Appearance With Correlated-Disorder Metasurfaces (pp. 119)
M. Chen, T. Wu, A. Agreda, M. Tréguer-Delapierre, K. Vynck, R. Pacanowski, Philippe Lalanne

Silicon Quantum Photonics (pp. 121)
Vladimir Shalaev

Quasi-2d Materials: From Tailorable Photonics To New Physics (pp. 122)
Alexandra Boltasseva

A Large Language Model Agent for Autonomous Inverse Metamaterial Design (pp. 123)
Willie Padilla, D. Lu, J. M. Malof

Exotic Exciton Phases in Two-Dimensional Quantum Materials (pp. 124)
Wenkai Lou, Kai Chang

AI-Driven Photonics: From Metaphotonics to Silicon Photonics Integration (pp. 127)
Seokho Yun

Beyond the Voigt lineshapes: Efficient statistics-convolved approximants in the time domain (pp. 128)
L. J. Prokopeva, Alexander V. Kildishev

Non-Normality, Pseudospectra and Exponential Sensitivity (pp. 129)
Konstantinos Makris

Active Metastructures – Tailoring Space-Time and Breaking Reciprocity (pp. 130)
Harry Atwater

Functional “Meta”-Optical Fibers for Advanced Imaging and Endoscopy (pp. 131)
Ho Wai (Howard) Lee, Andrew Palmer, Yucheng Jin, Jin Yan, Beyonce Hu, Harvey Lin, Stuart Love, David Dang, M. Father, L. Liu, A. Teoh

Bio-inspired hierarchical phononic crystals and metamaterials (pp. 132)
Marco Miniaci

Transition Waves in Multistable Mechanical Metamaterials (pp. 133)
Vincent Tournat

Empowering Topological Photonics for OAM Manipulation (pp. 134)
Zhigang Chen

Tutorial

Nonlocal Metasurfaces (pp. 136)
Andrea Alu

New trends in nanophotonics and advanced materials

Photonic Crystal Information Processing Chips (pp. 138)
Xiaoyong Hu, Kun Liao

Advanced Self-powered Room-temperature Nir Plasmonic Photodetection And Reconstructive Spectroscopy (pp. 139)
Eslam Abubakr, Shiro Saito, Hironori Suzuki, Tetsuo Kan

Holotomography In Optics And X-ray: Advancing The Study Of Metamaterials (pp. 141)

Yongkeun Park

Momentum-Direct Infrared Interlayer Exciton and Photodetection in WSe2/InSe Heterostructures (pp. 143)
Jiong Yang, Chao Zhang

Accelerating Topological Pumps On Integrated Photonic Chips (pp. 145)
Wange Song

Enhancing Brightness And Directional Control Of Dark Excitons Via All-dielectric Metasurfaces (pp. 146)
Angela Barreda, Sebastian Klimmer, Giancarlo Soavi, Isabelle Staude

Dna Identification Using Surface-enhanced Raman Spectroscopy (sers) And Surface Plasmon Resonance (spr) Sensors: Identification Of Brca1 Gene Mutation Variants In Clinical Samples (pp. 148)
Agata Kowalczyk, Anna Nowicka, Aleksandra Michalowska, Michal Duszczyk, Malgorzata Sikorska, Jan Weyher, Sebastian Zieba, Artur Kowalik, Andrzej Kudelski

Topological Photonic Devices Based On Artificial Gauge Fields (pp. 150)
Cuicui Lu

Engineering Complex Structured Beams With Flat Optics (pp. 152)
Xianzhong Chen, Hammad Ahmed, Chunmei Zhang

Conducting Polymer-cellulose Devices For Tunable Infrared And Thz Optics (pp. 154)
Chaoyang Kuang, Shangzhi Chen, M. P. Jonsson

Spectroscopy Of Single Metal Nanoparticles For Single-molecule Biosensing (pp. 156)
Peter Zijlstra

Arbitrarily Configurable Nonlinear Topological Modes (pp. 157)
Duanduan Wan, Kai Bai, Meng Xiao

Mems-tunable Metasurfaces For Dynamic Vortex Beam Generation (pp. 158)
Chuanshuo Wang, Chao Meng, Lili Gui, Paul C. V. Thrane, Xianglong Mei, Hao Chen, Fei Ding, Kun Xu, Sergey I. Bozhevolny

Edge Bound State In The Continuum On Silicon Pillar Photonic Crystal (pp. 160)
Rodrigo Sato, Christian Vinther Bertelsen, Maxim Nikitin, Elena Lopez Aymerich, Radu Malreanu, Winnie Edith Svendsen, Andrei V. Lavrinenko, Osamu Takayama

Sub-wavelength Optical Lattice In 2d Materials (pp. 162)
Supratik Sarkar, Mahmoud Jalali Mehrabad, Daniel G. Suarez-Forero, Liuxin Gu, You Zhou, Mohammad Hafezi

Metasurface-Enhanced Single-Shot 3D Imaging for High-Precision Biological and Industrial Applications (pp. 164)
Huijie Hao, Jian Liu, Xumin Ding

All-optical control and detection of broken time-reversal symmetry and topological nonlinear optics (pp. 166)
Giancarlo Soavi

Creation of Novel Scattering Singularities in Generic Non-Hermitian Systems Probed Through Complex Time Delay (pp. 168)
Jared Erb, Nadav Shaibe, Thomas M. Antonsen, Steven Anlage

Non-noble metal plasmonic nanostructures (pp. 170)
Michal Horák, Michael Foltýn, Tomáš Šikola

Characterizing the mechanical properties of single bacteria in air by multimode tracking nanomechanical resonators (pp. 172)
Alicia Aparicio Millán, Elena Sentre Arribas, Jose Jaime Ruz, Sergio García López, Priscila Monteiro Kosaka, Montserrat Calleja, Javier Tamayo, Eduardo Gil Santos

High-resolution photothermal imaging using mid-infrared photo-induced force microscopy - modeling and experiment (pp. 174)
Maryam Ali, Shohely T. Anindo, Robin Schneider, Christin David, Daniela Täuber

Hyperuniform Disordered Materials for Solar and Solar-Thermal Absorbers (pp. 176)
Marian Florescu

Developing quantitative multiscale models for nonlinear molecular plasmonics (pp. 178)
Maxim Sukharev

Metasurface with gap and collective surface plasmon modes (pp. 180)
Anatoliy Pinchuk, Yeshchenko Oleg

Nonlocal metasurfaces and thin film devices for all-optical image processing and phase contrast imaging (pp. 182)
Ann Roberts

Chern insulators: nonlinearity and switching (pp. 184)
Justin Cole

Active Conducting Polymer Plasmonics and Metasurfaces (pp. 185)
Magnus Jonsson

Microenvironment Responsive Bio-Acoustic Metamaterials for Precision Medicine (pp. 186)
Hanchuan Tang

Tailored Resonant Metasurfaces for Enhanced Third-order Nonlinear Optics (pp. 188)
Hailun Xie, Lili Gui, Kun Xu

Structurally engineered phosphors for high color-conversion efficiency (pp. 190)
Tae-Yun Lee, Hansol Lee, Heonsu Jeon

Investigate the Growth of (multi)metallic nanoparticles Synthesized by physical vapor deposition (pp. 192)
Julien Ramade, Maël Costes, Sophie Camelio, Sophie Rousselet, Frederic Pailloux, Marc Marteau, Kevin Dusaillant, David Babonneau

Time-resolved vector polarimetry for identifying topological features of surface plasmon polaritons (pp. 194)
Pascal Dreher, Alexander Neuhaus, Timothy Davis, Bettina Frank, Harald Giessen, Frank Meyer zu Heringdorf

Single Crystals of Two-Dimensional Layered Perovskite Heterostructures (pp. 196)
Alexander Schleusener, Mehrdad Faraji, Martina Borreani, Linhan Li, Miao-Ling Lin, PingHeng Tan, Sirous Khabbaz Abkenar, Giorgio Divitini, Roman Krahne

Development of three-dimensional bulk metamaterials suppliable as meta-atomic grains (pp. 198)
Yoshiaki Kanamori

Large-diameter Infrared Si Metalenses through Deep-UV Lithography (pp. 200)
Kai Sun, Xingzhao Yan, Jordan Scott, James Monks, Jun-Yu Ou, Otto Muskens

Plasmonic nanohole array for tumor cell and tissue biosensing (pp. 202)
Alfredo Franco, Dolores Ortiz, Carlos Velásquez, Víctor García-Milán, Sara Marcos, Rubén Martin-Laez, Fernando Moreno, José Luis Fernández-Luna

Near-Infrared Photodetector Enhancement via Plasmonic Diffraction (pp. 204)
Soh Uenoyama

Reconfigurable Plasmonics Enabled by Phase Change Materials (pp. 206)
Yael Gutierrez, Gonzalo Santos, Capucine Laprais, Lofti Berguiga, Saul Vazquez Miranda, Mateusz Rebarz, Shirly Espinoza, Sebastien Cueff, Maria Losurdo

Recognition of Shiga Toxins by Plasmonic SERS Metasurface PCA Assisted (pp. 207)
Massimo Rippa, Alessia Milano, Valentina Marchesano, Domenico Sagnelli, Bryan Guilcapi, Amalia D'Avino, Maurizio Brigotti, Stefano Morabito, Joseph Zyss, Lucia Petti

Boosting the magnetic response of a composite nanostructure in the near-visible region with a Fano resonance (pp. 209)
Maximilian Grimmer, Monika Fleischer

Electric field induced second order nonlinearity in amorphous As2S3, SiOx and SiNx (pp. 211)

Laurids Wardenberg, Krishna Koundinya Upadhyayula, Georg von Freymann, Vadim Talalaev, Michael Hanke, Andre Kühling, Joerg Schilling

Superconducting Nanowire Single Photon Detectors for photon counting applications in the mid-infrared (pp. 213)

Dmitry Morozov, Daniel Kuznesof, Ciaran Lennon, Umberto Nasti, Robert H. Hadfield

Freestanding Ultra-thin Bic Membrane Metasurface For High-q Surface Emission In The Visible (pp. 215)

Chih-Zong Deng, Ya-Lun Ho

Steering Plasmonic Optical Losses Using Alkali Metals (pp. 217)

Yuhan Yang, Jie Liang, Lin Zhou

Manipulation Of Light Propagation In Photonic Crystals Via Non-hermitian Photonic Band Engineering (pp. 219)

Takuya Inoue, Masahiro Yoshida, Susumu Noda

Exploration Of Optical Chirality Based On The Orbital Angular Momentum Of Light Using A Single Chiral Metallic Nanostructure As A Probe (pp. 221)

Shun Hashiyada, An'an Wu, Yoshito Tanaka

Susceptibility Invariance And Disorder-induced Statistical Properties In Time-varying Media (pp. 223)

Bo Zhou, Enzong Wu, Zuojia Wang

Scalable Integration Of Multiple Single-photon Sources For Fiber Quantum Network (pp. 225)

Woong Bae Jeon, Donghyun Park, Jongsung Moon, Kyu-Young Kim, Mohamed Benyoucef, Je-Hyung Kim

Second-order Coherence Of Bose-einstein Condensation In Plasmonic Lattices (pp. 227)

Evgeny Mamonov, Sioneh Eyvazi, Lukas Freter, Päivi Törmä

Optical Picometrology (pp. 229)

Kevin F. MacDonald, Thomas A. Grant, Cheng-Hung Chi, Huanli Zhou, Anton N. Vetlugin, Eric Plum, Stefan Rotter, Nikolay I. Zheludev

Negative Frequency Generation And Temporal Diffraction (pp. 230)

Euan Hendry

Self-hydridized Plasmonic Excitations And Hot Electron Generation In Aluminum Nanorods (pp. 232)

J. Martin, O. Avalos-Ovando, T. Simon, G. Arditi, F. Lamaze, J. Proust, L. Tizei, M. Kociak, A. Govorov, O. Stéphan, Davy Gerard

Enhancing Thermoplasmonic Sensing Via Plasmonic Nanoplatforms (pp. 233)

Andreea Campu, Simion Astilean, Monica Focsan

Low-loss Resonant Nonlinear Nanophotonics In The Visible Spectral Range Using Wafer-bonded Crystalline Alinp (pp. 234)

Radoslaw Kolkowski, Seyed Ahmad Shahahmadi, Serguei Novikov, Jani Oksanen, Andreas Liapis, Huayu Bai, Timo Stolt, Matti Kaivola, Andriy Shevchenko

Fluorescence-based Chiral Sensing With Silicon Metasurfaces (pp. 236)

Tom Sistermans, Artemijs Krimovs, Robert Pal, Alberto Curto

Nanophotonics For Integrated Chiroptical Sensing Of Drug Solutions (pp. 238)

Raju Adhikary, Ambaresh Sahoo, Massimiliano Aschi, Isabella Daidone, Matteo Silvestri, Matteo Venturi, Giovanna Salvitti, Carino Ferrante, Paola Benassi, Davide Tedeschi, Andrea Marini

Large-area Nanohelices As Chiral Metasurface For Engineering Optical Chirality (pp. 240)

Thu H. H. Le, Hisako Sato, Takuo Tanaka

Transition Metal Dichalcogenide Lateral Heterostructure-based Excitonic Platform For Photonics And Optoelectronics (pp. 243)

Hassan Lamsaadi, Aurélien Cuche, Gonzague Agez, Ioannis Paradisanos, Dorian Beret, Laurent Lombez, Pierre Renucci, Delphine Lagarde, Xavier Marie, Ziyang Gan, Antony George, Kenji Watanabe, Takashi Taniguchi, Andrey Turchanin, Nicolas Combe, Bernhard Urbaszek, Jean-Marie Poumirol, Vincent Paillard

Wavefront Engineering Of Microcavity-empowered Multi-resonant Metasurfaces (pp. 245)
Shih-Hsiu Huang, Hsiu-Ping Su, Zijin Yang, Yuzhi Shi, Qinghua Song, Pin Chieh Wu

Photonics And Ai For Next-generation Smart Applications (pp. 246)
Luigi Di Lauro, A Aadhi, Imtiaz Alamgir, Pavel Dmitriev, Bennet Fischer, Celine Mazoukh, Nicolas Perron, Evgeny Viktorov, Anton Kovalev, Armaghan Eshaghi, Mario Chemnitz, Piotr Roztocki, Shervin Vakili, Brent Little, Sai Chu, David Moss, Roberto Morandotti

Optical Pulling Forces For 3-dimensional Motion Control In Plasmonic Nanomotors (pp. 248)
Guillermo Serrera, Yoshito Y. Tanaka, Pablo Albella

Nonlinear Optics In The Xuv Spectral Range (pp. 250)
Luca Assogna, Emiliano Principi, Matteo Silvestri, Ambaresh Sahoo, Giovanni Batignani, Giuseppe Fumero, Laura Foglia, Riccardo Mincigrucci, Davide Tedeschi, Claudio Masciovecchio, Tullio Scopigno, Andrea Marini, Carino Ferrante

Labyrinthine Magnetic Domains In Epitaxial Magnetooptical Garnet Films For Synchrotron Analysis And Optical Modulator Applications (pp. 252)
Taichi Goto

Quasi-babinet Principle In Dielectric Resonators And Mie Voids (pp. 254)
Masoud Hamidi, Kirill Koshelev, S. Gladyshev, A. C. Valero, M. Hentschel, H. Giessen, Y. Kivshar, Thomas Weiss

Chiral Semiconductor Nanophotonics (pp. 256)
Alberto G. Curto

Resonant Light Absorption Driving By Bound States In The Continuum In Hybrid metasurfaces (pp. 258)
Andrey Evlyukhin, M. A. Poleva, C. Rockstuhl

Multilayer And Microbead Structures For Ultraviolet To Near Infrared Spectroscopic Applications Based On Metal-free Phosphors (pp. 260)
David Hernandez-Pinilla, Barun Kumar Barman, Keisuke Watanabe, Hiroyuki Yamada, Thien Duc Ngo, Tadaaki Nagao

Exfoliation Of Millimeter-sized Flakes Of 2d Transition Metal Dichalcogenides On Arbitrary Substrates (pp. 262)
Ermes Peci, Riccardo Galafassi, Valentina Venturino, Emma Spotorno, Francesca Telesio, Michele Magnozzi, Maurizio Canepa, Francesco Bisio

Design Of Broadband Multilayer Metamaterials Based On Genetic Algorithm And Neural Network (pp. 264)
Kotaro Kajikawa

Surface Acoustic Wave Stimulated Brillouin Scattering (pp. 266)
Moritz Merklein

Permittivity-driven Ultrafast Photonic Bound States In The Continuum (pp. 267)
Andreas Tittl

Enhanced Sensing With Ultrastrong Coupling Condition (pp. 269)
Wen-Hui (Sophia) Cheng, Alexis Angelo R. Garcia, Cheng-An Mao

Self-illuminated Plasmonic Biosensor Enabled By Inelastic Tunnelingluminescence (pp. 270)
Jihye Lee, Yina Wu, Ivan Sinev, Mikhail Masharin, Sotirios Papadopoulos, Eduardo Dias, Lujun Wang, Ming Lun Tseng, Seunghwan Moon, Jong-Souk Yeo, Lukas Novotny, Javier Garcia de Abajo, Hatice Altug

Characteristics Of Optical Chiral Fields Around Nanostructures Revealed By Scanning Near-field Optical Microscopy (pp. 272)
Kohei Imura

Hybrid Photoresists In Multi-photon Lithography: Optical Properties Andpost-processing Strategies (pp. 274)
Dimitra Ladika, Michalis Stavrou, Gordon Zyla, Artur Harnik, Frederik Dumur, Mikas Vengris, Maria Kafesaki, David Gray, Saulius Juodlazis, Mangirdas Malinauskas, Maria Farsari

Exploring Channelrhodopsin-2 And Gold Nanoparticle Interaction For Optogenetics (pp. 276)
Roberto Messina, Luca Bellucci, Stefano Corni, Lucia Cascino, Stefania D'Agostino, Laura Zanetti Polzi

Neural Network-optimized Multifunctional Metasurfaces For Adaptive High-frequency Wireless Communication (pp. 278)
Miguel Beruete, Damián Rodríguez-Trujillo, Alicia E. Torres-García, Mikel Aldea, Jorge Teniente, Asier Marzo-Perez

Temporal Topological Aharonov-bhom Phase In Quantum-systems Under Electric And Gravitational Scalar Potentials (pp. 280)
Michael Tobar, Michael Hatzon, Graeme Flower, Maxim Goryachev, Jeremy Bourhill, Raymond Chiao, Nader Inan, Michael Scheibner, Jay Sharping, Douglas Singleton

Two-dimensional Semiconductors For On-chip Polarization-sensitive Photodetectors (pp. 282)
Marcos Guimaraes

Controlled Synthesis Of Silver-coated Gold Nanostars For Tunable Optical Properties (pp. 283)
Nicolas Pazos Perez

Tailoring The Emission And The Photodynamics Of Quantum Emitters With Simple And Optimized High-index Dielectric Nanostructures (pp. 285)
Swaroop Palai, Mélodie Humbert, Romain Hernandez, Peter Wiecha, Jonas Muller, Etienne Palleau, Frank Fournel, Vincent Larrey, Aurélie Lecestre, Guilhem Larrieu, Christian Girard, Vincent Paillard, Laurence Ressier, Aurelien Cuche

Optimising Cross-polarisation Conversion Of Ghost Hyperbolic Polaritons With A Twist (pp. 287)
Mark Cunningham, Rair Macêdo

Broadband Third Harmonic Generation Through Strong Coupling Between All-dielectric Metasurfaces And Epsilon-near-zero Materials (pp. 290)
Hui-Hsin Hsiao

Efficient Modeling Of Particle Acceleration In Structured Dielectric Waveguides Driven By Short-pulse Laser Excitation (pp. 292)
Andrea Locatelli, Gino Sorbello, Davide Guarnera, Roberta Palmeri, Giorgio Mauro, Giuseppe Torrisi, Nunzio Salerno, Davide Rocco, Luca Vincetti

Nonlinear Photonics In Low-index Time-varying Systems (pp. 294)
Marcello Ferrera, Wallace Jaffray, Sven Stengel

Continuous Translational Symmetry Breaking Metamaterial Design For Photonic Integrated Circuits To Free Space Outcouplers (pp. 296)
Alexei Azarov, Dhriti Maurya, Daron Westly, Vladimir Aksyuk

Optical Fresnel Zone Plate Lenses Fabricated Entirely Of colored Photoresist With I-line Stepper (pp. 298)
Kuniaki Konishi

Integrating Superconductors With Silicon Photonic Circuits For High-performance Quantum Optic Applications (pp. 300)
Jeff Young, Mohammad Khalifa, Phillip Kirwin, Joseph Salfi

Recent Progress In Metasurface Fluorescence Biosensors: Expansion Of The Targets To Next-generation Nucleic Acid Biomarkers (pp. 302)
Masanobu Iwanaga

Anisotropic Nonlinearities In Crystalline Gold And How To Exploit Them (pp. 304)
Sergejs Boroviks, Olivier Martin

Fabrication Of Polymer Structures In The Sub-micron Range As Potential Landscapes For Photon Bose-einstein Condensates Via Direct Laser Writing (pp. 306)
Sven Enns, Julian Schulz, Kirankumar Karkihalli Umesh, Frank Vewinger, Georg von Freymann

Scanning Near-field Optical Microscopy On Hyperuniform Disordered Photonic Materials (pp. 308)
Nicoletta Granchi, Gabriele Calusi, Kris Stokkereit, Matteo Lodde, Camilla Gonzini, Andrea Fiore, Marian Florescu, Francesca Intonti

Spectroscopic Proof Of The Non-thermal Reactant Activation in Plasmon-photocatalysis (pp. 310)
Zee Hwan Kim

Active Modulation Of Optical Response In Transparent Conducting Oxide Films (pp. 312)

Stefania Benedetti, Alessandro di Bona, Sergio D'Addato, Alexandr Petrov, Piero Torelli, michele Magnozzi, Stefano Colace, Maurizio Canepa, Francesco Bisio

Photonic Force Microscopy In Front Of Epsilon-near-zero (enz) Surfaces (pp. 314)

Maria Grazia Donato, Michael Hinczewski, Theodore Letsou, Mohamed ElKabbash, Rosalba Saija, Pietro Giuseppe Gucciardi, Nader Engheta, Giuseppe Strangi, Onofrio Maria Maragò

Extracting Resonances In Nanophotonic Systems From Light Scattering Simulations (pp. 316)

Felix Binkowski, Fridtjof Betz, Lin Zschiedrich, Sven Burger, Martin Hammerschmidt

Towards Photonic Orbitronics: Exploiting The Orbital Angular Momentum Of Light (pp. 318)

Max Weber, Julian Schulz, Ian Heil, Christina Jörg, Georg von Freymann

Direct Determination Of Carrier Parameters In Plasmonic Indium Tin Oxide Nanocrystals Exploiting Magnetoplasmonic Modulation (pp. 320)

Alessio Gabbani, Elisa Della Latta, Xiaoyan Li, Andrea Scarperi, Francesca Martini, Francesco Biccari, Mathieu Kociak, Marco Geppi, Silvia Borsacchi, Francesco Pineider

Chiral Metasurface Photodetectors For Circular-polarization-selective Phase Contrast Imaging (pp. 322)

Ahmet Erturan, Jianing Liu, Maliheh Azimi Roueini, Nicolas Malamug, Lei Tian, Roberto Paiella

Harmonic Generation From Aluminium And Gold Nanolayers And Nanogratings: Bound And Hot Electron Contributions (pp. 324)

Shroddha Mukhopadhyay, Crina Cojocaru, Maria Antonietta Vincenti, Kent Hallman, Michael Scalora, Jose Trull

Hyperbolic Plasmon Polaritons In Van A Der Waals Crystal At Visible Frequencies (pp. 326)

Femtosecond Laser Delamination Cavities And Their Applications (pp. 328)

Pavel Varlamov, Akira Barros, Aditya Swaminathan, Jan Marx, Andreas Ostendorf, Anna Semisalova, Denys Makarov, Alexey Lomonosov, Paolo Vavassori, Yannis Laplace, Michele Raynaud, Vasily Temnov

UV Upconversion In Lanthanides-doped Thin Films Assisted By Photonic Crystals. (pp. 330)

Damien Rinnert, Emmanuel Drouard, Antonio Pereira, Céline Chevalier, Aziz Benamrouche, Benjamin Fornacciari, Hai Son Nguyen, Gilles Ledoux, Christian Seassal

Miniaturized Microfluidic Plasmonic Chip For Enhanced Biosensing (pp. 332)

Andreea Campu, Daria Stoia, Dana Maniu, Simion Astilean, Marc Lamy de la Chapelle, Monica Focsan

Natural Hyperbolic Van Der Waals Materials Towards Low-loss Near Unity Linear Dichroism (pp. 333)

Nicola Melchioni, Andrea Mancini, Lin Nan, Anastasiia Efimova, Giacomo Venturi, Antonio Ambrosio

Two-dimensional Gold Flakes For Nonlinear And Low-loss Plasmonics (pp. 335)

Alexey Krasavin, Chenxinyu Pan, Lufang Liu, Anatoly Zayats, Limin Tong, Pan Wang, Zhenxin Wang

Infrared Electroluminescence And Energy Transfer In Hbn-encapsulated Graphene Devices Under High Bias Voltage (pp. 336)

Yannick De Wilde

Unified Framework For Enhancing Chiral Light-matter Interactions (pp. 338)

Chloe Doiron

Fabrication Of Plasmonic Transition Metal Nitride Thin Films And Nano-arrays (pp. 340)

Ryan Bower, Ethan Muir, Gwilherm Kerherve, Bruno Rente, Arutiun Ehiasarian, Peter Petrov

Multilayer Structures For Broadband Switchable Absorption And Switchable Radiative Cooling Based On Phase-change Materials (pp. 342)

Georgios Veronis, Md Tanvir Emrose, Ming Zhou, Shanhui Fan

Detection Of Ammonia In Water Using Self-assembled Plasmonic Colorimetric Sensor (pp. 343)

M. Soudi, P. Cencillo-Abad, S. Ghimire, Debashis Chanda, Kausik Mukhopadhyay

Visualization Of Thermal Extraction Process Achieved By Metamaterial Absorber (pp. 345)
Wakana Kubo

Twisted Moiré Metasurfaces With Emissive Gap Layers Enabling Giant And Tunable Chiral Emission (pp. 347)
Zijie Jiang, Zhao Sun, Zhuofei Gan, Wen-Di Li

Optimization Of Photonic Structures For Cmos Image Sensors Using Adjoint Sensitivity (pp. 348)
Rishad Arfin, Jeongwoo Son, Jens Niegemann, Dylan McGuire, Mohamed H. Bakr

Modulation And Amplification Of Waves By Metasurfaces (pp. 350)
Ilya Shadrivov

Negative Refraction Of Light Using Atoms Instead Of Metamaterials (pp. 351)
L. Ruks, K. E. Ballantine, Janne Ruostekoski

Development of A Silicon Nitride Platform for Next Photonic Integrated Circuits (pp. 353)
Brahim Ahammou, Narges Dalvand, Boris Le Drogoff, Youssef Ouldhnini, Abir Radi, Majid Taghavi Dehaghani, Kulbir Kaur Ghuman, Joëlle Margot, Michael Ménard, Mohamed Chaker

Vectorial Metasurface For Polarization Encoding And Imaging (pp. 354)
Fengjun Li, Zilan Deng, Xiangping Li

Highly Sensitive Cmos Image Sensor Integrating Color-routing Nanostructures (pp. 355)
Choonlae Cho, Sangyun Lee, Sookyoung Roh, Sungmo Ahn, Suyeon Lee, Junho Lee, Subeom Song, Seokho Yun

Non-lorentzian Effects For Exciton-plasmon Systems At Strong Coupling (pp. 357)
Tigran Shahbazyan

Sub-1-volt, Reconfigurable Gires-tournois Resonators For Colored Monopixel Array (pp. 359)
Young Min Song

Single-shot Weak Measurement For Spin Hall Effect Of Light Using A Metasurface (pp. 361)
Minkyung Kim

Laser Color Printing On Disordered Metal-dielectric Multilayer Structures (pp. 363)
Piotr Nyga, Michal Nowak, Marcin Woszto, Tomasz Wojciechowski, Bartosz Bartosewicz, Przemyslaw Wachulak

The General Boundary Conditions For All Interfaces, Including Arbitrary Moving Metasurfaces And Instantaneous Changes In Constitutive Relations. (pp. 365)
Jonathan Gratus, Simon Horsely, Martin McCall

Harnessing The Power Of Mid-infrared Metasurfaces For Ultrafast And High-efficiency All-optical Modulation (pp. 367)
The Linh Pham, Amirmostafa Amirjani, Kacper Pilarczyk, Nils Deßmann, Thanh Tung Nguyen, Ewald Janssens

Injecting Physics Knowledge In Neural Networks For A Wide Range Of Photonic Devices: Qnm-net (pp. 369)
Viktor Lilja, Albin Svärdsby, Timo Gahlmann, Philippe Tassin

Suspended Algaas Integrated Nonlinear Photonics (pp. 371)
Changzheng Sun, Yuqian Zhang, Bing Xiong, Jian Wang, Zhibiao Hao, Lai Wang, Yanjun Han, Hongtao Li, Lin Gan, Yi Luo

Far-field Petahertz Sampling Of Plasmonic Fields (pp. 373)
Kai-Fu Wong, Weiwei Li, Z. Wang, V. Wanie, E. Mansson, D. Hoeing, J. Blöchl, T. Nubbemeyer, A. Azzeer, A. Trabatton, Holger Lange, Francesca Calegari, Matthias F. Kling

Degenerate Metasurface Eigenstates: Coupling And Interfering For Maximum-chiral Optics (pp. 375)
Maxim Gorkunov, Alexander Antonov, Yuri Kivshar

Non-hermitian Skin Effect In Lossy Anisotropic Nanophotonic Systems (pp. 377)
Yuto Moritake, Nozomi Ogawa, Issei Takeda, Masaya Notomi

Electrically Tunable Free-electron Nonlinearity In Heavily-doped Ingaas (pp. 379)

Valeria Giliberti, Tommaso Venanzi, Andrea Rossetti, Huatian Hu, Raffaella Polito, Andrea Notargiacomo, Antonio Valletta, Francesco Mattioli, Adel Bousseksou, Gregoire Beaudoin, Isabelle Sagnes, Raffaele Colombelli, Markus Ludwig, Daniele Brida, Marialilia Pea, Cristian Ciracì, Michele Ortolani

Material Aspects For Ultra-stable Laser Interferometers (pp. 381)

Nico Wagner, Bess Fang, Sebastian Häfner, Michael Hartman, Michael Jetter, Thomas Legero, Mateusz Naroznik, Michael Zimmer, Stefanie Kroker

Ultrafast Plasmonic Hot Carriers: From Light Generation To Pulsed Photocatalysis (pp. 383)

Andrea Schirato, Yang Luo, Shaoxiang Sheng, Giulio Cerullo, Alessandro Alabastri, Manish Garg, Peter Nordlander, Giuseppe Della Valle

Chiral Photoacoustic Spectroscopy On Plasmonic Materials (pp. 385)

Claudia Skubisz, Emilija Petronijevic, Grigore Leahu, Teemu Hakkarainen, Eero Koivusalo, Mircea Guina, Roberto Li Voti, Concita Sibilia, Alessandro Belardini

Next-generation Implantable Neural Probes: Advanced Photonics On The Tip Of Multimode optical Fibers For Enhanced Endoscopic Sensing (pp. 387)

Linda Piscopo, Maria Samuela Andriani, Luciana Algieri, Liam Collard, Di Zheng, Muhammad Fayyaz Kashif, Cinzia Montinaro, Mohammadrahim Kazemzadeh, Stella Aslanoglou, Filippo Pisano, Antonio Balena, Marco Bianco, Marco Pisanello, Barbara Spagnolo, Michele Scaraggi, Tommaso Fellin, Massimo De Vittorio, Ferruccio Pisanello

Incident Light Selective Metasurfaces (pp. 389)

Classical-Quantum Correspondence In Photonic Temporal Crystals (pp. 395)

Bumki Min

Harnessing Plasmonic Nanostructures For Selective Light-driven Co_2 Reduction (pp. 396)

Anjalie Edirisooriya, Zelio Fusco Beck, Ning Lyu, Christin David, Fiona Beck

Complex Modulation Of Light In Polarization And Space Using Laser-written Multi-plane Light Conversion (pp. 398)

Oussama Korichi, Markus Hiekkamäki, Robert Fickler

Integration Technique Of Micro- And Nano-lasers On Si By Epitaxial Growth Using Iii-v-on-si Wafer (pp. 400)

Takuro Fujii, Koji Takeda, Erina Kanno, Takuma Tsurugaya, Tomonari Sato, Shinji Matsuo

New Materials For Metaoptics From Infrared (ir) To Deep-ultraviolet (duv) (pp. 402)

Zeng Wang

Probing Nanoscale Light-matter Interactions With Fast Electrons And Near-field Optical Probes (pp. 403)

Carlos Maciel Escudero, Ermin Malic, Rainer Hillenbrand, Javier Aizpurua

Automated Design Of One-dimensional Photonic Crystals For Surface Wave Enhanced Chiroptical Spectroscopy (pp. 405)

Jonathan Barolak, Francesco Michelotti, Agostino Occhicone, Marco Finazzi, Paolo Biagioni, Giovanni Pellegrini

Exponentially Sensitive Lattices: Pseudospectral Scalings (pp. 407)

Ioannis Kiorpelidis, Konstantinos G. Makris

Subwavelength Metamaterials For High-performance Power And Modal Control In Silicon Photonics (pp. 409)

Raquel Fernández de Cabo, Alejandro Sánchez-Sánchez, Yijun Yang, Daniele Melati, Carlos Alonso-Ramos, Pavel Cheben, Aitor V. Velasco, David González-Andrade

Unconventional Phenomena From Space-time Modulation Of Dispersive Media (pp. 411)

Carlo Rizza, Alessandra Contestabile, Maria Antonietta Vincenti, Giuseppe Castaldi, Michael Scalora, Vincenzo Galdi

Engineered Single-photon Emitters In Materials For Integrated Quantum Photonics (pp. 413)
Alexander Senichev, Zachariah O. Martin, Samuel Peana, Pranshu Maan, Artem Kryvobok, Demid Sychev, Alexei S. Lagutchev, Alexandra Boltasseva, Vladimir M. Shalaev

Optical Fiber Microstructure Devices Inscribed By Femtosecond Laser And Their Sensing Applications (pp. 415)
Xuewen Shu

Multi-Temperature Modeling Of Hot-Carrier Dynamics In Photonic Metastructures (pp. 417)
Andrea Schirato, Giulia Crotti, Giuseppe Della Valle

Effect Of Disorder In 3d Photonic Networks On Their Photonic Band Gaps (pp. 419)
Florin Hemmann, Vincent Glauser, Ullrich Steiner, Matthias Saba

Nano-Optomechanical Disk Resonators: Operating Principles And Sensing Applications (pp. 421)
Elena Sentre-Arribas, Alicia Aparicio-Millán, Ivan Favero, Aristide Lemaître, Oscar Malvar, Jose Jaime Ruz, Montserrat Calleja, Javier Tamayo, Eduardo Gil-Santos

Ab Initio Simulation Of Nonlinear Optical Response In Periodic Semiconducting Nanostructures (pp. 423)
Mitsuharu Uemoto

Lasing Emission From Guided Mode-Assisted Quasi-Bound States In The Continuum In All-Dielectric Metasurfaces (pp. 425)
Ayesheh Bashiri, Aleksandr Vaskin, Muyi Yang, Katsuya Tanaka, Marijn Rikers, Thomas Pertsch, Isabelle Staude

Real-Space Renormalization Group On Topological Scattering Under Strong Disorder (pp. 427)
Zhe Zhang, Romain Fleury

Photodegradation Of Dyes Using Fe3O4-Au-Pd Hybrid Nanoparticles Synthesized Liquid-Phase (pp. 429)
Yukie Yokota, Taiga Uehara, Mao Takeda

Photonic Antiferromagnetic Topological Insulator With A Single Surface Dirac Cone (pp. 431)
Yihao Yang

Spin-Orbit Coupling And Tunable Lasing In Liquid-Crystal-based Photonic 1d Crystals (pp. 433)
Jacek Szczytko, Marcin Muszyński, Pavel Kokhanchik, Przemyslaw Oliwa, Piotr Kapuscinski, Daniil Bobylev, Eva Oton, Rafal Mazur, Przemyslaw Morawiak, Wiktor Piecek, Przemyslaw Kula, Witold Bardyszewski, Barbara Piętka, Dmitry Solnyshkov, Guillaume Malpuech

Room-Temperature Exciton-Polariton Condensation In Prism-Shaped Gan Microcavity Structures (pp. 435)
Yong-Hoon Cho

High-Temperature Superfluorescence In Perovskites (pp. 436)
Kenan Gundogdu

Multipartite Light-Matter Interactions In Hybrid 2d-Material Nanophotonic Cavities (pp. 437)
Chenjiang Qian, Viviana Villafañe, Pedro Soubelet, Andreas V. Stier, Jonathan J. Finley

From Exceptional Point To Bound States In The Continuum And From Lasing To Coherent Perfect Absorption, Or There And Back Again Using Non-hermitian Metasurfaces (pp. 438)
Yaoyao Liang, Yara El Droubi, Liubov Ivzhenko, Maciej Krawczyk, Andriy Serebryannikov, Anatole Lupu

Chirality Transfer In Silicon Nanoparticles With Chiral Molecules (pp. 440)
Hiroshi Sugimoto, Hiroki Kasai, Kento Shintani, Shahin Ghamari, Frank Vollmer, Minoru Fujii

Imaging Method Of The Photodegradation Mechanism At The Nanoscale Over A Gold Metasurface (pp. 442)
Marlo Vega, Paul-Ludovic Karsenti, Paul G. Charette, Julien Moreau, Michael Canva, Jean-François Bryche

Non-Hermitian Dynamics In Bosonic Systems: Classical And Quantum Realizations (pp. 443)
Yogesh Joglekar

Past, Present And Future Of Mass Diffusion Metamaterials (pp. 444)
Juan Manuel Restrepo Florez

Enhanced Photo-Excitation Of Spin-Forbidden Gray Exciton In 2d Materials By Using Spin-Orbit-Coupled Vector Vortex Beams (pp. 445)
Shun-Jen Cheng

Higher-Order Mie Resonant Metasurfaces For Ultrafast All-Optical Light Manipulation (pp. 447)
Claudio Hail, Lior Michaeli, Harry Atwater

Snapshot Polarimetric Stereoscopic Imaging And On-Chip High Dynamic Range Correction System (pp. 448)
Shuming Wang

Building Complex Nanophotonic Device With Self-Assembled Colloidal Particles (pp. 450)
Weihua Zhang

Van Der Waals Polaritonic Crystals And Their Applications In Thz Detection (pp. 451)
Huanjun Chen, Ximiao Wang, Shaojing Liu, Hongjia Zhu, Shaozhi Deng

Plasmonic Sensing On Nanofibers For In Vivo Protein Measurement In The Brain (pp. 452)
Jean-Francois Masson, M. H. Jodaylami

Ultrafast Manipulation Of Collective Modes Via Chiral Fermions In A Charge Density Wave Weyl Semimetal (pp. 453)
L. Cheng, Z. X. Wei, Y. G. Yao, Jingbo Qi

Coexisting And Cooperating Light-matter Interaction Regimes In Apolaritonic Photovoltaic System (pp. 455)
Roberto Termine, Vincenzo Caligiuri, Svetlana Siprova, Attilio Golemme, Aniket Patra, Giuseppe E. Lio, Antonio De Luca

Nanostructured Surfaces For Enhanced Spectroscopy And Nonlinear Optics (pp. 456)
Luca Razzari

Configurable Quantum Simulator For Few Atoms In A Super-Resolved Optical Tweezers (pp. 457)
Vincent Mancois, Kelvin Lim, Haijun Wu, Yijie Shen, David Wilkowski

Optical Skyrmions From Metamaterials (pp. 458)
Yijie Shen, Nilo Mata-Cervera

Thermal Photonics For Advanced Energy Conversion Systems (pp. 459)
Atsushi Sakurai

Quadrupole Topological Phase Constructed By Gyromagnetic Photonic Crystal (pp. 460)
Peiheng Zhou, Gui-Geng Liu, Qindong Xie, Longjiang Deng, Baile Zhang

Polarization Optics Using Nonlocal Dielectric Metasurfaces (pp. 461)
Yu Geun Ki, Changhyun Lee, SeokJae Yoo, Soo Jin Kim

Extreme-Ultraviolet Spatiotemporal Optical Vortices (pp. 463)
Rodrigo Martin-Hernandez, Guan Gui, Luis Plaja, Henry Kapteyn, Margaret Murnane, Miguel Ángel Porras, Chen-Ting Liao, Carlos Hernandez-Garcia

Optical Properties Of Nanoporous Gold And Their Change Upon Electrochemical Oxidation (pp. 465)
Maurice Pfeiffer, Xinyan Wu, Manfred Eich, Alexander Petrov

Low-Loss Phase Change Materials For Integrated Photonics (pp. 466)
Ioannis Zeimpekis, A. Shoaa, Q. Luo, I. Johnson, D. Lawson, L. Rozaqi, P. Deoli, D. Trubacs, S. Blundell, O. L. Muskens, F. Gardes

Optical Response In Twisted Bilayer Graphene (pp. 467)
M. Sanchez, J. Gonzalez, Tobias Stauber

Heterostrucutred Photonic Media For Phz Optoelectronics Applications (pp. 469)
Václav Hanus, Beatrix Fehér, Peter Dombi

Modifying Perovskite Solar Cell Architecture To Limit The Effective Radiative Recombination To Enhance The Open Circuit Voltage (pp. 470)

Martina D'Andrea, R. Runjun, F. Bernal-Texca, Jordi Martorell

Active IR and THz Light Modulators Based on Epsilon-Near Zero InAs and GaSb Semiconductor Frequency-Selective Surfaces (pp. 471)

Julien Guise, Fernando Gonzalez-posada Flores, Stephan Blin, Thierry Taliercio

High-Speed Self-Biased 2d Ins Photodetector (pp. 473)

Srinivasa Tamalampudi, Ghada Dushaq, Mahmoud Rasras

Integrated Photonic Platforms For Nonlinear Light Generation In The Ultraviolet And Visible Regions (pp. 475)

Natale Pruiti, Elissa McKay, Eugenio Di Gaetano, Cosmin Suciu, Daniel Kelly, Stuart May, Marc Sorel

Colloidal Self-Assembly As Templating For 3d Second-harmonic Photonic Crystals (pp. 476)

Thomas Kainz, Helena Weigand, Ülle-Linda Talts, Rachel Grange, Ullrich Steiner, Viola Vogler-Neuling

Multi-Photon Lithography For Advanced Micro-optics And Large-Area Metasurfaces (pp. 478)

Gordon Zyla, Dimitra Ladika, Vasileia Melissinaki, Michalis Stavrou, Ivan Kassamakov, Savvas Papamakarios, Dimitrios Zografopoulos, Anna Christoforidou, George Kenanakis, Odysseas Tsilipakos, Mangirdas Malinauskas, Maria Farsari

Strong Light-Matter Interaction In Dielectric Hybrid Metasurfaces (pp. 479)

Giorgio Adamo, Marco Marangi, Alexander M Dubrovkin, Andrea Zacheo, Cesare Soci

Rapid, Full-wafer Fabrication Of All-inorganic, High-efficiency Metaoptics And Ar Waveguides Via Additive Nanoimprint Lithography (pp. 480)

James Watkins

Monolithic Integration For Silicon Photonics (pp. 481)

Frederic Gardes, Ilias Skandalos, Xingshi Yu, Afrooz Shoaa, Qianbin Luo, Thalia Dominguez Bucio, Ipsita Chakraborty, Michele Paparella, Ioannis Zeimpekis, Huiyun` liu, Alwyn Seeds

Controlling And Applying The Loss Of Electromagnetic Metasurface Based On Machine Learning (pp. 482)

Peng Fu, Yang Guo, Changzhi Gu

Development Of Plasmonic Components For Artificial Neural Networks (pp. 483)

Martin Aeschlimann

DNA Origami Self-Assembled Diamond Lattice Photonic Crystals (pp. 484)

Xin Yin, Gregor Posnjak, Paul Butler, Oliver Bienek, Mihir Dass, Seungwoo Lee, Ian Sharp, Tim Liedl

Photon Manipulation with the Interface of Synthetic Temporal Photonic Lattices (pp. 486)

Bing Wang

Nonlinear and Optomechanical Applications Harnessing Silicon Nanostructures (pp. 488)

P. Nuño Ruano, J. Zhang, D. González-Andrade, H. E. B. Ferhart, T. T. D. Dinh, D. Medina-Quiroz, S. Edmond, P. Cheben, D. Marris-Morini, E. Cassan, L. Vivien, N. D. Lanzillotti-Kimura, Carlos Alonso Ramos

Cavity-Induced Attractive Interactions in Van der Waals Quantum Material (pp. 489)

F. Helmrich, T. F. Nova, H. S. Adlong, I. Khanonkin, E. Jöchl, M. Kroner, G. Scalari, J. Faist, Atac Imamoglu

BICs and Quasi-BICs in Unpatterned Media (pp. 490)

Rodrigo Berte, T. Possmayer, A. Tittl, L. de S. Menezes, S. A. Maier

Flat Band Finetuning and its Photonic Applications (pp. 491)

Sergej Flach

Programmable Nanophotonic Devices with Low-loss Phase-Change Materials (pp. 492)

Fouad Bentata, Capucine Laprais, Stéphane Monfray, Nicolas Baboux, Xavier Letartre, Guillaume Saint-Girons, Patrice Genevet, Lotfi Berguiga, Sébastien Cueff

Near-Unity Absorption in Semiconductor Nanowire Metasurfaces (pp. 493)

Michael Reimer

Switching of Topological Edge Transmission in Si Photonics Platform (pp. 494)
Tomohiro Amemiya, Sho Okada, Liyan Hu, Qianshuo Wang, XingXiang Wang, Xiao Hu

Second Harmonic Generation of High-Coherence Light in Si3N4 Microresonators (pp. 495)
Kerry Vahala, Z. Yuan, B. Li, J. Ge, P. Liu, M. Li, J.-Y. Liu, Y. Yu, H.-J. Chen, J. Bowers

Very Large-Scale Integration for Fibers (VLSI-Fi): Assembling Fiber-Embedded Photonics and Optoelectronics by Melt-Shaping Multimaterial Cores (pp. 496)
Alexander Gumennik

Bulk Embedded Laue type Photonic Crystals (pp. 498)
Darius Gailevičius, E. Aleksandravicius, G. Tamošauskas, G. Kontenis, A. Dubietis, K. Staliūnas

Overcoming Integration Challenges in Photonic AI Accelerators (pp. 500)
Angel Ortega-Gomez, Nikolaos Farmakidis, Håvard Hem Toftevaag, Yi Zhang, Harish Bhaskaran

Plasmonic Nanoparticle Synthesis and characterization: Harnessing Enhanced Visible Absorption for Dye Molecule Applications (pp. 502)
Amina Badir, Siham Refki, Zouheir Sekkat

Interfacing the brain by photonic technologies (pp. 503)
Massimo De Vittorio, F. Pisanello

Modeling Electromagnetic Wave Interactions With Ferroelectric Vortex Lattices In The Sub-thz Regime (pp. 504)
Marvin Degen, Ramaz Khomeriki, Vakhtang Jandieri, Jan T. Svejda, Pingjuan L. Werner, Douglas H. Werner, Jamal Berakdar, Daniel Erni

Metamaterial Grating Distributed Feedback Laser Spatial Coupled-mode Modelling (pp. 506)
Henri Benisty, Yaoyao Liang, Abderrahim Ramdane, Anatole Lupu

Discretization effects in topological plasmonics (pp. 508)
Alexander Neuhaus, Pascal Dreher, Frank Meyer zu Heringdorf

Terahertz metasurface for realizing high-Q chiral BICs (pp. 510)
Xinyue Liang, Jian Liu, Xumin Ding

Transport Properties Of Coupled-resonator Phononic Graphene Ribbons (pp. 512)
Rafael Méndez-Sánchez, Yael Hernández-Espinosa, Edgar Sotelo-Parra, Angel M. Martínez-Argüello

Orienting Fluorophores For Highly Efficient Plasmonic Nanoantennas (pp. 514)
Karol Kolataj, Aleksandra Adamczyk, Guillermo Acuna

Mechanically Machinable, Printable Photonic Materials (pp. 516)
Jong G. Ok, Minwook Kim, Kwangjun Kim

Linear Logic Operations In A Quasi-Digital System (pp. 517)
Ross Glyn Macdonald, Alex Yakovlev, Victor Pacheco-Peña

Emitting properties of a-Si:C:H-coated 2D-opaline photonic crystals (pp. 519)
S. I. Pavlov, M. E. Bochkarev, S. A. Dyakov, V. G. Golubev, S. A. Grudinkin, Mikhail Limonov, A. B. Pevtsov

Hybrid Nanomaterials and Metastructures for Photonics, Sensing and Energy

Rhodium Nanospheres For Expanding Plasmonic Applications With Uv And Visible Light (pp. 522)
Vincenzo Amendola

Multiplexed, Label-free Biosensing With Plasmonic Nanoparticles (pp. 524)
Stephan Kastner, Andre Heewig, Florian Seier, Andrea Csaki, Wolfgang Fritzsche

Plasmonic Nanostructures On Paper Lateral Flow Assays For Point-of-care Testing (pp. 526)
Nianqiang Wu

Colloidal Synthesis Of Chiral Plasmonic Nanocomposites Via Circularly Polarized Light Irradiation (pp. 528)
Koichiro Saito, Yoshihiro Nemoto, Yoshie Ishikawa

Magnetic Micro- And Nanorods For Viscosity Imaging Using Heterodyne Holography (pp. 530)
Clémence Gentner, Zhu Zhang, Jean-François Berret, Pascal Berto, Hadrien Robert, Robert Kuszelewicz, Gilles Tessier

Chiral Photogrowth On Plasmonic Nanostructures Under Circularly Polarized Light (pp. 532)
Lucas Vazquez Besteiro

Directional Light Scattering In Mie-resonant Si Particles With Ultra-thin Plasmonic Shells (pp. 533)
Emmanuel Idowu, Kevin O'Connor, Jonathan Veinot, Sabrina Lacomme, Julien Proust, Jérôme Plain, Xiaoyan Li, Mathieu Kociak, Alexandre Baron, Virginie Ponsinet, Lucien Roach, Peter Wiecha, Glenna Drisko

Chiral Silicon Meta Biosensors (pp. 535)
Dominic J.P. Koyroytsaltis-McQuire, Rahul Kumar, Tamas Javorfi, Giuliano Siligardi, Adiran Lapthorn, Nikolaj Gadegaard, Malcolm Kadodwala

Chiro-optical Microscopy Of Plasmonic Materials And Chiral Near-field Interaction With Molecules And Materials (pp. 536)
Hiromi Okamoto, Shun Hashiyada, Hyo-Yong Ahn, Junsuke Yamanishi

Chiral Photochemical Amplification In Mesoporous Plasmonic Shurikens Demonstrating Asymmetric Catalysis (pp. 538)
Olga Guselnikova, Pavel Postnikov, Markus Valtiner, Jonathan P. Hill, Joel Henzie, Daniel T. Payne, Martin Kartau, Iliyana Samardzhieva, George Lefroy Brookes, Malcolm Kadodwala, Alexander O. Govorov, Affar S. Karimullah, Yusuke Yamauchi

Photocatalytic hydrogen evolution with plasmonic and photonic nanomaterials (pp. 542)
Alberto Naldoni

From Symmetry to Chirality: Near-Field Optical Activity in Achiral Gold Nanoparticles (pp. 543)
Minyu Chen, Thinhinane Aoudjit, Baozhong Deng, Yuqing Zhao, Ali Issa, Sylvie Marguet, Davy Gerard, Lucas Vázquez Besteiro, Safi Jradi, Bin Wei, Alexander Govorov, Tao Xu, Renaud Bachelot

Plasmonic Materials for Healthcare and Solar Energy Harvesting Applications (pp. 545)
Fang Xie

Pancake Meta-photonics: Stacking Layers To Prepare Quasi-3d Metasurfaces (pp. 546)
Shunsuke Murai

Sensing Mechanical Resonances Of Living Human Cells Using Nanomechanical Resonators (pp. 547)
Jose Jaime Ruz, Verónica Puerto-Belda, Carmen Millá, Álvaro Cano, Marina Lopez Yubero, Sergio García, Priscila Kosaka, Montserrat Calleja, Javier Tamayo

Organic Optoelectronic Devices And Biofunctionalized Nanoplasmonic Gratings: Integration Into Miniaturized Optical Biosensors (pp. 549)
Margherita Bolognesi, Mario Prosa, Stefano Toffanin

Dna Origami Self-assembled Optical Antennas For Single-photon Chiral Emission (pp. 551)
Fangjia Zhu, Maximilian Lengauer, Maria Sanz-Paz, Karol Kolataj, Sophie Brasselet, Guillermo Acuna

Experimental Femtosecond Pulse Trains For Time-modulation Metamaterials In The Terahertz Spectral Band (pp. 552)
William Wardley, C. M. Hooper, I. R. Hooper, S. A. R. Horsley, E. Hendry

Attomolar Sensing Of Cancer Markers Using A Novel Plasmonic Nanocomposite Thin Film For Early Stage Disease Diagnosis (pp. 554)
Manon Gireau, Fusheng Du, Joelle Youssef, Georges Humbert, Shuwen Zeng, Corinne Champeaux, Frédéric Dumas-Bouchiat

Topological Thermal Emitters (pp. 556)
Said Ergoktas

DNA Sensing With Whispering Gallery Mode Microlasers (pp. 557)
Soraya Caixeiro, Robert Dörrenhaus, Anna Popczyk, Marcel Schubert, Stephanie Kath-Schorr, Malte C. Gather

(Photo-) catalytic Activity Of Sub-5nm Gold Nanoparticles Limited By Coulomb Repulsion (pp. 558)

Monalisa Garai, Thomas A. Klar

Collective Behavior Of A Plasmonic Particle Array With A Chiral Arrangement Under Modal Coupling Regime (pp. 560)
Tomoya Oshikiri

Photocatalysis And Local Growth Driven By Plasmonic Hot Electrons (pp. 562)
Eva Yazmin Santiago

Hybrid Tmdc/plasmonic Systems (pp. 563)
Ermes Peci, Emma Spotorno, Michele Magnozzi, Lorenzo Ramò, Valentina Venturino, Maria Caterina Giordano, Maurizio Canepa, Francesco Bisio

Statistical Evaluation And Dipole Determination By Polarimetric Spectroscopy Yielding The Orientation Of Gold Nanorods (pp. 565)
P. Christian Simo, Annika Mildner, Michaela Zbytovska, Dieter P. Kern, Monika Fleischer

Single-particle Chiral Optical Microscope With High Precision (pp. 567)
Wei-Shun Chang, Angel Thomas, Vidhi Singla, Oscar Avalos Ovando, Trang Nguyen, Tamie Vo, Alexander Govorov

Photoluminescence-based Polarization Conversion In Quantum Rods Aggregate-containing Hybrid Polymer System (pp. 568)
Yutaka Okazaki, Yoshihiro Kawahara, Shoma Kimura, Hayaki Shimizu, Kan Hachiya, Takashi Sagawa

Meta-Atoms Based On Self-assembly Of Gold Nanoparticle On Polymer Microspheres (pp. 570)
Hiroshi Yabu

Hot-electron Dynamics And Speciality Optical Fibres For Quantum Applications (pp. 572)
Kristina Rusimova

Experimental Measurement Of Nanoscale Circular Dichroism In Plasmonic Chiral Structures Using Electron Beams (pp. 574)
Malo Bézard, Simon Garrigou, Yves Auad, Jérémie Béal, Hugo Lourenço-Martins, Davy Gérard, Mathieu Kociak

Highly Efficient And Reversible Chirality Transfer Between Protein And Achiral Plasmonic Assemblies (pp. 576)
Ziwei Zhou, Ningwei Sun, Nina Tverdokhleb, Artur Movsesyan, Anja Maria Steiner, Patrick T. Probst, Vaibhav Gupta, Bo Yin, Nicolás Pazos-Peréz, Ramón A. Álvarez-Puebla, Mirjam Hofmaier, Martin Müller, Holger Merlitz, Olga Guskova, Yaroslava G. Yingling, Franziska Lissel, Tobias A. F. König, Zhiming Wang, Alexander O. Govorov, Nicholas A. Kotov

Surface Plasmon Enhanced Photocatalysis (pp. 578)
Dongling Ma

Sensing 3d Electromagnetic Landscapes With Enhanced Quantum Light-matter Interaction At The Single-molecule And Nanometer Resolution (pp. 580)
R. Margoth Cordova Castro

Reconfigurable Integrated Photonics For Next-Generation Optical Computing And Quantum Technologies (pp. 582)
Alina Karabchevsky

Colloidal Quantum Optoelectronics (pp. 583)
Hilmi Volkan Demir

From Hairy Particles To Particle-Based Metamaterials (pp. 584)
Andreas Fery

Hyperdoped silicon nanocrystals embedded in a silica matrix for infrared plasmonics (pp. 586)
Clavel Berclis Kengne, Xavier Devaux, Mathieu Stoffel, Michel Vergnat, Hervé Rinnert

Controlled Self-assembly Of Polymer-grafted Nanoparticles Toward Hyperuniform Materials (pp. 588)
Kyoungweon Park, Derek Huang, Kenya Hazell, Anesia Auguste, Andrew Gillman, Rich Vaia, Larry Drummy

A Platform for Single-Crystal Nanomaterials and Metasurfaces with Application in Nanophotonics, Sensing and Energy Harvesting (pp. 590)

Sasan V. Grayli, Albert Adserias, Finlay MacNab, Gary Leach

Photopolymerized Molecularly Imprinted Polymers for Plasmonic Sensing Platforms (pp. 592)
A. Khitous, C. Molinaro, Olivier Soppera

Finite Element Analysis of Light Scattering in Resonant Multi-Dielectric Coverslips for Enhanced Total Internal Reflection Fluorescence Microscopy (pp. 594)
Y. Toumi, R. Gurram, F. Lemarchand, A. Moreau, C. Favard, J. Lumeau, G. Demesy, Aude Lereu

Metasurfaces by Two-Photon Polymerization Gray Scale Lithography (pp. 596)
Dewa Ade-Onojobi, Kiernan E. Arledge, Xitlali G. Juarez, Nazli Rasouli, Chase T. Ellis, Joseph G. Tischler

Hybrid Self-assembled Plasmonic Metasurfaces For Applications In Photonics (pp. 598)
Tomas Tamulevičius, Klaudijus Midveris, Gvidas Klyvis, Tomas Klinavičius, Asta Tamulevičienė, Mindaugas Juodėnas, Domantas Peckus, Joel Henzie, Sigitas Tamulevičius

Environmental Permittivity-asymmetric Bic Metasurfaces With Electrical Reconfigurability (pp. 600)
Haiyang Hu, Wenzheng Lu, Alexander Antonov, Rodrigo Berté, Stefan A. Maier, Andreas Tittl

High-resolution And Broadband Metafiber Refraction Index Sensors (pp. 602)
Jiyong Wang, L. Zhang, M. Qiu

N-Heterocyclic Carbene As Robust And Conductive Linkages To Couple Gold Nanoparticles and Conductive Polymers (pp. 603)
Ningwei Sun, Franziska Lissel

Biocompatible Plasmonic Nanoparticle-doped Hydrogel For Facile Optical Detection Of Cortisol (pp. 605)
Alexandra Nicolae-Maranciuc, Dan Chicea, Andreea Campu

Nanocomposite Materials For Biosensors Made By A Dual Pulsed Laser Source (pp. 606)
Manon Gireau, Fusheng Du, Joelle Youssef, Georges Humbert, Shuwen Zeng, Corinne Champeaux, Frédéric Dumas-Bouchiat

Silicon Nanoparticle Arrays for Studies on Colloidal WS2 Nanosheets (pp. 608)
Melanie Sommer, Markus Fröhlich, Lukas Lang, P. Christian Simo, Jannika Lauth, Monika Fleischer

Silver Nanocubes Decorated Silicon Nanostructures Used As 3d Active Sers Platforms For Detection Of Microplastics (pp. 610)
Adina Boldeiu, Pericle Varasteanu, Oana Brancoveanu, Gabriel Craciun, Razvan Pascu, Andrei Avram, Cosmin Romanitan, Iuliana Mihalache, Mihaela Kusko

Angularly Resolved Optical Response of Organic Molecules in Single and Collective Plasmonic Gold Nanosphere ystems (pp. 612)
Felix Schneider, Daniel Schäfer, Sebastian Schlücker, Alfred J. Meixner, Dai Zhang

Synthesis of silver and gold nanoparticles with tunable plasmonic properties for light-assisted anticancer therapy (pp. 614)
Aleš Panáček, Lucie Válková, Lucie Hochvaldová, Anastassiya Pedan, Hana Kolářová, Libor Kvítek

Advanced passive and active metasurfaces and zero-index materials

Nonlocal Metalens For Far-field Label-free Super-resolution Imaging (pp. 617)
Bohan Zhang, Yuanmu Yang

Room-temperature, Tunable Lasing From Quasi-2d Perovskites Integrated With Plasmonic Lattices (pp. 618)
Yu-Jung Lu

Symmetry-breaking And Disorder-assisted Bound States In The Continuum (pp. 620)
Qinghua Song

Shaping Photon Emission With Emitter-coupled Metasurfaces (pp. 622)
Fei Ding

Nonlinear Optics Driven By Out-of-equilibrium Electron Dynamics In Epsilon-near-zero Media (pp. 623)
Matteo Silvestri, Ambaresh Sahoo, Luca Assogna, Matteo Venturi, Raju Adhikary, Paola Benassi, Carino Ferrante, Davide Tedeschi, Alessandro Ciattoni, Andrea Marini

Terahertz Modulators Enabled By Vanadium Dioxide: From Materials Optimization To Devices (pp. 625)
Xi Wang

Electrochemically-tunable Oxide Materials For Metasurfaces (pp. 627)
Vivian Ferry

Electrochemically Active Mid-ir Metasurfaces Based On Conjugated Polymers (pp. 629)
Po-Chun Hsu

Thermo-optical Effects In Nanoantennas And Metasurfaces (pp. 631)
Giulia Tagliabue

Heterogeneous High-entropy Alloy (hea) Plasmonics For Superior And Low-cost Photocatalytic Hydrogen Evolution Reaction (her) (pp. 632)
Chun-Yen Chen, Yu-Hsuan Cheng, Alex Sam, Arya Pilakunnath, Ta-Jen Yen

Accelerating The Design Of Photonic Metamaterials With Artificial Intelligence (pp. 634)
Yongmin Liu

Dynamic Ir Beam Steering And Switching With Active Metasurfaces (pp. 636)
Min Seok Jang

Towards Tunable Metamaterial-based Torque Sensing (pp. 637)
Michael Töfferl, Alexander Schossmann, Maximilian Saiko, Peter Banzer, Alexander Bergmann

Active And Dynamic Optical Phase Gradient Metasurfaces Enabled By Resonant Nanophotonics And Electro-Optic Materials (pp. 639)
David Barton, Sahil Dagli, Sina Abedini Dereshgi, Jennifer Dionne

Metasurface For Multi-Functional Edge Imaging And Quantitative Phase Imaging (pp. 641)
Zhaowei Liu

Highly Confined, Low-Loss Infrared Phonon Polaritons In Perovskite Oxide Membranes (pp. 642)
Yin Liu

Liquid-Metal-Based Reconfigurable Metasurfaces For Display And Sensing Applications (pp. 643)
Peter Qiang Liu

Metasurface-Based Optical Elements For Biomedical Applications (pp. 644)
S. Vyas, C. H. Chu, JerLiang Yeh, Yuan Luo

Confinement-Induced Nonlocality, Topological Darkness, And Goos-Hänchen Effect Enhancement In Transdimensional Plasmonic Film Systems (pp. 646)
Igor Bondarev, Svend-Age Biehs

Ultra-Sensitive Infrared Gas Molecular Measurement Using Three-Dimensional Broadband Metasurface Absorber (pp. 648)
Takuo Tanaka

Nonreciprocal And Directional Control Of Infrared Emissivity In Semiconductor Enz Systems (pp. 650)
Aaswath Raman

Multi-Layer Flat Optics: Challenges And Opportunities (pp. 651)
Ahmed Dorrah

Far-Field Radiation And Polarization Engineering Using Luminescent Metasurfaces (pp. 653)
Elise Bailly, Anne Nguyen, Jean-Paul Hugonin, Jean-Jacques Greffet, Benjamin Vest

Multi-polar High Quality Factor Metasurfaces (pp. 655)

Mark Lawrence, Bo Zhao, Shuqin Dai, Samuel Ameyaw, Lin Lin

Nanofocusing of the Orbital Angular Momentum Laser Beam for Nanoimaging (pp. 656)
Zhenrong Zhang

Metasurface for Bioimaging and Thermal Radiation Management (pp. 657)
Guangwei Hu

Merging Nanophotonics and Optical Fibers for Flexible Beam Control Using 3D Nanoprinting (pp. 659)
Markus Schmidt, Bennet Fischer, Matthias Zeisberger, Mohammad Khosravi, Shahrzad Hosseinabadi, Oleh Yermakov

High Contrast Nanoscale Chirality Imaging (pp. 660)
Seongmin Im, Gayatri Chandran, Yang Zhao

Bright and Dark Lasing in Nanoplasmonic Metasurfaces (pp. 662)
Ortwin Hess

Tunable focus manipulation in multicore meta-fibers through 3D nanoprinted phase-only holograms (pp. 664)
Mohammadhossein Khosravi, Torsten Wieduwilt, Matthias Zeisberger, Adrian Lorenz, Markus Schmidt

Transient Optical Symmetry Breaking For The Ultrafast Switching Of A Metasurface Quasi-bic (pp. 666)
Giulia Crotti, Andrea Schirato, Olesiya Pashina, Olga Sergaeva, Mihail Petrov, Costantino De Angelis, Giuseppe Della Valle

Addressing The Challenge Of Phase-only Dynamic Modulation Of Transmissive Metasurfaces (pp. 668)
Juyoung Kim, Ruzan Sokhoyan, Harry Atwater, Min Seok Jang

All-dielectric Electrically-tunable Metasurface For Efficient Beam Steering (pp. 670)
Junghyun Park, Byung Gil Jeong, Sun Il Kim, Minkyung Lee, Young Kim, Jang-Woo You, Wontaek Seo, Byung-Hoon Ko, Seokho Yun

Optical Charge Trap Memory Based On Graphene/zno Heterostructures For Long-term Retention And Adaptive Learning (pp. 672)
Junhyung Kim, Seungmin Shin, Hyeongdoh Lee, Min Seok Jang, Himchan Cho

Dynamic Multi-Wavelength Coded Aperture Imaging Using Reconfigurable Metasurfaces (pp. 674)
Reza Marzban, Hamed Abiri, Ali Adibi

Dynamic Control Of Bound States In The Continuum By Mems-enabled Hybridization Of 1d And 2d Metasurfaces (pp. 676)
Fedor Kovalev, Mariusz Martyniuk, Andrey Miroshnichenko, Ilya Shadrivov

Seyedhadi Badri, Artem S. Vorobev, Liam O'Faolain

On-chip Lasers On Waveguides: A Meta-morphosis In Waveguide Imaging (pp. 1514)

Scattering-based microscopy with an evanescent field enhances signal-to-noise by suppressing background. Waveguides generate evanescent waves, but edge-coupling of light is difficult to use. Bonding a VCSEL to a waveguide platform enables an easy coupling via a grating coupler. Integrating a metasurface into the VCSEL tilts emission, improving waveguide excitation. Plenary presentations

Applications of highly nonlinear epsilon-near-zero materials in photonics

Robert W. Boyd

Department of Physics and School of Electrical Engineering and Computer Science
University of Ottawa, Ottawa, ON Canada

The Institute of Optics and Department of Physics and Astronomy
University of Rochester
Rochester, NY USA

Abstract: Optical materials display extremely large nonlinear response in a spectral band around their plasma frequency. This presentation reviews the origin of this behavior and provides examples of such materials and of applications enabled by this response.

Research reported in 2016 [1] showed that materials such as indium tin oxide (ITO) display an unprecedentedly large nonlinear refractive index when excited at a frequency where the dielectric permittivity is nearly vanishing. The large nonlinear response of these epsilon-near-zero (ENZ) materials, some million times larger than that of silica glass, suggest that these materials would prove extremely useful in the development of new classes of photonic devices. In this contribution, we review the history of the understanding of nature of the nonlinear response of ENZ materials and the development of ENZ-based photonic devices. Specific investigations over the past eight years have led to increased understanding of topics including (1) the origin of the enhancement of the nonlinear optical response, (2) the possibility of using nanofabrication methods to create ENZ behavior at any specified wavelength, and (3) the exploration of what interactions and devices are enabled through use of ENZ materials. In this contribution, we review the recent history of the development of the field of ENZ science and of the development of ENZ applications.

Nanoplasmonic Quantum Photonics

Ortwin Hess[1]

[1]School of Physics and CRANN Institute, Trinity College Dublin, The University of Dublin, Dublin 2, Ireland
*corresponding author: ortwin.hess@tcd.ie

Abstract: Nanoplasmonic quantum photonics revolutionizes quantum information technologies by enabling room-temperature quantum operations through extreme nanoscale field confinement and strong photon-emitter coupling. This facilitates ultrafast single-photon emission, multipartite entanglement, near-field coupling, and quantum sensing, enhanced by quantum nanoplasmonic coherent perfect absorption, paving the way for practical quantum devices operable at ambient conditions.

Nanoplasmonic quantum photonics represents a groundbreaking advancement, bridging nanotechnology and quantum information processing to overcome fundamental limitations of conventional quantum devices. This approach enables quantum operations at room temperature, achieving significant miniaturization, enhanced speed, and practicality by leveraging cavity quantum electrodynamics (cQED) in the strong coupling regime, where coherent photon-emitter interactions produce polariton states [1,2] while previously, single quantum emitter strong coupling required complex and costly cryogenic setups, severely restricting broad applicability.

Nanoplasmonic cavities offer a transformative solution by confining electromagnetic fields to scales far below the diffraction limit. Nanoparticle-on-mirror (NPoM) architectures enable sub-nanometric confinement and intense electromagnetic field enhancement, allowing unprecedented room-temperature strong coupling at the single-molecule level [3]. Chikkaraddy et al. demonstrated practical room-temperature strong coupling within these cavities, significantly impacting quantum photonic device development [3]. Additionally, near-field coupling techniques have been shown to strongly couple single quantum dots at room temperature, further illustrating the power of nanoplasmonics in achieving robust quantum interactions at ambient conditions [4].

Recent advances underscore the capability of nanoplasmonics for ultrafast single-photon generation, multipartite entanglement, and quantum sensing. Near-field transducers (NFTs), originally designed for data storage applications, now enable highly efficient optical field focusing into nanoscale volumes, significantly increasing quantum dot emission rates and facilitating precise control over quantum states. Xiong et al. emphasized the significance of room-temperature plexcitonic strong coupling and associated ultrafast quantum dynamics, essential for efficient quantum state manipulation and entanglement [5]. NFTs have successfully supported both bipartite and tripartite entanglement under ambient conditions, paving the way for scalable quantum information processing systems [6,7]. Quantum sensing has also benefited from nanoplasmonic platforms, where quantum plasmonic immunoassays have demonstrated extraordinary sensitivity and specificity at the single-molecule detection limit, highlighting their potential in biomedical and diagnostic applications [8]. Continued refinement of these technologies addresses existing challenges, such as fidelity enhancement and improved coherence control.

Addressing the pivotal challenge of coherence preservation, quantum nanoplasmonic coherent perfect absorption (qnCPA) introduces an innovative solution [9]. qnCPA exploits directional energy transfer from plasmonic waveguides to selectively excite and maintain polaritonic states, effectively mitigating dissipation effects. Jalali-Mola et al. highlighted the potential of slow-wave nanoplasmonic waveguides to mediate coherent

interactions among distant quantum emitters, an essential step toward robust quantum networks and chip-scale quantum technologies [10].

These developments position nanoplasmonic quantum photonics as a key driver in revolutionizing practical quantum device implementation, significantly enhancing scalability, coherence, and ambient operational viability for next-generation quantum technologies

Robust Edge States in Topological Lattices for Quantum information Transfer

J. Zurita[1], C.E. Creffield[2]and G. Platero[1*]

[1] *Materials Science Institute of Madrid (CSIC) , Spain*
[2]*Department of Physics of Materials, Complutense University of Madrid, Spain* [2]
[*]gplatero@icmm.csic.es

Abstract: This talk will deal with the transfer of quantum information using protected topological edge states. I will discuss the long-range transfer in a dimer chain, a 1D topological insulator, and in the Creutz-Ladder lattice and the role of topological domain walls to speed up the particle transfer.

Abstract:

Integrated photonics and meta-optics enable compact, precise light control, advancing optical metrology in applications like atomic clocks and gravitational wave detectors. This work explores nanophotonic devices for precision experiments and atom chips, focusing on light-matter interactions and the impact of material properties on performance and precision.

Metastructures That Compute and Optimize

N. Engheta

University of Pennsylvania, USA
engheta@seas.upenn.edu

Abstract: I will present some of the most recent results of our ongoing research projects on nonlocal metasurfaces and metastructures that perform ultrafast analog computation, such as vector-matrix multiplication, matrix inversion, constrained optimization, equation solving, etc. Time permitting, I will also discuss how incoherent light can be used for certain analog computations.

What I Wish I Had Known, as I Searched for the First 3d Photonic Bandgap

Eli Yablonovitch

Electrical Engineering and Computer Sciences Dept.,
UCLA/University of California, Berkeley, USA
eliy@eecs.berkeley.edu

Abstract: The first 3-dimensional Photonic Bandgap was found by Edison-ian search, trial-and-error, guided by physical intuition. The 4-year search was beset by pseudo-gaps, and required deep physical insights to find the right geometry (diamond unit cell in a face-centered-cubic lattice). Nonetheless, there do exist mathematical techniques for 3d geometry optimization that could have led to the right structure more quickly.

Summary:

The optimization problem is exacerbated by the reality that any geometrical design could have millions of design parameters that define a desirable shape. With a particular goal in mind, the adjustment of any one design parameter, requires a revision of all the other parameters, making it hard, or impossible to converge on a good design. Essentially this is a problem in multi-variable calculus: How to co-optimize the millions of parameters that are implicit in any geometrical shape? It might be called “Shape Calculus”.

Fortunately there are elegant mathematical methods that have emerged that permit the co-optimization of millions of variables, but requiring only two solutions of Maxwell’s Equations [1]. The mathematical approach is sometimes called the “Adjoint Method”, and it is a merger the chain rule of calculus, with linear algebra [2].

The earliest application of the adjoint method was for military logistics in the 1950’s, and called Operations Research. Indeed the mathematics has been rediscovered numerous times in the past 70 years, within various fields, wherever some optimization over many variables is needed. This has many names. For example, in neural networks this is called “Back-Propagation”, in photolithography it’s called Inverse Lithography Technology, (ILT), but it is also used in Control Theory, mechanical design, etc.

One of the first electromagnetic applications of the “Adjoint Method” was toward the design of lithographic masks for the photographic process by which electronic chips are manufactured. These masks consist of thin-film Chromium on glass, intricately patterned, to photographically project out the sub-wavelength shapes of transistors, wires, and other components on an integrated circuit. These metal film masks, so heavily used in electronics manufacturing, can be regarded as the original “meta-surface” [3].

Sub-wavelength transistor images were desired, but it was not at all clear what the mask pattern should be, that would produce those desired sub-wavelength images. The first company founded to employ the “Adjoint Method” for photo-lithography was Luminescent Inc., (2002). Luminescent introduced the slogan ILT “Inverse Lithography Technology” to be understood as a sub-category of Inverse Electromagnetic Design. Today, almost all memory chips and micro-processors use thin-film chromium masks and ILT software in their design and manufacture, meta-surfaces indeed [4].

Whether it's a meta-lens or any other type of electromagnetic function, there is no need to slavishly follow a periodicity constraint. Mathematical methods have been developed, to efficiently optimize any type of electromagnetic function. I will provide some examples: "Silicon Photonics" couplers, optical antennas, solar cell surface textures, etc

Modulating Optical Properties in Time Using Plasmonic Resonances

John Pendry[1]

[1]Imperial College London, UK
*corresponding author: j.pendry@imperial.ac.uk

Abstract: Plasmonic effects in Indium Tin Oxide enable rapid switching of transparency which can be exploited to modulate THz radiation on a fs time scale.

Short Abstract: Plasmonic effects in Indium Tin Oxide enable rapid switching of transparency which can be exploited to modulate THz radiation on a fs time scale.

With the growing interest in extreme time modulation of material properties attention has turned to materials such as Indium Tin Oxide which is commonly doped to give a Fermi energy of around 1eV and plasma frequency, ω_p, of similar magnitude. Thin films of ITO are transparent to visible light with frequency well above ω_p. It is well known that heating the electrons with a fast laser pump pulse lowers ω_p and hence switches between opaque and transparent for near IR radiation [1]. Along with extremely rapid switching times of the order of the few cycles, contrast levels of the order of 50% are commonly observed.

Basics of the mechanism are understood: rapid heating of electrons followed by slow equilibration with lattice phonons. Controversy over details remains, but recent experiments shed light on the time scales of the several processes taking place. Experiments in Sapienza's group at Imperial College revealed the existence of extremely fast processes by generating Young's fringes in frequency [2]. It was evident from these experiments that switching happened faster than any of the known time scales: 100fs pulse width for the pump and probe, 300fs electron-electron scattering time. The origin of the fast event will remain a mystery until the excitation process can be probed with single cycle pulse widths.

My talk will speculate about possible mechanisms at play and suggest experiments that will help further our understanding. Time permitting I shall discuss the theoretical challenges awaiting for the new ultrafast material experiments.

Quantum Aspects of Light Propagation in Time-Varying Media

John Pendry[1]

[1]Imperial College London, UK
[*]corresponding author: j.pendry@imperial.ac.uk

Abstract: Recent experiments demonstrate ultra-fast modulation of refractive indices opening up the field of space-time modulation [1-3]. Breaking time invariance presents new challenges to theory with the removal of conservation of energy/frequency. New conservation laws are emerging which deepen our understanding of these systems. A recent review can be found here [4].

Typically space -time structures involve no physical movement of material meaning that movement at any speed can happen without violating causality. This removes many theoretical obstacles to theoretical treatment. Many new phenomena are being found such as novel amplification mechanisms that work by squeezing lines of force together. Some systems can be regarded as reversible heat engines capable of heating or cooling radiation incident upon them.

Quantum aspects of 4D systems are rich field of study particularly for systems in uniform motion which obey PT symmetry and therefore have some elements in common with traditional QED but with the difference that frequency is not conserved. In particular transitions between positive and negative frequencies can be induced and are associated with spontaneous emission of radiation as photon pairs. By analogy between a refractive index and gravitational metrics, systems have been found which model the Schwarzschild singularity and emit Hawking-like radiation. Other systems that make travelling-wave modulations of a medium's impedance but leave the speed of light a constant, are analogous to the interaction of gravitational waves with electromagnetic fields.

Acknowledgements, if any, including all funding information, should be gathered into a brief statement at the end.

Chemically Functionalized Two-Dimensional Materials for Quantum Photonic Science and Technology

Mark C. Hersam[1*]

[1]Northwestern University, Evanston, IL 60208, USA
[*]Corresponding author: m-hersam@northwestern.edu

Abstract: Chemical functionalization allows tailoring of the properties of 2D materials and the degree of coupling across heterointerfaces. In this talk, the prospects of 2D materials for quantum photonic science and technology will be discussed with a focus on how chemical functionalization can enhance quantum emission in 2D transition metal dichalcogenides.

Layered two-dimensional (2D) materials interact primarily via van der Waals (vdW) bonding, which has created opportunities for heterostructures that are not constrained by epitaxial lattice matching [1]. However, since any passivated surface interacts with another via non-covalent forces, vdW heterostructures are not limited to 2D materials alone. In particular, 2D materials can be integrated with a diverse range of other materials, including those of different dimensionality, to form mixed-dimensional vdW heterostructures [2]. Furthermore, chemical functionalization allows tailoring of the properties of 2D materials and the degree of coupling across heterointerfaces [3]. In this talk, the prospects of mixed-dimensional heterostructures for quantum photonic science and technology will be discussed with a focus on how chemical functionalization can manipulate and enhance quantum emission in 2D transition metal dichalcogenides [4]. In addition to technological implications, this talk will explore fundamental issues including band alignment, doping, trap states, and charge/energy transfer across heterointerfaces [5].

Empowering chiral metamaterials with gain materials

I. Katsantonis[1,2], A. Tasolamprou[1,3], M. Kafesaki[1,2*,]

[1]Institute of Electronic Structure and Laser, Foundation for Research and Technology Hellas (FORTH), Heraklion, Crete, Greece
[2]Dept. of Materials Science and Engineering, Univ. of Crete, Greece
[3]Dept. of Physics, National and Kapodistrian University of Athens, Athens, Greece
[*]corresponding author: kafesaki@iesl.forth.gr

Abstract: We will review our recent works on chiral metamaterials involving gain materials and on chiral metamaterials combining gain and loss. Special attention will be given to parity-time symmetric chiral metamaterials and to chiral metamaterials for circularly polarized laser emission.

Chiral metamaterials, i.e. metamaterials lacking any mirror symmetry plane, constitute one of the most fascinating metamaterial categories, as they enable interesting polarization-related effects, allowing different polarization control properties and capabilities. Such capabilities include, among others, giant polarization rotation and giant circular dichroism, enabled by ultra-subwavelength structures (see, e.g,. Fig. 1).

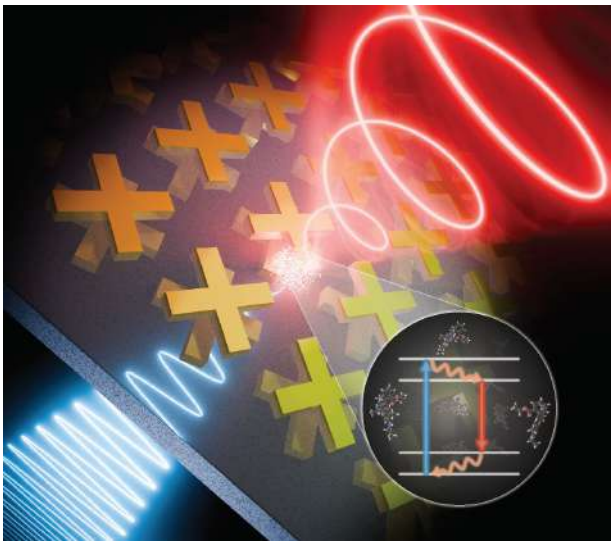

Fig. 1. Artistic demonstration of circularly polarized wave emission by an ultrathin plana chiral structure embedding a gain material. The basic structure-building-block is a pair of mutually twisted metallic crosses. The structure can give almost pure circularly polarized laser emission if excited by a pump wave of linear polarization. The laser emission can be switched from left- to right-handed by tuning the pump wave polarization. Picture reprinted from [1].

Adding gain media into chiral metamaterials and exploiting the chiral resonant electromagnetic fields in such media, one can not only greatly enhance the chiral response, but also enable novel and important for applications wave phenomena. Among such phenomena of particular interest are the ones enabled by Parity-Time (PT) symmetric chiral metamaterials, i.e. chiral metamaterials that combine gain and loss in a balanced way as to respect combined parity and time reversal symmetry. As we will show in this talk such media enable unidirectional perfect reflection, highly asymmetric wave absorption, simultaneous coherent-prefect absorption (CPA) and lasing, CPA-lasing of elliptically and circularly polarized waves, multiple and highly controllable exceptional points and PT-related phases, and dynamically controllable optical rotation and circular dichroism [2-4]. Some of those phenomena remain to a large degree intact if one departs from the strict PT-symmetry as to enable practically realizable metamaterial configurations.

Another category of important chiral-gain phenomena are related with electromagnetic wave emission and lasing. As we will show in the talk, properly designed chiral metamaterials can give not only circularly polarized emission lasing but also lasing of dynamically controllable polarization, able to be switched between left- and right-handed [1].

All these results highlight the rich response of the chiral-gain media and their importance in current and future polarization-related phenomena and applications.

We acknowledge funding by the EU-MSCA project CHARTIS, Project No. 101007896.

Photonic Metamaterial Time Crystals and Timetronics

Nikolay I. Zheludev[1,2]

[1)]Optoelectronics Research Center, University of Southampton, UK
[2)]Institute for Advanced Study, Texas A&M University, USA
zheludev@soton.ac.uk

Abstract: We discuss recent developments in understanding functionalities and developing applications of time crystals - a new state of matter, a many-body interacting system that exhibits a spontaneous mobilization transition to the robust state of oscillation, breaking time translation symmetry under an infinitely small change of the external driving force.

Light-driven nonreciprocal forces in an array of nano-opto-mechanical oscillators (e.g. metamaterial) can underpin the functionality of Time Crystal, a many-body interacting system that exhibits a spontaneous mobilization transition to the robust state of oscillation under an infinitely small change of the external driving force. Such time crystals are a form of Active Matter with life-mimicking dynamics accompanied by the breaking of time translation symmetry, ergodicity, and local entropy decrease. This is of interest to optical "timetronics" – a data processing and communications technology relying on the unique functionalities of time crystals.

Computational Models of Light Management in Photovoltaics and LEDs

V. E. Ferry[1*]

[1]Department of Chemical Engineering and Materials Science, University of Minnesota-Twin Cities, Minneapolis MN 55455 USA

[*]corresponding author: veferry@umn.edu

Abstract: This talk will discuss the computational models for light management strategies in photovoltaics, including systems that integrate luminescent solar concentrators in greenhouses and reduce the temperature of outdoor panels.

This talk will discuss a few case studies where computational models provide insight into energy systems, and determine the design rules that guide experimental work. One example is in agrivoltaics, the dual use of land for agricultural production and electricity generation. One strategy is to create a greenhouse with a luminescent solar concentrator (LSC) roof and sidewalls. The LSC simultaneously generates electricity on site and filters transmitted sunlight, and it is possible to tune the properties of the LSC (light emitting material, concentration, and architecture) to promote both electricity generation and crop yield. The system is complex, since integrating the LSC into the greenhouse also changes the heating and cooling needs. By developing models that account for these factors, we can identify the optimal characteristics of the light-emitting materials, which in turn informs experimental development.

A second example is the design of structures that increase energy yield of a photovoltaic panel installed outdoors through a combination of anti-reflection of above-bandgap radiation and below-bandgap reflection to mitigate performance losses due to heating. Our computational models first determine the characteristics that are necessary in these dual-purpose photonic structures, then find the materials and structures to realize those refined performance goals. These models are validated with outdoor experimental measurements.

Rethinking Linking – Topology in Magnetism, and Plasmonics

M. Azhar[1], R. Knapman[1], P. Gessler[1], A. Neuhaus[1], P. Dreher[1], F. Meyer zu Heringdorf[1] and K. Everschor-Sitte[1*]

[1]Faculty of Physics and CENIDE, University of Duisburg-Essen, 47057 Duisburg, Germany
[*]corresponding author: karin.everschor-sitte@uni-due.de

Abstract: Topology in physics explores robust, fault-tolerant states of matter aiming at practical applications. Similar topological structures arise in magnetism, optics, and plasmonics despite differing physics. A challenge is understanding them when traditional mathematical topological frameworks are not necessarily applicable. Linking and geometry offer intuitive ways to describe these complex textures.

The field of topology and topological excitations in physics is spurred by the key idea of robust and fault-tolerant states of matter for technological applications. In recent years, many topological field configurations observed and predicted in magnetism[1] have been emulated in optics[2] and plasmonics[3], despite the fundamentally different underlying physics. While magnetic systems host topological field configurations as (meta-)stable states, plasmonic textures require an out-of-equilibrium system to sustain the collective dynamical redistribution of charge density in a solid. Unlike the typically non-volatile, vector fields of constant amplitude studied in magnetism, topological electromagnetic excitations are more complex and highly tunable. Their increased complexity arises from two key aspects: (i) both electric and magnetic fields – or their combinations – can form topologically non-trivial configurations, and (ii) these vector fields may have time-varying or even vanishing amplitudes. The high degree of tunability stems from the ability to tailor geometry and external drives to generate specific topological electromagnetic excitations. Thus, rather than relying on intricate material engineering to shape energy landscapes for stabilizing magnetic topological states, plasmonics requires engineering of excitation geometries and drive mechanisms.

In terms of topological characterization, the fields share similar challenges. Homotopy theory comprises topological indices, such as the Skyrmion winding number in two dimensions and the Hopf index in three dimensions – which can be expressed as integral expressions to be calculated for vector fields. However, these indices rely on certain prerequisites that real-world textures may violate. One of these prerequisites is that the field configuration is uniform at the boundary (or at infinity). This, however, does not apply to three-dimensional structures that are effectively "two plus one" dimensional – those consisting of two-dimensional textures extending periodically along a third direction. Notable examples include (twisted) Skyrmion tubes, screw dislocations, and space-time Hopfions[4].

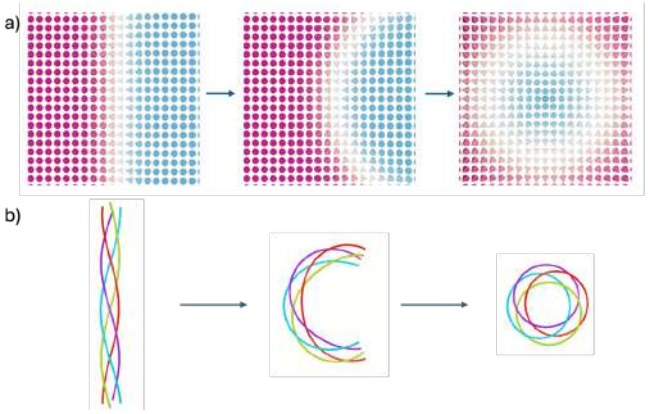

Figure 1: Connection of linking and topology. a) connecting the ends of a domain wall to a Skyrmion; b) linking the ends of a Skyrmion tube to obtain a Hopfion.

Rather than computing the integral expression of the topological index for field configurations, the concept of linking provides deeper insight into their nature, as illustrated in Figure 1. For instance, Skyrmions can be

regarded as extended domain walls whose ends are connected to each other, while Hopfions can be interpreted as linked or braided Skyrmion tubes.

By employing a discrete geometric definition of the Hopf index, a general framework for the description of three-dimensional textures beyond the constraints of homotopy theory is established[5]. This approach overcomes the pitfalls and limitations of using the conventional Whitehead integral formula to compute the Hopf index in finite volumes[6]. Furthermore, it naturally provides a foundation for space-time Hopfions and explains the emergence of topological textures with arbitrary Hopf indices. In particular, it enables the interpretation of non-integer Hopf values as states of "mixed topology," capable of continuously transitioning between multiple topological sectors. This is exemplified in Figure 2 with the "Twiston", a peculiar topological texture which possesses a fractional Hopf index and can evolve into either a Hopfion (Hopf index 1) or a Skyrmion tube (Hopf index 0), both of which have integer Hopf indices.

This framework not only enhances our understanding of magnetic topological field configurations but also reveals their fundamental connections across diverse physical systems.

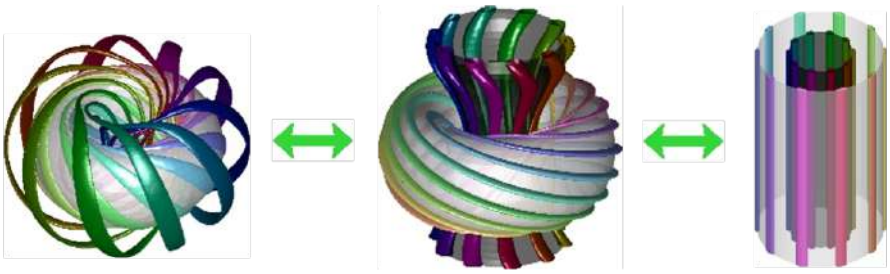

Figure 2: A Twiston with a fractional Hopf index (middle panel) can transform into a Hopfion with Hopf index 1 (left) or Skyrmion tube which has a Hopf index of 0 (right).

Wavefront microscopy for nanophotonics

Guillaume Baffou

[1]Institut Fresnel, CNRS, Aix Marseille University, Centrale Med, Marseille, France
[*]corresponding author: guillaume.baffou@fresnel.fr

Abstract: Cross-grating wavefront microscopy (CGM) consists of the association of a 4-wave diffraction grating and a camera separated by millimeter distance. We show how CGM can be used to measure the optical properties of nanoparticles, 2D material a metasurfaces, such as the complex optical polarizability, conductivity, refractive indices, and cross-sections.

Cross-grating wavefront microscopy (CGM) is a high-resolution, high-sensitivity wavefront imaging technique [1,2]. It consists of the association of a 4-wave diffraction grating and a camera separated by millimeter distance. Mostly used in biology this last decade, it is now becoming popular in nanophotonics applications as well. This contribution is aimed to explain (i) how we turned CGM into a thermal microscopy technique to map the temperature of gold nanoparticles under illumination [3], enabling applications in physics [4], chemistry [5] and biology [6] at the nano/microscale; (ii) how CGM can map all the optical properties of 2D materials and nanoparticle arrays [7] (namely the complex optical conductivity, complex refractive index, transmittance, reflectance, absorbance) from a single image acquisition; (iii) how CGM can retrieve the complex optical polarizability of nanoparticles, along with the extinction, scattering and absorption cross sections from a single image acquisition [8,9], and finally (iv) how CGM can fully characterize metasurfaces [10].

CGM images. (a) Temperature distribution around laser-heated gold nanoparticles. (b) Wavefront distortion image of 100-nm gold nanoparticles used to compute their optical cross sections. (c) Wavefront distortion imagex of MoS2 structures, used to map their complex refractive index. (d) Wavefront distortion created by a metalens. (e) Polarization resolved image of a plasmonic corral.

[*]corresponding author: konstantin.bliokh@dipc.org

Abstract: I will present recent theoretical and experimental results on: (i) subwavelength high-intensity vortices around 'holes' in 2D wave systems: from polaritons to ocean waves, (ii) Bessel-type vortices, displacement-field skyrmions, and polarization Möbius strips in sound and water waves, and (iii) manipulation of floating particles using topologically structured water waves.

50 years ago, Nye and Berry published a seminal work [1] introducing phase singularities, also known as wave vortices. This initiated a surge of interest in topological structures in linear waves [2]. Since then, a variety of topological wave structures has been discovered, such as polarization singularities [3], polarization Möbius strips [4,5], and skyrmions [6]. Although topological wave forms were mostly studied for optical fields, these can equally appear in any linear waves, from water waves to quantum mater waves.

Here, I will provide an overview of recent theoretical and experimental works describing new type of wave vortices which appear around subwavelength 'holes' in 2D planes [7], polarization singularities and Möbius strips in sound and water waves [8,9], wave vortices and skyrmions in water waves [10–12]. Furthermore, I will show that structured water waves have the dynamical momentum and angular-momentum properties entirely similar to those in optical and acoustic fields [10], which enables trapping and manipulation of floating particles [13], similar to optical and acoustic tweezers [14].

Abstract: Hybrid plasmonic nanosystems based on weak or strong coupling are discussed in terms of controlling the spatial distribution, and associated symmetry, of the active medium in the vicinity of the metallic nanocavities.

Over the past 20 years, hybrid plasmonic light nano-emitters or nano-absorbers, based on weak or strong coupling between metallic nanocavities and quantum nano-emitters/absorbers, have given rise to major research efforts.[1,2]

One of the main current challenges is to control the spatial distribution on the nanometric scale, and the associated symmetry, of the active medium (emitting or absorbing entities) in the vicinity of the metal nanoparticles.[3,4]

We describe the main principles of weak and strong coupling and present examples of achievements demonstrating weak or strong coupling on hybrid nanosystems.

In particular, through selected examples, we show that controlling the spatial distribution of the active medium has opened up new avenues, such as polarization-sensitive photoluminescence[1,3,4], lifetime engineering[5], local spatial symmetry group control[1], controlled donor-acceptor energy transfer[3,6], polarization-driven single-photon switching[4], and chiral nano-emitters (see illustration of this last case in Fig. 1).

Some future challenges will be discussed in more detail.

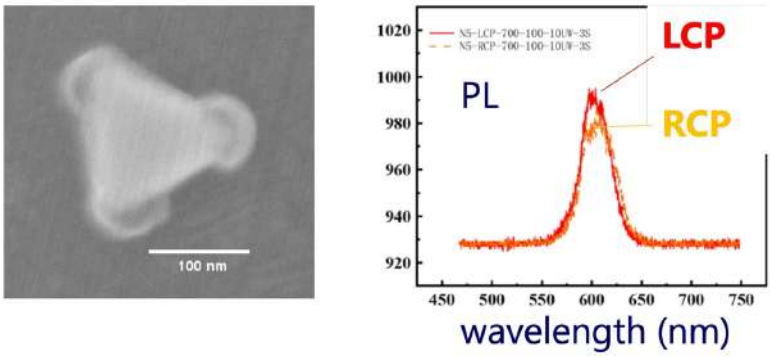

Figure 1. Chiral hybrid nanosource of light. Left: SEM image of a gold nanotriangle surrounded by a nano-emitters-containing medium presenting 2-D chirality. Right: Photoluminescence (PL) from the hybrid nanosystem excited at 405 nm by two kinds of polarization: left-hand circular polarization (LCP) and right-hand circular polarization (RCP). Not published data.

Abstract: The spectral frequency response of a hypersonic phononic wave propagating along a non-trivial topological waveguide is obtained by laser Doppler vibrometry. The guided mode at 2.115 GHz is shown to propagate with minimal loss.

The topological nanoelectromechanical structure in this work is based on the phononic analogue of the valley Hall effect (VHE). The valley pseudospin characterizes degenerate energy extrema in momentum space, with its topological nature arising from the nontrivial Berry curvature localized at k points in the reciprocal space. An interface waveguide 18.84 µm long was designed to exhibit a full phononic gap between 2.058 and 2.198 GHz and to support a topologically protected edge mode. The scanning electron microscopy (SEM) image of the fabricated device and the simulations are depicted in Fig.1(b). The waveguide is fabricated in a membrane nanocrystalline Si (nc-Si) [1] 220 nm thick and characterized using laser Doppler vibrometry. The device features aluminum (Al) interdigitated transducers (IDTs) on an aluminum nitride (AlN) layer deposited on the nc-Si film in order to launch the acoustic excitation focused at the entrance of the topological waveguide. The phonon propagation was studied by swiping the frequency of the surface acoustic waves (SAW) from 1.9 to 2.4 GHz.

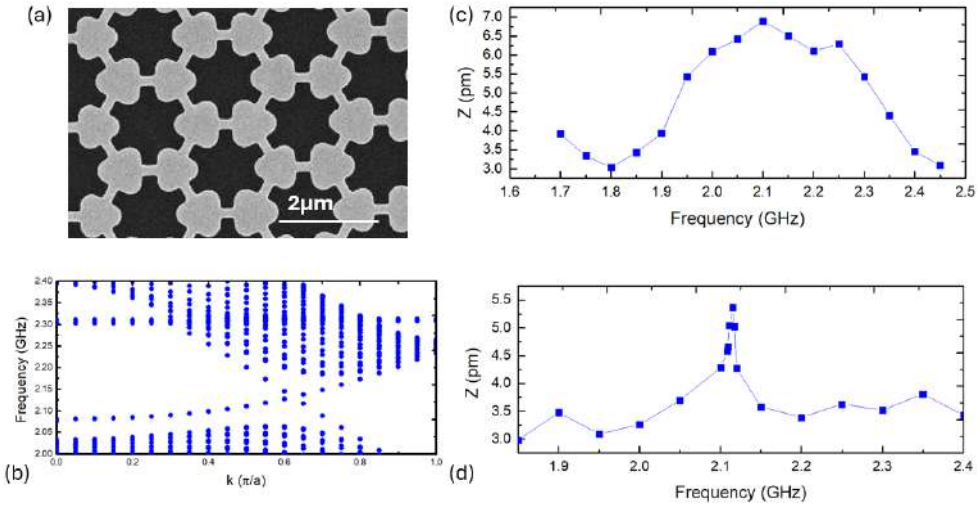

Figure. 1 (a). SEM image of the fabricated structure. (b) Simulated phononic bandgap and topological edge modes. (c, d) Out-of-plane displacement magnitude versus frequency at the entrance and exit of the interface waveguide, respectively.

Frequency specific SAWs were generated by a vector network analyzer from 1.90 GHz to 2.40 GHz in steps of 50 MHz. This signal was transfer to Al electrodes via electrical probes. The full width at half maximum of each input signal was 10 KHz. The out-of-plane displacements were measured at the entrance and exit of the waveguide as shown in Fig.1(c) and (d). Fig.1(c). shows the broad band envelope of the SAWs generated by the IDTs. The displacement field at the exit of the waveguide in Fig.1(d) shows that within the bandgap, phonos at 2.115 GHz are guided with minimal loss, whereas other frequencies experience a strong attenuation.
We suggest that our results constitute a demonstration of phonon propagation with low attenuation (-2.1dB) in a topological phononic waveguide.

We acknowledge the support from the project LEIT funded by the European Research Council, H2020 Grant Agreement No. 885689.

AI to Discover and Synthesize Sub-terahertz Chips beyond Human Intuition

Kaushik Sengupta

Princeton University, Princeton, NJ, USA
*corresponding author: kaushiks@princeton.edu

Abstract: Traditionally, chip-scale high-frequency system design has been in the domain of the expert, dominated by thumb rules and trial and error techniques. With AI, not only designs can emerge orders of magnitude faster, but it can lead to new design spaces previously unexplored resulting in circuits that are beyond human intuition and insights---circuits that can break through many of the traditional trade-offs and performance limits. We demonstrate here for the first time how AI can not only allow design times that are orders of magnitude faster, but also unearth new architectures that are beyond human intuition.

Bio: Dr. Sengupta received his Ph.D. in Electrical Engineering from Caltech in 2012. Dr. Sengupta joined the Department of Electrical and Computer Engineering at Princeton University, Princeton, NJ, as a Faculty Member in 2013, where he is currently a Professor. His research interests include novel chip-scale architectures for intelligent sensing and communication for a wide range of emerging applications.

Dr. Sengupta is an IEEE Fellow. He received the DARPA Young Faculty Award in 2018, the Bell Labs Prize in 2017, the Young Investigator Program Award from the ONR in 2017, the 2015 Microwave Prize, and multiple best paper awards in IEEE IMS and RFIC. He served as a Distinguished Lecturer for the IEEE Solid-State Circuits Society from 2019 to 2020 and for the IEEE Microwave Theory and Technology Society from 2021 to 2023. He is a recipient of the 2021 IEEE Microwave Theory and Technology Outstanding Young Engineer Award and the 2022 IEEE Solid-state Circuits New Frontier Award. He currently serves as the co-chair of the IEEE Solid-state Directions Sub-committee and as a technical advisor for the wireless start-up company, GuRu, based in Pasadena, CA. His group received IEEE Journal of Solid-State Circuits Best Paper of the Year in 2023.

Tailoring the visual appearance with correlated-disorder metasurfaces

Abstract: We will review our current effort to model the resonance of individual resonators and collections of them with various theories, including quasinormal modes expansion and multiple scattering.

Disordered metasurfaces, comprising non-periodic arrangements of meta-atoms, have recently emerged as a versatile platform for harnessing both near- and far-field scattered light in a wide range of applications [1].

Quantitatively predicting the scattering properties of disordered metasurfaces requires advanced knowledge of the nanoscale resonances, mesoscale interferences and macroscale light transport to compute the bidirectional reflectance distribution function (BRDF). Understanding the link between appearance and morphology represents a fantastic challenge because metasurfaces offer a multitude of degrees of freedom to harness the diffuse and specular light

Despite this difficulty, some of the authors have recently succeeded in designing the very first simulation tool to predict the appearance of disordered metasurfaces [2]. The modelling platform may find use in several branches of visual arts, to predict the appearance of augmented reality devices using metasurfaces, design unusual effects for counterfeiting applications… Importantly, the tool predicts the possibility to create fancy appearances, unseen so far with the nanostructures available in nature, see the Supplementary Videos 1 & 2 in [2,3] for a rapid glance.

At the conference, we will review our recent efforts to model and understand the optical properties of disordered metasurfaces with various theories: independent scattering approximation [1], multiple scattering, quasinormal mode analysis [4], and ray-tracing rendering.

We will also present striking visual appearances created by the metasurfaces designed with these theories.

Abstract: We discuss scalable quantum photonics circuitry based on room-temperature single-photon emitters in silicon nitride that we recently discovered in this technologically important material platform. We also consider integration of SiN single-photon emitters with waveguides as well as the quantum emission enhancement through integration with resonant cavities and plasmonic nanostructures. This hybrid dielectric-plasmonic design paves the way for advanced quantum photonic systems by leveraging the benefits of both cavity confinement and plasmonic enhancement. Furthermore, we discuss a new approach for all-optical modulation using silicon avalanche photodiode, where the avalanche multiplication produces significant refractive index changes at ultra-low, single-photon intensities, enabling record-high nonlinearity in a telecom-compatible platform with a potential for integrated silicon quantum photonics.

Quasi-2D Materials: From Tailorable Photonics to New Physics

Abstract: The recent advent of tailorable, quasi-two-dimensional (2D) materials such as 2D transition-metal carbides and nitrides (MXenes) and transdimensional (TD) plasmonic ceramics, including several atomic layers thin titanium-, zirconium-, and hafnium nitrides, as well as ultra-thin transparent conducting oxides (TCOs) is currently driving the development of new concepts and devices for on-chip circuitry, communication, sustainable energy and quantum technologies. These materials exhibit great tailorability of their linear and nonlinear optical properties, remarkable dynamic tunability under external electric, optical, mechanical and other stimuli, strong plasmonic behavior, and high optical nonlinearities. These platforms also offer pathways to uncovering new optical and quantum phenomena ranging from epsilon-near-zero (ENZ) behavior to strongly correlated electronic systems. In this talk, we discuss the designer-like characteristics of MXenes, achievable with the choice of transition metal and control of stoichiometry, remarkable tailorability of properties of TD materials with the thickness, and ultra-fast TCOs response. We also explore new device concepts for flat optics/metasurfaces, all-optical switching, high-harmonic-based XUV generation that utilize ENZ regime and extremely strong light confinement. Finally, we analyze physical effects in atomically thin TD plasmonic films enabling metal-to-insulator transitions. Our work paves the way to novel device designs with tailorable optical materials.

A Large Language Model Agent for Autonomous Inverse Metamaterial Design

W. J. Padilla[1*], D. Lu[1], and J. M. Malof[2]

Abstract: An agentic framework consists of large language models coordinating the completion of complex tasks and have recently shown novel results. We propose and demonstrate an agentic system capable of the inverse design of a material which achieves a desired spectra. The future of this rapidly growing field is discussed.

Recent progress in the integration of multiple Large Language Models (LLMs) has enabled such systems to carry out complex tasks that are difficult to achieve with single LLMs. Such an assembly of coordinated LLMs is termed an Agentic Framework and they have also demonstrated the capability for autonomous novel scientific research. We discuss the development of an Agentic framework which is capable of understanding a natural language input, developing a deep learning forward model, optimizing model parameters, carrying out numerical simulations in CST, utilizing short term and long term memory, and realizes a final metamaterial design using a deep inverse model. The Agent achieves a forward deep learning model with an accuracy on par with the best models developed by human deep learning experts. We demonstrate the effectiveness of our Agentic Framework through a comparison on three photonic benchmark problems, and highlight the future of this fascinating field.

Exotic exciton phases in two-dimensional quantum materials

W. K. Lou, Kai Chang*

Center for Quantum Matter, Zhejiang University, Hangzhou, P. R. China
*Corresponding author: kchang@zju.edu.cn

Abstract: Exciton insulator phases has attracted intensive interests in 2D systems. We demonstrated the existence of topological exciton insulating phases in InAs/GaSb semiconductor quantum wells. For InAs/GaSb quantum wells, which can even survive under intense in-plane magnetic fields [1]. In van der Waals systems, we identify not only conventional exciton insulator phases but also a novel topological exciton density wave state [2]. Recently, we propose a scheme to realize exciton supersolidity in 2D heterostructures through light-engineered artificial gauge fields [3].

Summary: Excitons, light-induced quasiparticles in two-dimensional systems, have garnered significant attention owing to their distinctive electronic configurations and promising electro-optical device applications. Through BCS-like theoretical frameworks, we establish the existence of topological exciton insulating phases in 2D semiconductor systems. The coupled BCS-like equations can be expressed as:

$$\Delta\left(\vec{k}\right)=\sum_{k'}V^{ab}_{k-k'}\frac{\Delta\left(\vec{k'}\right)}{E\left(k'\right)}\left[1-f\left(\frac{E\left(k'\right)-\eta\left(k'\right)}{2}\right)-f\left(\frac{E\left(k'\right)+\eta\left(k'\right)}{2}\right)\right] \quad (1)$$

$$\xi\left(\vec{k}\right)=\varepsilon\left(\vec{k}\right)-\mu-\sum_{k'}V^{ab}_{k-k'}\left[1-\frac{\xi\left(\vec{k'}\right)}{E\left(k'\right)}\right]\left[1-f\left(\frac{E\left(k'\right)-\eta\left(k'\right)}{2}\right)-f\left(\frac{E\left(k'\right)+\eta\left(k'\right)}{2}\right)\right] \quad (2)$$

$$\eta\left(\vec{k}\right)=\varepsilon_M\left(\vec{k}\right)-\mu-\sum_{k'}V^{ab}_{k-k'}\left[1-f\left(\frac{E\left(k'\right)-\eta\left(k'\right)}{2}\right)+f\left(\frac{E\left(k'\right)+\eta\left(k'\right)}{2}\right)\right] \quad (3)$$

where $\epsilon_P(\boldsymbol{k})$ and $\epsilon_M(\boldsymbol{k})$ are defined as $\epsilon_P(\boldsymbol{k}) = \epsilon_b(\boldsymbol{k}) + \epsilon_a(\boldsymbol{k})$ and $\epsilon_P(k) = \epsilon_b(\boldsymbol{k}) - \epsilon_a(\boldsymbol{k})$, respectively, and $f(x)=1/(e^x+1)$ is the Fermi distribution function. $E(\boldsymbol{k})$ is the pair-breaking excitation spectrum. From the relation $\Delta^2(\boldsymbol{k}) = E^2(\boldsymbol{k}) - \xi^2(\boldsymbol{k})$, we can obtain the gap function $\Delta(\boldsymbol{k})$ by solving the above coupled equations self-consistently. Focusing on two representative systems - InAs/GaSb quantum wells and van der Waals heterostructures - we reveal critical phase transitions.

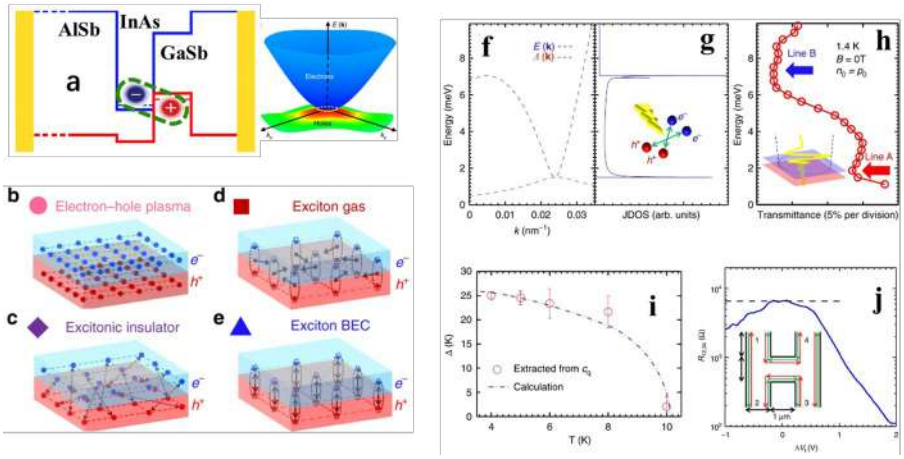

Figure 1. Evidence for a topological excitonic insulator in InAs/GaSb bilayers

For InAs/GaSb quantum wells (intrinsic 2D topological insulators), incorporation of electron-hole Coulomb interactions fundamentally alters the ground state, transforming it into a topological exciton insulator that persists under intense in-plane magnetic fields [1]. It possesses a unique band structure that allows for the spontaneous formation of spatially separated electron layers (InAs layer) and hole layers (GaSb layer) in intrinsic samples [see Fig. 1(a)], even without optical excitation. The model (see Eqs. (1)-(3)) predicted the emergence of an exciton insulator phase in the system and suggested the use of terahertz transmission spectra to verify its existence. The terahertz transmission spectrum exhibits two absorption peaks, and experimental measurements of the terahertz absorption peak positions aligned with theoretical predictions, resolving the long-standing issue of optically observing exciton insulator phases [see Fig. 1(f)-(h)]. Furthermore, electrical transport measurements revealed that the gap is independent of in-plane magnetic field strength but significantly depends on electron-hole density and system temperature [see Fig. 1(i)]. Additionally, the system exhibits conductive behavior of helical edge states [see Fig. 1(j)], further supporting the idea that the system enters a two-dimensional topological exciton insulator state.

In van der Waals systems, we identify not only spin-triplet exciton insulator phases [2] but also a novel topological exciton density wave state [3]. Based on the first-principles calculations coupled with the Bethe-Salpeter equation, the topological exciton density wave is investigated in two-dimensional monolayer WSe_2. We find that the topological excitonic insulator phase can exist in monolayer WSe_2(Fig. 2(b)), and it is robust against in-plane strain. In this system, the energy minimum of exciton bands is shifted to a finite in-plane momentum, forming a Fulde-Ferrell-Larkin-Ovchinnikov-like state. Using the Gross-Pitaevskii equations, stripe-patterned exciton density waves with a nonzero velocity emerge in monolayer WSe_2(Fig. 2(g)-(i)). Our findings pave a new way for exploring the interplay between electron correlation and nontrivial topology.

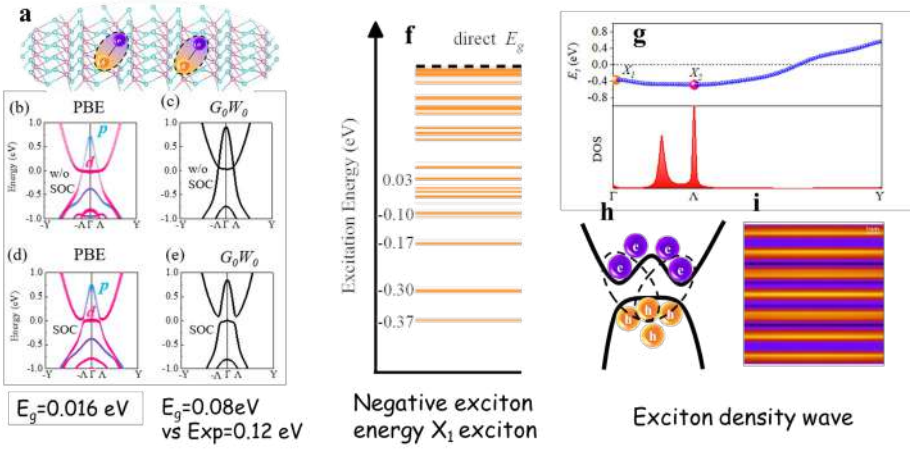

Figure 2.Topological Exciton Density Wave in Monolayer WSe2

Furthermore, we present an interesting scheme for realizing exciton supersolidity in 2D heterostructures through light-engineered artificial gauge fields [4].

Howardhw.lee@uci.edu

Abstract: Optical metasurfaces represent an important avenue towards novel optical functionality and innovative applications, thanks to their exceptional capability to manipulate the phase, amplitude, and polarization of transmitted, reflected, and diffracted light. Since their first integration onto the optical fiber endfaces a decade ago, the resulting “meta”-optical fiber platform has demonstrated immense potential, both in exploiting the strengths of optical fibers and overcoming their limitations, enabling revolutionary next-generation photonic devices.

In this talk, I will review the various material platforms (metallic, dielectric, and compound structures) and geometric platforms which have been utilized in “meta”-fiber devices to date. I will present our recent development of “Meta”-optical fiber, an advanced optical fiber integrated with emerging metasurface concepts. I will present the development of ultrathin optical metalens which is cascaded on the facet of optical fiber that enables advanced optical functions via wavefront shaping such as light focusing. I will also discuss the ability to develop tunable meta-optical fiber for advanced beam steering and dynamic focusing, and their potential application for biomedical imaging. These advanced “meta”-optical fibers open a pathway to revolutionary in-fiber optical imaging/endoscopy, biomedical imaging, lasers/spectroscopies, and optical/quantum communication devices.

Bio-inspired hierarchical phononic crystals and metamaterials

Marco Miniaci

IEMN - Université de Lille, France

Abstract: Phononic crystals and elastic metamaterials are traditionally regarded as artificially engineered materials designed to exhibit wave manipulation capabilities not typically found in natural systems. However, recent pioneering research has revealed that many biological structures—characterized by complex, often hierarchical organizations with periodic or gradient arrangements across multiple length scales—naturally demonstrate remarkable wave control functionalities. In this talk, I will explore the potential and limitations of bio-inspired phononic crystals and metamaterials. Particular emphasis will be placed on their dynamic behavior, analyzed through both numerical simulations and experimental investigations.

Transition waves in multistable mechanical metamaterials

V. Tournat[1*]

[1] Laboratoire d'Acoustique de l'Université du Mans (LAUM), UMR 6613, Institut d'Acoustique - Graduate School (IA-GS), CNRS, Le Mans Université, France
[*]corresponding author: vtournat@univ-lemans.fr

Abstract: Multistable metamaterials, composed for example of bistable mechanical units elastically coupled to their nearest neighbors, have recently been conceived in diverse ways, particularly within the family of flexible mechanical metamaterial architectures. Such multistable metamaterials can support progressive fronts, also called transition waves, switching sequentially its multistable units front one equilibrium to another, and resulting in the local or global reconfiguration of the medium. In addition, these nonlinear metamaterials are also known to support a rich variety of nonlinear waves, as vector solitons, breathers, cnoidal waves, among others. In this presentation, I will highlight the fundamentals and a selection of recent results on transition waves triggering, propagation, and discuss some of their potential applications. In general, these reconfiguration fronts obey nonlinear reaction-diffusion equations and show specific properties not necessarily found in other waves supported by periodic and/or nonlinear media, e.g., strong nonreciprocity, robustness, extreme amplitude dependent behavior… They can consequently be implemented for applications involving local or global reconfiguration of a medium, manipulating mechanical memory, controlling waves in space and time, mechanical computing or be the vector for material embedded intelligence.

Empowering Topological Photonics for OAM Manipulation

Zhigang Chen
The MOE Key Laboratory of Weak-Light Nonlinear Photonics,
TEDA Applied Physics Institute and School of Physics,
Nankai University, Tianjin, China
zgchen@nankai.edu.cn

Abstract: In this talk, we present a few demonstrated examples of topology-driven photonic applications based on the simplest topological model. Building on these foundations, we introduce our design and implementation of more advanced photonic structures that enable robust optical vortex transport and effective manipulation of orbital angular momentum (OAM).

Tutorial

Nonlocal metasurfaces

Andrea Alù

[1]City University of New York, USA

Abstract: The use of engineered nonlocal responses in metasurfaces has been recently unveiled as a paradigm for extreme wave control, enabling rational control over space, time, frequency and momentum of the incoming signals, as well as analog-based image processing and computing. Several recent demonstrations of metasurfaces performing edge-detection and image-processing using engineered spatial nonlocality have shown a path towards ultrafast, efficient, massively parallel analog image processing based on passive devices, which holds the promise for being extended towards general analog computing platforms. Space-time nonlocal metasurfaces performing the space- and time-derivatives of the incoming signal were also envisioned by tailoring their frequency and momentum dispersion. In this tutorial, I will discuss the basics of nonlocality engineering in metasurfaces and their various implementations and opportunities for this field of research, showcasing compact meta-structures with reconfigurable properties that can perform mathematical operations, solve compact mathematical problems and address the issues of reprogrammability and cascaded responses. I will discuss how these findings may open exciting opportunities for applications in imaging, automotive vehicles, sensing and computing, and serve as a pre-processing tool for simplifying complex computing architectures.

New trends in nanophotonics and advanced materials

Photonic Crystal Information Processing Chips

Xiaoyong Hu[1*], and Kun Liao[1]

[1] Department of Physics, Peking University, China
[*]corresponding author: xiaoyonghu@pku.edu.cn

Abstract: Several topological photonic crystal chips are realized and used to photonic information processing applications. Silicon-based optical neural network chip is fabricated to perform topological state simulation functions.

Topological photonic crystal provides an excellent platform for the photonic information processing chips owing to the unique properties of topological photonic states. However it is still a great challenge to construct topological photonic information processing chips. Several topological photonic crystal chips are realized and used to photonic information processing applications, including silicon-based topological photonic crystal chips and surface plasmonic topological photonic chips. Silicon-based optical neural network chip is fabricated to perform topological state simulation functions.

Abstract: Combining metal's plasmonic properties with the interface characteristics of a Schottky junction, we demonstrated effective broadband filter-free NIR spectroscopy. A single tunable device delivers excellent responsivity, wavelength-specific detection(up to 2.3μm), and enhanced spatial resolution. We emphasize extending the spectral range for reconstructive spectroscopy while scaling down infrared-spectroscopy to chip level.

Introduction

The development of plasmonic photodetectors, especially in the near-infrared (NIR) region, has gained significant attention due to their non-destructive nature. Schottky plasmonic spectrometers can effectively detect NIR light, providing a compact and simplified approach to optical sensing [1]. Accurate and reliable detection of NIR with high sensitivity is crucial; however, it presents challenges due to the inherently low energy. Prior studies have laid a solid foundation for NIR detection [2]. However, responsivity was limited to a few tens of μA/W, and spectroscopy of the longer wavelength range beyond 1400 nm is not yet clearly demonstrated while maintaining detection selectivity [3]. In addition, typical Au/Si photodetectors exhibit unstable interface properties, reliability issues, and plasmonic shifts. This work demonstrates a low Schottky-barrier photodetector with a plasmonic assist that receives NIR light at room temperature, enhancing device adhesion and modifying charge carrier generation and transport processes.

Description of the New Method or System

The study meticulously engineered an embedded grating structure. Device geometry is designed through extensive experimental and modeling results, ensuring wavelength-specific plasmonic photodetection with a one-to-one correspondence between absorption angles/wavelengths for guaranteed selectivity. This allows for unique determination and inverse calculation of multiple parallel incident spectrums. While maintaining gold as a plasmonic antenna, interface properties are modified by incorporating an interfacial layer acting as a Schottky interlayer metal, a diffusion barrier, an adhesion promoter, and to suppress the formation of intermetallic compounds or plasmonic resonance shifts.

Experimental Results

Combining different metals in the plasmonic structure can potentially broaden the device operation range, considering the modification of junction barrier height and interface properties. This produced the highest responsivity of ten times compared to previous reports [4], due to the lowered barrier height, facilitating the transport of low-energy photogenerated carriers at room temperature and zero biasing conditions while maintaining high linearity and sensitivity to low light intensities (less than 25 μW at 1900 nm) (Fig. 1). It further demonstrated clear SPR peaks even with parallel exposure to visible light. It maintained higher stability with

neither hysteresis nor deterioration in photocurrent measurements over 380 days so far. The sharp and selective SPR peaks facilitated the expansion of the spectral range for reconstructive spectroscopy to longer wavelengths. Since the degree of surface sensitivity can be controlled by collecting photoelectrons emitted at different emission angles to the surface plane by changing the incident photon energy, the reconstruction of multiple parallel incident wavelengths could be successfully demonstrated (Fig. 2). Making it a powerful technique for investigating the electronic and chemical structures of various nanolayers and devices for green chemistry. With further incorporation of a refractory diffusion barrier/interfacial layer to our structure (as confirmed by XPS), long-term stability and durability testing demonstrated less than a 5% decline in responsivity with no observable plasmonic shift. Meanwhile, conventional Au/Si devices exhibited a plasmonic shift in SPR peaks of 1.5° per SPR peak and a responsivity reduction exceeding 30%.

This research represents a significant leap in NIR photodetection and spectroscopy, with far-reaching implications across applications for various scenarios such as gas sensing and environmental monitoring.

Holotomography in optics and X-ray: advancing the study of metamaterials

Y.K. Park[1*]

[1] Physics Department, KAIST, South Korea
[2]Tomocube Inc. South Korea
[*]corresponding author: yk.park@kaist.ac.kr

Abstract: Holotomography reconstructs 3D refractive index distributions of unlabeled samples with high resolution. This talk covers advancements in visible-light and X-ray techniques, machine learning integration, and dielectric tensor tomography, emphasizing applications in cell biology and industrial fields like semiconductors and display technologies.

Holotomography (HT) is an imaging technology that enables label-free, three-dimensional visualization of refractive index (RI) distributions in biological and material specimens. By combining high-resolution optical and X-ray modalities, HT addresses limitations inherent in traditional microscopy methods. Through quantitative reconstruction of RI distributions, HT serves as a powerful tool for uncovering structural details and dynamic processes in a variety of samples ranging from living cells to complex materials.

HT reconstructs 3D RI maps by capturing multiple 2D images of the sample under varying illumination conditions. Optical HT operates using coherent or low-coherence light sources, while X-ray HT extends the methodology to denser and larger samples by leveraging higher penetration depth. Reconstruction relies on advanced phase retrieval algorithms and the integration of machine learning techniques to enhance image quality and address challenges such as noise and missing cone artifacts.

Key advances include the introduction of dielectric tensor tomography (DTT), which expands HT capabilities to measure 3D anisotropic properties such as birefringence and molecular alignment. DTT uses polarized illumination and vectorial field measurements to reconstruct 3D dielectric tensor distributions, enabling detailed characterization of optically anisotropic materials. This is particularly valuable for applications in liquid crystals, biomolecular structures, and soft matter physics

The following applications of HT will be discussed:

Biology and Medicine: HT is widely applied in cell biology for non-invasive imaging of live cells and tissues. Its ability to visualize subcellular structures, such as lipid droplets, mitochondria, and nuclei, without labeling is transformative. HT supports long-term studies of cellular dynamics and phase-separated biomolecular condensates, critical for understanding pathophysiological states and drug interactions

Material Science: The combination of HT and DTT enables precise visualization of 3D molecular orientations and phase distributions in liquid crystals and other anisotropic materials. This capability is crucial for studying the properties and dynamics of soft materials, enabling the design of advanced functional composites

Industrial Applications: In semiconductor and display technology, HT offers detailed defect analysis and quality inspection by identifying variations in material properties at micro and nano scales. Its X-ray implementation provides insight into thicker and denser materials where optical techniques face limitations.

HT's fusion with artificial intelligence (AI) significantly enhances its capabilities. AI-driven algorithms address noise reduction, segmentation, and automated analysis, improving the accuracy of RI reconstruction and facilitating real-time imaging. Furthermore, combining HT with complementary modalities such as Raman spectroscopy and fluorescence microscopy adds chemical specificity to its imaging, unlocking new possibilities in biomedical and industrial research.

The ongoing development of HT focuses on improving imaging speed, resolution, and depth penetration. The integration of high-speed sensors and adaptive optics aims to push the boundaries of temporal resolution, enabling the capture of fast dynamic processes. Expanding HT's application to organoid and tissue imaging, regenerative medicine, and high-throughput drug screening holds promise for addressing critical challenges in healthcare and technology.

In conclusion, holotomography stands at the forefront of imaging innovation, offering unparalleled insights into the microanatomy and material properties of diverse samples. Its versatile applications across disciplines make it a pivotal tool in both fundamental research and practical applications.

Momentum-direct infrared interlayer exciton and photodetection in WSe_2/InSe heterostructures

Jiong Yang[1,2*] **and Chao Zhang**[1,2]

[1]School of Optoelectronic Science and Engineering & Collaborative Innovation Center of Suzhou Nano Science and Technology, Soochow University, Suzhou 215006, China

Abstract: Momentum-direct interlayer excitons (IX) in the infrared are crucial for excitonic devices but remain underexplored. We construct a WSe_2/InSe heterostructure that hosts momentum-direct IX and manifests near-infrared interlayer absorptions at room temperature, realizing photodetection at 1150 nm with an optimal photoresponsivity and response time of 33 A/W and 3.7 μs.

When layered semiconductors form van der Waals heterostructures (vdWH) with type-II band alignment, interlayer charge transfer facilitates the accumulation of electrons in the layer with lower conduction band minimum (CBM) and holes in the layer with higher valence band maximum (VBM).[1, 2] Those electrons and holes interact strongly *via* the Coulomb force due to the sub-nanometer interlayer spacing and form spatially separated electron-hole pair quasi-particles, namely interlayer excitons (IX). To date, IX have been detected or predicted, mainly in the visible range, in hetero- and homo-bilayers among transition metal dichalcogenides (TMD), metal chalcogenides, black phosphorus, and other layered semiconductors.[3-6] One of the challenges for IX-based excitonic devices is the severely reduced luminescence quantum yield of momentum-indirect IX recombinations that could result from the lattice mismatch and stacking misalignment in vdWH.

Layer engineering of vdWH that host IX has attracted widespread attentions to realize direct bandgap transitions.[7-9] One of its advantages is that IX emission energies can be precisely tuned as band structures of layered semiconductors gradually evolve with the layer number. Besides, for vdWH consisting of TMD monolayers, the typical and most widely studied IX platforms, the CBM and VBM are located at different positions in the reciprocal space (*k*-space), even though TMD monolayers possess direct bandgaps at the K point in *k*-space. Such momentum mismatch of carriers hinders photoexcitation and IX recombination in vdWH.

In addition to intralayer absorptions followed by ultrafast interlayer charge transfer in vdWH, IX can be formed by excited electrons and holes from one-step interlayer absorptions.[10, 11] Because of the staggered band alignment in type-II vdWH, interlayer absorptions occur at longer wavelengths compared to intralayer absorptions, and thus can be readily applied to infrared photodetections. Such IX-driven infrared photodetectors have been demonstrated to realize a trade-off between the low dark current and the detection of long wavelength.[12]

In this work, we report the observation and manipulation of momentum-direct near-infrared (NIR) IX at room temperature in a vertical type-II vdWH consisting of bilayer (2L) WSe_2 and five-layer (5L) InSe. First-principles density functional theory (DFT) calculations indicate that, in the 2L-WSe_2/5L-InSe vdWH, the CBM and VBM both locate at the Γ point of the first Brillouin zone, thus forming a direct bandgap and facilitating interlayer carrier photoexcitation and recombination. Raman and photoluminescence (PL) spectroscopies were utilized to characterize the efficient interlayer coupling. Specifically, a NIR IX emission peak at 1130 nm was detected and manipulated by temperature, excitation power, electric field, and the layer

number. By conducting absorption spectroscopy, we observed intralayer absorption peaks of 2L WSe_2 and 5L InSe, as well as the vdWH interlayer absorption at ~1110 nm. The binding energy of the IX was extracted to be 43 ± 5 meV, well above the thermal energy at room temperature (26 meV), indicating its stable existence at room temperature. As the IX owns a permanent out-of-plane dipole moment, we further demonstrated its electrical tunability by applying a vertical electrical field, and the IX emission energy was linearly tuned from 1.04 to 1.22 eV. By taking advantage of the direct interlayer absorption, we fabricated a photoconductive NIR photodetector modulated by strong photogating effect based on the 2L-WSe_2/5L-InSe vdWH, achieving a responsivity of 33 A/W, a specific detectivity of 1.8×10^{10} Jones, and a fast response time of 3.7 μs at 1150 nm.

Abstract: We demonstrated the acceleration of adiabatic evolutions by leveraging the concepts of the quantum metric, adiabatic infimum, and shortcut to adiabaticity (STA), respectively. Specifically, we achieved fast topological pumping and non-Abelian braiding in integrated photonic waveguides, significantly enhancing on-chip functionality and efficiency within high-density integrations.

Topological photonics has paved the way for robust optical transport and light manipulation through the emergence of edge states in topologically distinct systems. Topological pumps, originally proposed by Thouless, have gained considerable attention for their ability to facilitate robust excitation transfer in systems with topological edge states, showing great potential for on-chip functional devices like quantum state transfer and reliable integrated photonic interconnects. However, their on-chip applicability is limited by the need for slow evolution speeds to satisfy adiabaticity requirements. In this talk, I will discuss our recent efforts to overcome this challenge.

Firstly, we have identified a direct link between adiabaticity and the quantum metric, an underexplored aspect of quantum geometry compared to the Berry curvature. By reducing the quantum metric through long-range coupling in the Rice-Mele model, we increased the evolution speed of topological pumps between nontrivial edge states without affecting bulk state evolution. We validated our findings experimentally using bilayer integrated silicon waveguides at telecommunication wavelengths [1]. Additionally, we propose and demonstrate the adiabatic infimum of topological pumps using on-chip lithium niobate on insulator (LNOI) waveguides. Our systematic investigation of the adiabatic criterion reveals its dependence on the effective Berry connection between modes and modulation speed. By minimizing the effective Berry connection along the loop, we achieve fast parameter modulation and realize the infimum pump in the shortest possible length [2]. More recently, employing a shortcut to adiabatic (STA) strategy, we demonstrated compact trilayer 3D silicon photonic chips capable of performing non-Abelian braiding and photonic quantum gates, significantly reducing the size of the braiding apparatus and making it CMOS-compatible [3]. These advancements accelerate adiabatic evolutions, paving the way for more compact and efficient photonic integration.

Abstract: We investigate an all-dielectric metasurface featuring two symmetrically protected quasi-bound states in the continuum, designed to enhance both the excitation and emission of dark excitons in a tungsten diselenide monolayer. Simulations reveal a significant photoluminescence signal enhancement (∼520) accompanied by directional emission, presenting clear advantages for optoelectronic and valleytronic applications.

Efficient quantum emitters are crucial for the development of quantum photonic technologies based on single-photon sources. These sources need to produce single photons on demand with high efficiency, purity, and indistinguishability [1]. In this sense, different quantum emitters have been explored in the last years, such as nitrogen vacancy centers, quantum dots or excitons in 2D materials (transition metal dichalcogenides (TMDs), hexagonal boron nitride, phosphorene…) [2,3]. In particular, monolayer TMDs are highly promising due to their significant exciton binding energy arising from two-dimensional confinement and diminished dielectric screening, and their direct band gap leading to intense photoluminescence (PL) [4]. However, in order to fulfil the requirements for practical applications, efficiency and purity must still be improved. With this objective, the coupling of TMDs with metallic or dielectric nanostructures has been proposed [5-7]. The excitation of localized surface plasmons or Mie modes in metallic or dielectric nanostructures, respectively, can increase the local density of optical states (LDOS), promoting the spontaneous emission in TMDs according to the Purcell effect [8].

In recent years, significant progress has been made in the study of quasi-bound states in the continuum (quasi-BIC) within symmetry-broken all-dielectric metasurfaces. The exceptionally high Q-factors associated with quasi-BIC resonances have made them highly attractive for enhancing light-matter interaction [9].

In this work, we analyze the excitation and emission enhancement of dark excitons in a tungsten diselenide monolayer under normal light incidence. Our study focuses on the coupling of the TMD material with an all-dielectric metasurface showing two symmetrically protected quasi-bound states in the continuum (q-BIC) at the excitation and emission wavelengths, respectively [10].

Our findings reveal a significant enhancement in the photoluminescence signal (approximately 520-fold), achieved through the combined effects of excitation and emission amplification. These results hold promising implications for the experimental investigation of spin-forbidden dark excitons with possible applications in valleytronics and opto-electronics.

Abstract: Surface-enhanced Raman scattering (SERS) spectroscopy and surface plasmon resonance (SPR) are promising methods for detection of specific DNA fragments. In this contribution, we describe construction and tests with clinical samples of SERS and SPR sensors for the identification of six the most popular in Poland variants of *BRCA1* gene mutations.

The deoxyribonucleic acid (DNA) is the carrier of genetic information for all living organisms. Even a small mutation in DNA sentence can cause many diseases. Therefore, developing sensitive, fast and precise methods for detection of DNA mutations is very important from a practical point of view. Promising methods for detection of specific DNA fragments are surface-enhanced Raman scattering (SERS) spectroscopy [1-4] and surface plasmon resonance (SPR) [5,6]. In this contribution we describe construction and tests with clinical samples of SERS and SPR sensors for the identification of six the most popular in Poland variants of *BRCA1* gene mutations (5370C>T, 300T>G, 5382insC, 4154delA, 185delAG, and 3819delGTAAA). Both sensors were based on the selective hybridization of target DNA with the capture DNA immobilized on plasmonic substrates (see Figure 1). Moreover, in both sensors the same thiolated capture DNA was used.

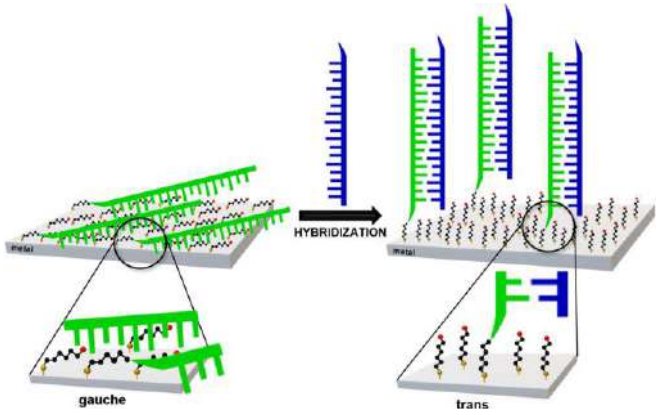

Figure 1. Scheme of the SERS DNA sensor based on rearrangement of the alkanethiol chains (alkanethiolate linking moiety of single stranded DNA and 6−mercaptohexan−1−ol). Reprinted from ref. [3]. CC BY license.

The mutation identification process using SPR detector relied on the shape of the SPR sensorgrams, whereas for the SERS sensors, the intensity of the Raman band at about 715-735 cm^{-1} (this band is due to the superimposition of mainly the band due to the ν(C−S) vibration of the alkanethiol chain in the *trans*

conformation and the band due to the breathing vibration of adenine) was used as an analytical signal (see Figure 2). The demonstrated biosensors are characterized by the low detection limit at the level of pg·μL^{-1}, wide analytical range and high selectivity. It was found that for different DNA sequences, a SPR or SERS sensor achieves greater detection sensitivity, which means that the selection of the optimal sensor type depends on the sequence of the target DNA. The proposed analytical approaches demonstrated completely new capabilities of SPR and SERS techniques and new insights into gene mutation detection.

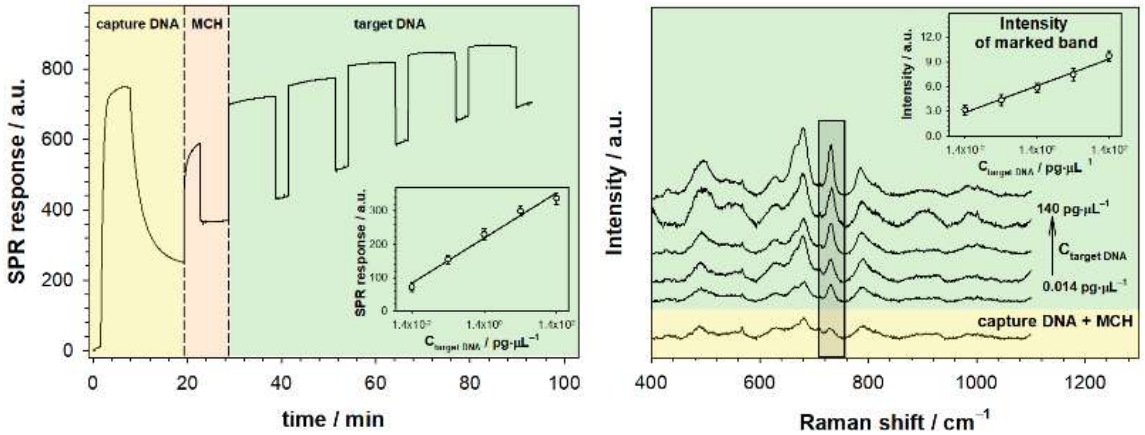

Figure 1. Example SPR curve and SERS spectra obtained before and after hybridization process with synthetic target DNA characteristic for the 4154delA mutation of the *BRCA1* gene. Insets: calibration curves. Experimental conditions: $C_{\text{capture DNA}}$ = 1.35 – 1.50 ng·μL^{-1} and $C_{\text{target DNA}}$ = 0.014; 0.14; 1.4; 14; 140 pg·μL^{-1}.

Topological photonic devices based on artificial gauge fields

Cuicui Lu[1]

[1]Beijing Institute of Technology, China
*corresponding author: cuicuilu@bit.edu.cn

Abstract: We realize on-chip topological rainbow nanophotonic devices by constructing synthetic dimensional photonic crystal. Recently, we further realize artificial gauge fields of both magnetic field and electric field, and observe different frequencies of Landau modes are localized at different positions of the photonic crystal, so we term this phenomenon “Landau rainbow”.

Topological photonics provides a robust platform for the realization of nanophotonic devices. We propose to construct synthetic dimensional topological photonic crystal by piecing a perfect photonic crystal and a deformed one to realize topological rainbow, where multiple topological photonic states spanning the whole bandgap can be realized at the interface. Figure 1a shows the fabricated photonic crystal sample. Multi-frequencies with different group velocities can be obtained and localized at different positions accompanied by multiple topological states (Fig.1b). Therefore, this contributes to the realization of topological rainbow device and slow-light devices.

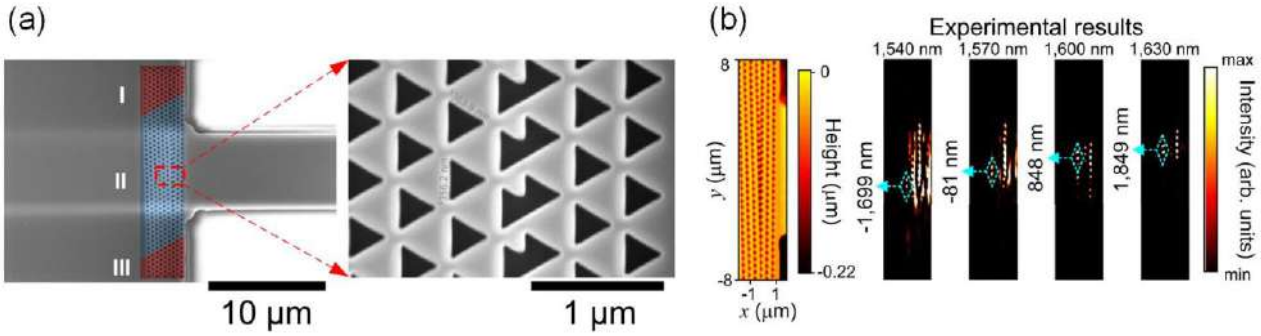

Fig. 1 On-chip topological rainbow. (a) SEM image of the topological photonic crystal. (b)Measured surface intensity of the electric field of the whole photonic crystal for incident different wavelengths using near-field scanning optical microscope system.

Recently, we simultaneously realize pseudo magnetic field (PMF) and pseudo-electric field (PEF) on a photonic crystal (PC) platform and observe a rainbow effect of the Landau zeroth modes. While PMF induces a series of discretized Landau levels of photons in a similar way as the quantum Hall effect for electrons (left figure of Fig.2a), PEF breaks the degeneracy of the flat band of Landau levels over a broad range (right figure of Fig.2a), thus different frequencies of the Landau modes can be dispersed into different spatial positions, leading us to term this phenomenon “Landau rainbow” (Fig.2b). The Landau rainbow, induced by the joint action of PMF and PEF, features robustness, broadband, and scalability, and may find applications in slow-light effect, multi-frequency divider, and optical information multiplexing.

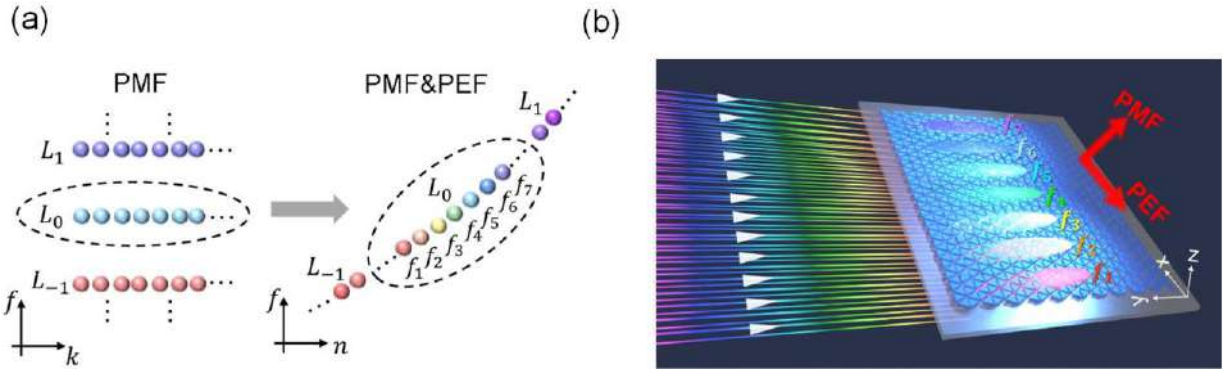

Fig. 2 Sketch of the Landau rainbow induced by pseudo-magnetic field (PMF) and pseudo-electric field (PEF). (a) The Landau levels are induced by PMF in *k* space, and the degeneracy of Landau levels is broken by the introduction of PEF in an aperiodic system. "*f*" denotes frequency and "*n*" represents the solution number. (b) The formed Landau rainbow effect, which can endow the zeroth Landau mode with different frequencies to be separated into different positions.

Engineering complex structured beams with flat optics

Xianzhong Chen, Hammad Ahmed, Chunmei Zhang*

School of Engineering and Physical Sciences, Heriot-Watt University, Edinburgh, UK
*corresponding author: x.chen@hw.ac.uk

Abstract: We experimentally demonstrated novel compact optical devices to generate complex structured beams such as new vector vortex beams and 3D polarization structures without relying on the complicated optical setup and realize their multifaceted control. The unprecedented design degree of freedom of optical metasurfaces has provided a compact platform to develop ultrathin optical devices for generating complex structured beams.

Vector vortex beams (VVBs) and 3D polarization structures represent typical complex structured beams. VVBs carry both orbital angular momentum (OAM) and polarisation information, allowing for high-dimensional information encoding. VVBs play a crucial role in singular optics and quantum optics and have been applied in many fields ranging from particle trapping to quantum entanglement. Polarization control has been used to record, process and store information. Light beams with 3D polarization distributions have received great attention owing to their peculiar optical features and practical applications such as higher resolution lithography and patterning of lyotropic chromonic liquid crystals by photoalignment.

Driven by device miniaturization and system integration, there is huge interest in developing ultrathin (light wavelength scale) and lightweight planar optical devices with novel functionalities that cannot be obtained with conventional optical elements. Optical metasurfaces are planar nanostructured interfaces and have recently attracted tremendous interests due to their unprecedented capability in the manipulation of the amplitude, phase and polarization at subwavelength scale. Optical metasurface have revolutionized design concepts in photonics, providing a new platform to develop unusual ultrathin optical devices. Optical metasurfaces have shown much promise for generating and manipulating complex structured beams. We have experimentally demonstrated grafted VVBs [1], multispectral grafted VVBs [2], superimposed Ince-Gaussian beams [3], cascaded multispectral polarization structures [4], and orbital angular momentum combs.

Multispectral manipulation will add more degrees of freedom. Furthermore, multifunctional optical devices have profound implications for research fields where light weight and integrated optical systems are highly desirable. There is an urgent need to develop multifunctional ultrathin devices that can simultaneously encode color and intensity information into 3D polarization profiles. A compact platform to generate and manipulate these beams is fundamentally challenging and technically impossible with conventional optics.

An innovative metasurface approach was proposed to break the current bottleneck. Many sophisticated optical tasks for grafted VVBs manipulation were completed for the first time. Grafted VVBs with multiple colours can realise asymmetric singularity modulation and colour selective functionalities, providing more degrees of freedom for multiplexing modulation and further increasing the capacity in optical communications and quantum information. The unique properties of the invented ultrathin devices will allow us to explore new phenomena in singular optics, nonlinear optics and quantum science, e.g., colour selective grafted VVBs, dynamic control of multispectral grafted VVBs and 3D polarization structures. The small volume, light weight, and color selective functionality bring 3D engineering capabilities closer to the real world and wearable devices

with smaller footprints. The flexible and controllable generation with customized complex structured beams of different colors (wavelengths) may be of interest to many practical applications such as vector beam generation, virtual reality, color displays, information security, and quantum science.

Abstract: Conducting polymers possess excellent reversible tunability for optical and electrical properties, enabling their various applications ranging from organic (opto)electronics to nanophotonics. In this talk, I will present our latest studies on conducting polymer devices for terahertz and infrared photonic applications.

Conducting polymers possess redox-tunable optical and electronic properties and have been explored in various areas, including electrochemical transistors, electronic skins, and thermoelectric generators. Recently, we reported their applications for plasmonic nanoantennas for near infrared applications, showing promising redox-state tunability towards spatiotemporally dynamic metasurfaces. In this study, we combined conducting polymers with sustainable cellulose nanofibrils (CNF) to form optoelectronic devices for tunable terahertz (THz) and infrared (IR) photonic applications.

The tunable electrical and optical properties of conducting polymers originate from the difference of their redox states, where at the oxidized state the polymers possess a high charge carrier density, while the charges are neutralized at the reduced state. Such redox state modulation can be realized by various ways, and in this talk, we chose both chemical and electrical switching approaches.

I will first present a conducting polymer-cellulose aerogel and demonstrate that it can provide broadband reversible tuning of THz transmission between 13% and 91% through chemical approach, while maintaining specular reflection loss below -30 dB in both states. We associate the exceptional THz modulation with the anomalous optical conductivity peak of conducting polymers, which enhances the THz absorption in its oxidized state while it decreases the reflection in its reduced state. We believe that such switchable THz materials provide a promising route towards large and broadband THz modulation for next-generation intelligent THz devices.[1]

By structural modification, we obtained a flexible conducting polymer-cellulose paper with highly suitable properties for electrically controlled IR devices. Both the specular reflection and emissivity could be modulated with large amplitudes (more than 40%) via the polymer redox state. This enabled various new application scenarios, where we focused on tunable radiative coolers, dynamic thermal camouflage, infrared anti-counterfeiting tags, and infrared dynamic displays. The devices are sustainable, cheap, flexible and mechanically robust, providing a versatile materials platform for active and adaptive IR optoelectronic devices.[2]

Spectroscopy of single metal nanoparticles for single-molecule biosensing

Peter Zijlstra[1]

[1]Eindhoven University of Technology, Department of Applied Physics, The Netherlands

[*]corresponding author: p.zijlstra@tue.nl

Abstract: In this talk I will discuss two biosensing platforms that exploit plasmon-enhanced single-molecule detection. The first platform enables fluorescence-free sensing for hours, and is based on reversible nanoparticle-on-film coupling. The second platform enables the study of multivalent single-molecule interactions with microsecond temporal resolution.

Accurately quantifying kinetic processes such as protein interactions is essential for advancing our understanding of disease mechanisms and for the development of future diagnostic technologies. I will introduce two plasmon-enhanced single-molecule sensing platforms designed to investigate biomolecular processes across a broad range of timescales, from microseconds to hours. First, I will discuss a dynamic nanoparticle-on-film sensor that utilizes resonant coupling between localized and propagating plasmons for single-molecule detection [1,2,3]. This platform enables continuous monitoring of fluctuating biomolecular concentrations over extended periods by exploiting low-affinity (reversible) interactions [4]. Next, I will present an innovative platform based on plasmon-enhanced fluorescence, capable of probing single-molecule dynamics at microsecond timescales [5,6]. I will explore the underlying signal generation mechanisms and demonstrate the platform's potential to quantify both mono- and multivalent interactions in real-time. Accurately quantifying such kinetic processes across a wide temporal range is essential for advancing our understanding of disease mechanisms and for the development of future diagnostic technologies.

Abstract: We utilize nonlinearity to deform, reshape, and design topological mode (TM) wave functions, enabling dynamically tunable, arbitrarily shaped nonlinear topological modes controlled by external intensity. The nonlinear spectral localizer is employed to characterize the topological origin of these modes.

Topological modes (TMs) are typically localized at boundaries, interfaces and dislocations, and exponentially decay into the bulk of a large enough lattice. Recently, the non-Hermitian skin effect has been leveraged to delocalize the wavefunctions of TMs from the boundary and thus to increase the capacity of TMs dramatically. Here, we explore the capability of nonlinearity in designing and reconfiguring the wavefunctions of TMs. With growing intensity, wavefunctions of these in-gap nonlinear TMs undergo an initial deviation from exponential decay, gradually merge into arbitrarily designable plateaus, then encompass the entire nonlinear domain, and eventually concentrate at the nonlinear boundary. Intriguingly, such extended nonlinear TMs are still robust against defects and disorders, and stable in dynamics under external excitation. Advancing the conceptual understanding of the nonlinear TMs, our results open new avenues for increasing the capacity of TMs and developing compact and reconfigurable topological devices.

Abstract: We present two electrically-driven MEMS-tunable metasurfaces for dynamic vortex beam generation: a single-layer optical metasurface for mode-switchable vortex lasers, and a double-layer metasurface for dynamic vortex wave plates, showcasing high mode purity and fast response at 1030 nm wavelength.

Optical metasurfaces (OMSs) have revolutionized light manipulation by offering compact and flexible optical devices. However, most OMSs are typically designed with well-defined optical responses, limiting their use in smart and adaptive photonic systems. Micro-electro-mechanical system (MEMS) provides a promising solution by supporting real-time reconfiguration of optical responses.[1,2] Here, we propose and demonstrate two MEMS-tunable metasurface platforms: (1) MEMS-OMS (single-layer OMS): integrated into a fiber laser, enabling rapid Gaussian-to-vortex mode switching.[3] (2) MEMS-BMS (bilayer OMS): functions as a dynamic vortex wave plate, toggling topological charges between $l = 2$ and $l = -1$ vortex modes. Both platforms leverage MEMS-actuated Fabry-Pérot (FP) resonance tuning, offering a novel solution for dynamic light manipulation.

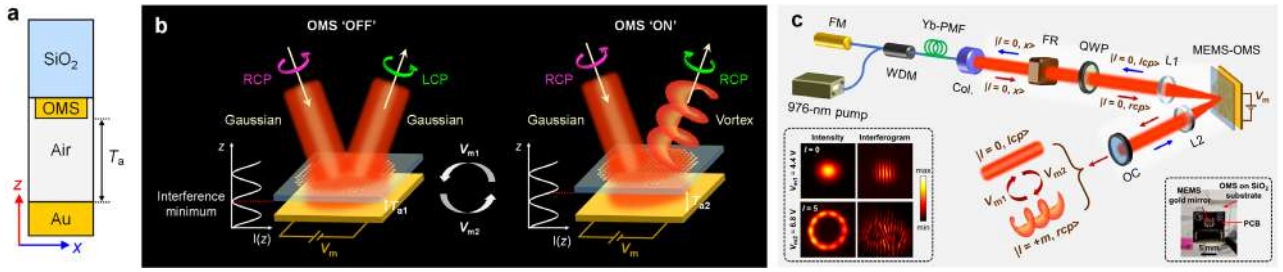

Fig. 1. (a) Schematic of the MEMS-OMS unit cell. (b) Working principle of the dynamic MEMS-OMS. (c) Schematic of the dynamic V-shaped vortex fiber laser. Bottom right inset: typical photo of the assembled MEMS-OMS component. Bottom left inset: measured intensity distributions and self-interference patterns of emitted Gaussian ($l = 0$, $V_{m1} = 4.4$ V) and vortex beams ($l = 5$, $V_{m2} = 6.8$ V).

The MEMS-OMS unit cell consists of a SiO_2 substrate, a gold (Au) nanobrick, and a movable MEMS Au mirror (Fig. 1a). The separation T_a between MEMS mirror and OMS can be precisely controlled by applying the voltage (V_m) to MEMS mirror. The MEMS-OMS operates in the periodic FP regime, with its optical response governed by the interplay of plasmonic and FP resonances. As shown in Fig. 1b, when the OMS layer is located at the interference minimum ('OFF' state, $T_{a1} = \sim k \times \lambda/2$, k is non-negative integers) induced by the incident and reflected fields, the MEMS-OMS functions as a standard mirror, reflecting left-handed circularly polarized (LCP) Gaussian beams ($l = 0$). When positioned away from the interference minimum ('ON' state) under a different V_m, the MEMS-OMS acts as a half-wave plate, imprinting a Pancharatnam-Berry (PB) phase to generate right-handed circularly polarized (RCP) vortex beams ($l = +m$). The MEMS-OMS component is assembled from an OMS fabricated on a SiO_2 substrate, a MEMS mirror, and a printed circuit board (PCB) for electrical connections (Fig.

1c, bottom right inset). The V-shaped laser cavity is formed between a fiber mirror (FM), a MEMS-OMS, and an output coupler (OC), with the intracavity beam evolution following a self-consistent polarization and mode transformation process (Fig.1c). This allows for controllable laser emission between Gaussian ($l = 0$, $V_{m1} = 4.4$ V) and vortex ($l = 5$, $V_{m2} = 6.8$V) modes (Fig. 1c, bottom left inset), featuring high mode purities (>95%) and fast response (100 μs).

The MEMS-BMS extends the dynamic functionality of metasurfaces by incorporating a BMS, consisting of MS1 and MS2 layers separated by an SU8 spacer, positioned above a MEMS-actuated Au mirror (Fig. 2a). This configuration allows independent phase modulation at two different separations, facilitating controlled mode switching between vortex beams with $l = 2$ and $l = -1$ under RCP light excitation (Fig. 2b). When the MS2 layer is in the 'OFF' state (interference minimum), the functionality of the MEMS-BMS is determined solely by the MS1 layer. Upon transitioning the MS2 layer to the 'ON' state (enhanced interference), the MEMS-BMS is jointly modulated by both MS1 and MS2 layers, enabling dynamic reconfiguration of the reflected vortex profiles. Scanning electron microscope (SEM) images of the fabricated BMS demonstrate good alignment between MS1 and MS2 layers (Fig. 2c). The detailed optical micrographs of the assembled MEMS-BMS component clearly show the piezoelectric material lead zirconate titanate (PZT) membrane cantilevers supporting a MEMS Au mirror, above which the circular BMS is fully covered (Fig. 2d, front view). Electrical connections were established by wire-bonding the MEMS mirror to the electrodes on the PCB (Fig. 2d, back view). The intensity and self-interference patterns of the reflected vortex beams with $l = 2$ ($V_{m1} = 4.8$ V) and $l = -1$ ($V_{m2} = 1.6$ V) confirm the dynamic mode-switching process (Fig. 2e). The faster response time (9 μs) is attributed to the intrinsic oscillation frequency, which is improved by the miniaturization of the MEMS mirror.

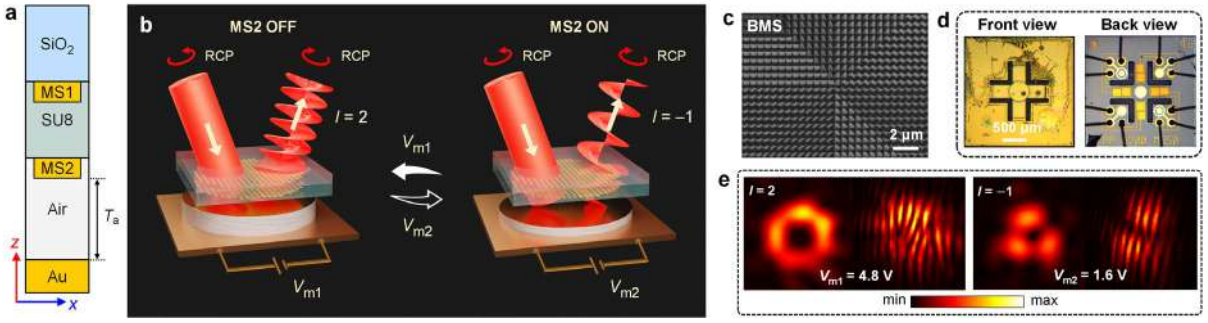

Fig. 2. (a) Schematic of the MEMS-BMS unit cell. (b) Working principle of the dynamic MEMS-BMS-based vortex wave plates. (c) SEM image of the fabricated BMS nanostructures. (d) Detailed optical micrographs of the assembled MEMS-BMS component. (e) Measured intensity distributions and self-interference patterns of reflected vortex beams with $l = 2$ ($V_{m1} = 4.8$ V) and $l = -1$ ($V_{m2} = 1.6$ V).

Our proposed MEMS-tunable metasurface platforms bridge static optics and adaptive systems, providing enhanced flexibility for dynamic light manipulation and paving the way for the next-generation photonic systems.

Abstract: We report the first observation of bound states in the continuum mode supported at the edge of truncated photonic crystal where the terminating row of silicon pillars has different diameter from the rest of photonic crystal. Additionally we demonstrate the tuning of resonance by depositing nanometer thick alumina film.

A bound state in the continuum (BIC) is a highly localized optical mode trapped in radiative region of dispersion, which occurs at a certain special point of the dispersion diagram due to destructive interference in the structure that suppresses the radiative mode [1]. Regardless of the presence of leakage radiation, BIC modes exhibit extremely high quality (Q) factors and narrow resonances. In a realistic experimental system with a finite number of periodic elements and imperfections of structure, such as surface roughness and absorption loss, a BIC is called a quasi-BIC, which still possesses a finite high Q-factor. High Q-factors and highly confined electric fields of BIC modes have been studied for various potential applications, such as lasing [2], light modulation [3], biochemical sensing [4 - 6].

A unique type of BIC modes supported at the edge of truncated two-dimensional photonic crystal (2DPhC), a periodic arrangement of dielectric or metallic elements with a period typically smaller than the wavelength of light, was predicted a decade ago [7]. In such systems, surface waves or edge states supported at the edge of 2DPhC become a BIC mode under certain condition, depending on the pillar diameter. As a result, the BIC propagates along the terminating array of dielectric pillars, being highly localized at their vicinity.

Here we report the first experimental demonstration of such edge bound states in the continuum supported at the terminating row of silicon (Si) pillars which diameter is bigger than that of the rest of a Si-pillar square lattice two-dimensional photonic crystal, as illustrated in Fig. 1(a) [8]. The Q-factor and resonance wavelength of the edge BIC modes can be significantly controlled by the diameter of Si pillars in the terminating row diameter and there is an optimum diameter to support edge BIC. Furthermore, we show that their Q-factor and resonance position also are sensitive to a presence of a few nanometer-thick dielectric layer conformally deposited around Si pillars, as shown in Fig. 1(b). We conformally deposited 2.5, 4.7, and 7.3 nm thick aluminium oxide (alumina) films by atomic layer deposition (ALD). A slight change of the dielectric environment induced by the dielectric nanofilm results in over 60% improvement of the Q-factor from 237 to 396 for the deposited alumina film thickness of 2.5 nm, which can serve as post-fabrication tuning of edge BIC. Meanwhile, the resonance wavelength shifts 1.1 nm per 1 nm increase of the film thickness (Fig. 1(b) inset). This shows the surface sensitivity to detect the presence of a dielectric nanofilm and a potential sensing application to detect biomarkers.

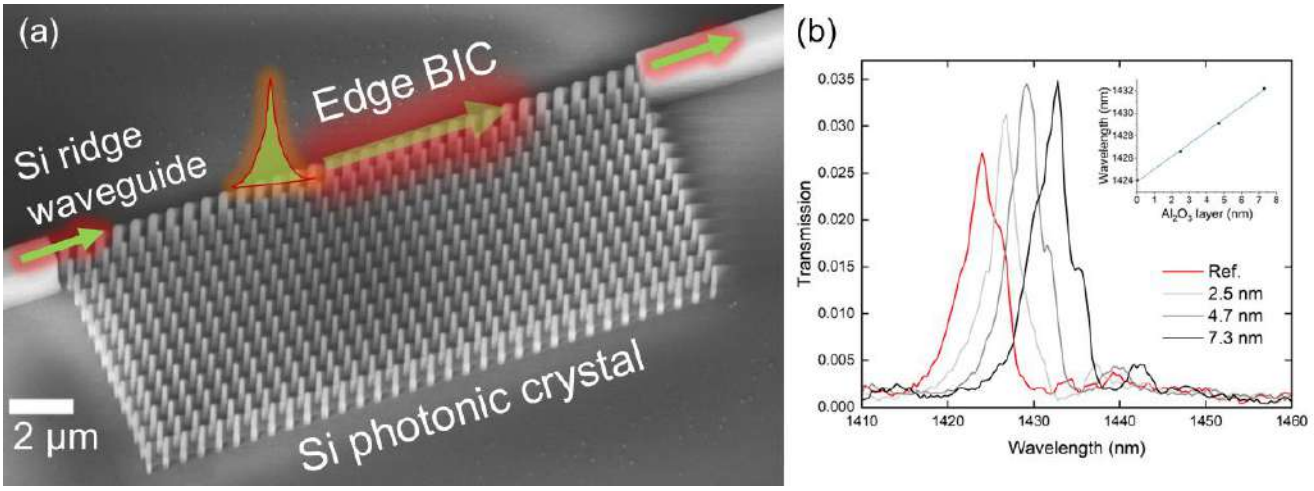

Figure 1: (a) Scanning electron microscope (SEM) image (birds-eye-view) of fabricated Si pillar photonic crystal structures connected with Si ridge waveguides. (b) Measured transmission spectra for different thickness of aluminum layer deposited. The inset shows the peak wavelength in terms of alumina layer thickness.

Abstract

Conventional schemes for exploring light-induced phenomena rely on uniform and diffraction-limited free-space optics, which limits spatial resolution and efficiency of light-matter interaction. We overcome these challenges using metasurface plasmon polaritons to form a sub-wavelength optical lattice which allows efficient near-field modulation of excitons with on-chip pump rejection and thermal management.

1 Introduction

Recently, light-matter interaction has been expanded as a control tool for inducing and enhancing emergent non-equilibrium phenomena [1]. However, conventional schemes for exploring such light-induced phenomena rely on uniform and diffraction-limited free-space optics, which limits the spatial resolution and the efficiency of light-matter interaction. Here, we overcome these challenges using metasurface plasmon polaritons (MPPs) proposed in Ref. [2] to form a sub-wavelength optical lattice [3, 4]. Specifically, we report a "nonlocal" pump-probe scheme where MPPs are excited to induce a spatially modulated AC Stark shift for excitons in a monolayer of $MoSe_2$, several microns away from the illumination spot.

Figure 1(a) illustrates our scheme. The metasurface device consists of a 1D array of silver nano-grooves and is designed to support a 1D lattice of MPPs with negligible diffraction around wavelengths close to the excitonic resonance. A pump laser (marked in red) is coupled into the MPP modes through the top coupler. The traveling MPPs form a sub-diffraction periodic potential for the $MoSe_2$ monolayer, whose exciton resonance lies at a wavelength $\sim$750 nm. A broadband beam (marked in white) probes the modulation of the transition metal dichalcogenide (TMD) excitons at a spot distant from the top coupler. Figure 1(c) shows the normalized electric field intensity $|E|^2$ in the x-z plane at 800 nm. The red curve in Fig. 1(b) shows the electric field intensity $|E|^2$ at the position of the TMD. Importantly, due to this sub-diffraction variation of $|E|^2$, the excitons experience a position-dependent AC stark shift: those located at the local maxima of $|E|^2$ experience a larger blue shift compared to other excitons.

2 Results

To demonstrate the sub-diffraction nonlocal AC Stark shift scheme, we excite the MPP modes using a 150 fs pulsed laser at 800 nm wavelength. Remarkably, we identify nearly two orders of magnitude reduction for the required modulation power compared to the free-space optical illumination counterpart for the same amount of AC Stark shift (Fig. 1f-g). Moreover, we demonstrate a broadening of the excitons' linewidth as a robust signature of MPP-induced periodic sub-diffraction modulation of the electric field (Fig. 1h-i). Additionally, our scheme provides protection from parasitic thermal and pump-induced noise ubiquitous in traditional "local" pump-probe spectroscopy. Our results open new avenues for exploring power-efficient

light-induced lattice phenomena below the diffraction limit in active chip-compatible MPP architectures.

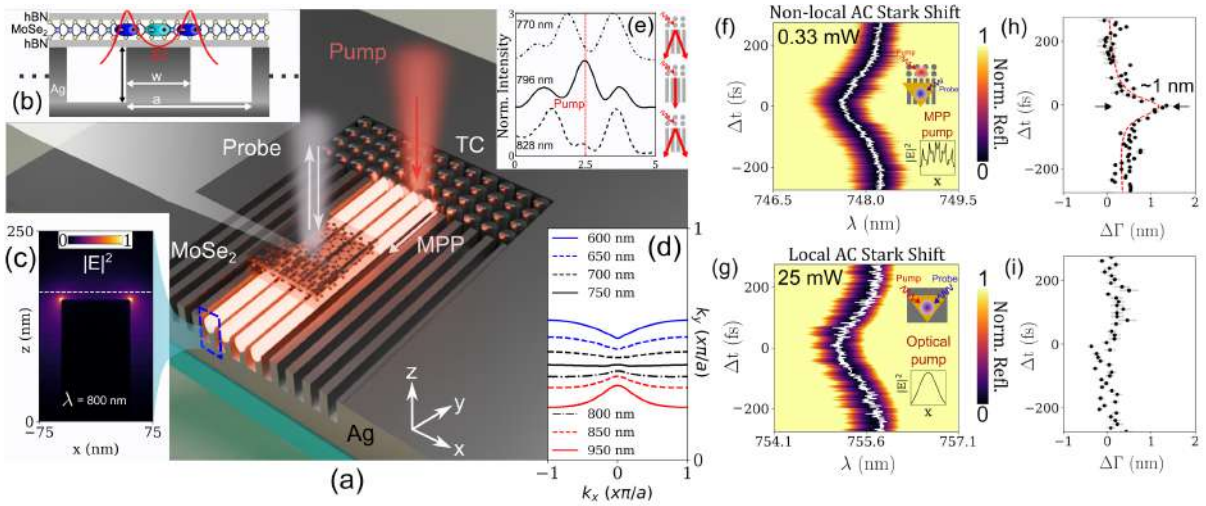

Figure 1: **Sub-wavelength optical lattice in 2D materials.** (a) Scheme for inducing AC Stark shift on a $MoSe_2$ monolayer using MPPs in a 1D lattice of silver grooves. The periodically modulated MPP modes are excited with a pump laser (red beam) at the top coupler (TC). The MPP device is designed to strongly confine the plasmonic modes, which propagate in the y-direction of the lattice with negligible diffraction within $700 \in 800$ nm, which is close to the excitonic resonance of ~ 750 nm in $MoSe_2$. A secondary broadband laser (white beam) probes the $MoSe_2$ excitons. (b) Schematic of the device cross-section. The red curve shows the strong $|E|^2$ modulation at the position of the $MoSe_2$ monolayer for a pump of 800 nm. (c) Normalized $|E|^2$ at the x-z cross-section of the device. The position of the TMD is marked by the dashed horizontal line. (d) Iso-frequency contours of the MPP device for different wavelengths of MPPs showing suppressed diffraction in the range 700-800 nm. (e) Experimentally measured spatial pattern of the emission from the output coupler for three different wavelengths: 770 nm, 796 nm and 828 nm. The red dashed line shows the position of the pump laser. (f-g) Measured nonlocal and local AC Stark shifts respectively. The white lines show the extracted exciton peak wavelength. The insets show the experimental schematic. (h-i) The change in linewidth $\Delta\Gamma$ of the exciton extracted from the numerical fitting of the nonlocal and local AC Stark shift data respectively.

Metasurface-Enhanced Single-Shot 3D Imaging for High-Precision Biological and Industrial Applications

Huijie Hao[1], Jian Liu[1], and Xumin Ding[1*]

[1] Advanced Microscopy and Instrumentation Research Center, School of Instrumentation Science and Engineering, Harbin Institute of Technology, Harbin 150080, China
[*]corresponding author: xuminding@hit.edu.cn

Abstract: We present a metasurface-enabled microscope for single-shot three-dimensional (3D) imaging, leveraging double-helix point spread function (DH-PSF) to achieve high axial localization accuracies in both 4*f* and 2*f* systems. This compact system facilitates rapid, high-precision 3D reconstruction of biological specimens and industrial samples, advancing meta-microscopy for bioimaging and semiconductor inspection.

3D imaging plays a critical role in biological research and industrial quality control. However, conventional techniques such as confocal and light-sheet microscopy often depend on bulky optical components and mechanical scanning mechanisms, which hinder operational efficiency [1, 2]. PSF engineering, particularly the DH-PSF, enables single-shot 3D imaging with high precision, which is suitable for multiple applications [3]. Metasurfaces, with their ability to manipulate light at subwavelength scales, present a promising avenue for the miniaturization of optical systems [4, 5]. Here, we integrate DH-PSF engineering with metasurfaces to develop a compact meta-microscope, achieving efficient, single-shot 3D imaging with exceptional precision and resolution.

Our meta-microscope is realized in two configurations: a 4*f* imaging system (Fig. 1a) and a 2*f* imaging system (Fig. 1b). The 4*f*-DH meta-microscope, with an NA of 0.7, achieves an axial localization accuracy of 0.12 μm over a 15.47 μm range. The 2*f*-DH meta-microscope, with an NA of 0.3, extends the detection range to 227.33 μm with an accuracy of 1.12 μm. Both systems utilize an all-dielectric metasurface to generate the DH-PSF, enabling rapid and precise 3D imaging without mechanical scanning.

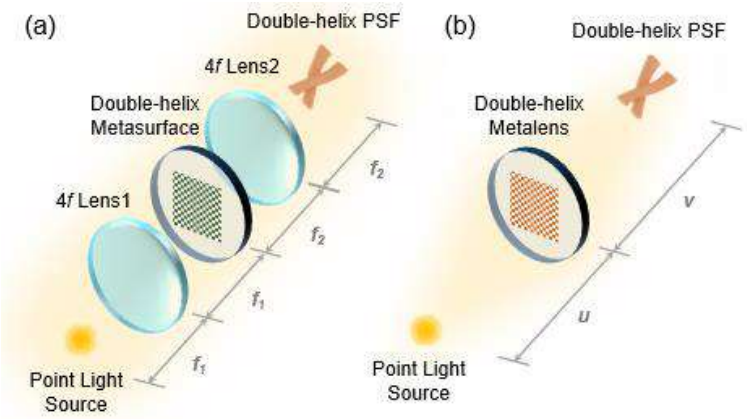

Fig. 1. Schematic of DH meta-microscope. (a) Sketch for the imaging process of 4*f*-DH meta-microscope, which is composed of a DH metasurface placed in the Fourier plane of the 4*f* system, where f_1 and f_2 are the focal lengths of two 4*f* lenses. (b) Mechanism of 3D-meta-imager composed of an integrated DH metalens. *u* and *v* represent the object distance and image distance respectively, which are related to the axial detection range and localization accuracy.

Figure 2 presents the 3D imaging and reconstruction capabilities of the DH meta-microscope. Three letter-shaped apertures—H, I, and T (Fig. 2a)—are positioned along the optical axis of the 2*f*-DH meta-microscope. Fig. 2b displays the raw image and reconstruction result of modulated objects recorded through the DH metalens, with the letters placed at the front focal, focal plane, and back focal plane. To further validate the 3D imaging performance of biological samples, peach anther particles (10–20 μm in size) were positioned on either side of a 170 μm thick cover glass. The raw data and reconstruction results are depicted in Fig. 2c and 2d. The results demonstrate the system's ability to simultaneously capture transverse intensity and axial depth information. This metasurface-enabled meta-microscope offers a compact, high-speed, and high-precision solution for single-shot 3D reconstruction.

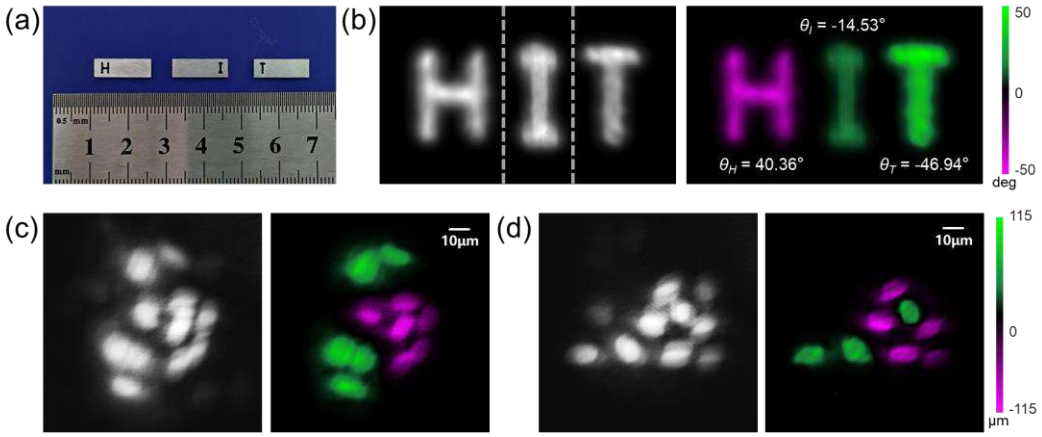

Fig. 2. 3D imaging results of DH meta-microscope. (a) Schematic diagram of the fabricated letter samples. The line width of the letters is 0.4 mm. (b) The reconstruction image of letters, where the rotation angles of H, I, and T are shown in the colored image. (c, d) Biological imaging demonstration of peach anthers.

All-optical control and detection of broken time-reversal symmetry and topological nonlinear optics

G. Soavi[1]

[1]Institute of Solid State Physics, Friedrich Schiller University Jena, Germany
[*]corresponding author: giancarlo.soavi@uni-jena.de

Abstract: I will discuss our recent experimental and theoretical efforts in the field of all-optical control and detection of broken time-reversal symmetry and topological nonlinear optics.

Layered materials, such as graphene and transition metal dichalcogenides (TMDs), possess unique nonlinear optical (NLO) properties [1], which allow a full control over the intensity [2,3], polarization [4] and orbital angular momentum [5] of the light emitted *via* perturbative harmonic generation processes.

Furthermore, TMDs have emerged as the ideal platform to study the interplay between space-inversion and time-reversal symmetries, which can be independently engineered in these layered materials by tuning the number of layers (space-inversion) and *via* excitation with circularly polarized light (time-reversal). In this talk, I will discuss our recently developed approaches to modulate the bandgap in TMDs using ultrafast and off-resonant excitation, and the possibility to subsequently detect broken time-reversal symmetry using second [6,7] and third harmonic generation. In particular, all-optical bandgap modulation can be achieved *via* the coherent optical Stark and Bloch-Siegert effects, with the additional degree of freedom to create either a symmetric or asymmetric bandgap opening in the ±K valleys, depending on the polarization state of the excitation beam. In monolayer TMDs, asymmetric bandgap modulation effectively corresponds to breaking of time-reversal symmetry. Subsequently, both symmetric and asymmetric all-optical bandgap modulation can be probed *via* polarization and intensity dependent measurements of perturbative NLO (**Figure 1**).

Finally, I will discuss our recent theoretical efforts to establish the background for the field of topological nonlinear optics [8]. I will show that the derivatives of the Berry curvature can be readily linked to the properties of specific crystal classes *via* a simple expression that involves the second order nonlinear susceptibility tensor. From this, we find features that are unique of chiral and polar crystal classes, and we discuss a possible and novel geometrical interpretation of circular dichroism and spontaneous polarization.

This work was funded by the German Research Foundation (DFG) (CRC 1375 NOA), project number 398816777 (subproject C4); the International Research Training Group (IRTG) 2675 ‘Meta-Active’, project number 437527638 (subproject A4); and the Federal Ministry for Education and Research (BMBF) project number 16KIS1792 SiNNER.

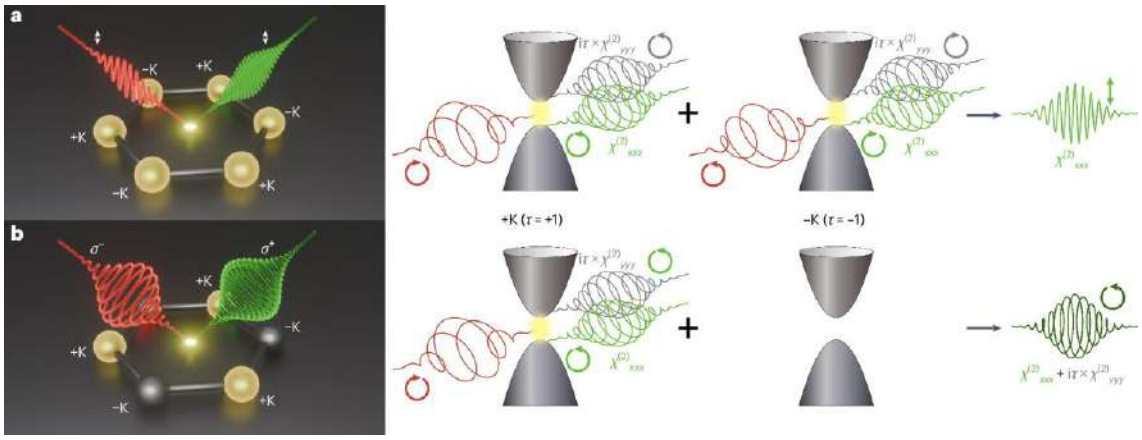

Figure 1. a, A linearly polarized FB (left, red) can be decomposed into right- and left-circular components that interact with both the ±K valleys in a symmetric way **b**, A right-circularly polarized FB (left, red) interacts only with the +K valley. This creates and probes an asymmetric bandgap modulation in the valleys, which corresponds to a situation where time-reversal symmetry is broken. Reprinted with permission from Ref. [6].

Creation of Novel Scattering Singularities in Generic Non-Hermitian Systems Probed Through Complex Time Delay

Jared Erb[1], Nadav Shaibe[1], Thomas M. Antonsen[1], and Steven M. Anlage[1*]

[1] Physics Department, University of Maryland, College Park, MD 20742-4111 USA
[*]corresponding author: anlage@umd.edu, website: https://anlage.umd.edu

Abstract: We utilize continuously tunable metasurfaces to find conditions for divergent complex time delay to create and identify numerous types of scattering singularities in generic complex microwave resonant systems in 1, 2, and 3-dimensions. We demonstrate novel properties of several composite scattering singularities in two- and three-dimensional parameter spaces.

The complete control of wave scattering in complex non-Hermitian settings is of interest for communications applications in indoor environments, among other things. This requires the ability to engineer the resonant spectrum of the underlying physical structures which is conventionally accomplished by carefully imposing geometrical and/or dynamical symmetries. In contrast, by taking active control over the boundary conditions in complex scattering environments which lack artificially-imposed geometric symmetries, we demonstrate via microwave experiments the ability to manipulate the spectrum of the scattering operator [1]. We utilize measurements of the scattering matrix to determine the complex time delay for wave propagation through the system [2-4]. Divergences of the complex time delay reveal the location of many different types of scattering singularities [5]. For example, by means of active control of the boundary conditions we can create, destroy and re-position exceptional point degeneracies (EPD's) in a two-dimensional (2D) parameter space [6]. The presence of EPD's signifies a coalescence of the scattering eigenmodes, which dramatically affects transport. The scattering EPD's are partitioned in domains characterized by a binary charge, as well as an integer winding number, are topologically stable in the two-dimensional parameter space, and obey winding number-conservation laws upon interactions with each other, even in cases where Lorentz reciprocity is violated; in this case the topological domains are destroyed. Ramifications of this understanding is the proposition for a unique input-magnitude and phase-insensitive 50:50 in-phase/quadrature (I/Q) power splitter for EPDs combined with conditions that enable Coherent Perfect Absorption (CPA) [7]. We also discovered a new way in which the CPA condition creates a novel type of splitter with fixed but arbitrary values for relative output and phase. We show that this condition can be tuned in frequency and in output power/phase ratio by means of the system metasurfaces. Our study establishes an important step towards complete control of scattering processes in complex non-Hermitian settings.

Non-noble metal plasmonic nanostructures

M. Horák[1*], M. Foltýn[1], and T. Šikola[1]

[1]Brno University of Technology, Brno, Czech Republic
[*]corresponding author: michal.horak2@ceitec.vutbr.cz

Abstract: We present an investigation of localized surface plasmon resonances in nanostructured non-noble metals at a single particle level, with a focus on their spectral tunability. The study specifically examines silver amalgam, gallium, and bismuth while the latter has been identified as a viable substitute for gold.

In metallic nanostructures, collective oscillations of free electrons are strongly coupled to the electromagnetic field, forming excitations known as localized surface plasmons. These excitations are characterized by a significant enhancement of the electromagnetic field within the surrounding dielectric, along with its confinement on the subwavelength scale. This property can be utilized to control various optical processes, even below the free space diffraction limit. Despite the considerable promise exhibited by gold-based plasmonic applications, their widespread utilization is impeded by two significant challenges. Firstly, the high fabrication costs associated with these applications pose a substantial obstacle, and secondly, the plasmon energy range is constrained by interband transitions, which limits their effectiveness. These challenges can be addressed by exploring alternative metals such as gallium, bismuth, lead, and tin. Theoretical predictions indicate that these metals could offer comparable plasmonic performance while providing a broader plasmon energy range [1]. In this contribution, we present an experimental investigation of the plasmonic properties of silver amalgam [2] and gallium nanoparticles [3] as well as bismuth plasmonic antennas [4] using scanning transmission electron microscopy (STEM) combined with electron energy loss spectroscopy (EELS) [5,6], which allows for single particle analysis.

Silver amalgam is one of the most suitable solid electrode materials in electroanalysis. An exploration of the plasmonic nature of its nanoparticles has been conducted, resulting in the observation of strong plasmon resonances spanning the ultraviolet to mid-infrared regions for sizes ranging from nano- to micro-scale [2]. These findings establish silver amalgam nanoparticles as promising candidates for applications within photochemistry and spectroelectrochemistry, where the synergy between their plasmonic and electrochemical qualities can be fully utilized.

Gallium is a plasmonic material offering facile and scalable preparation and good stability of nanoparticles. We have grown lens-shaped gallium nanoparticles directly on a silicon nitride membrane using an effusion cell and experimentally proven that their dipole mode can be tuned through their size from the ultraviolet to near-infrared spectral region [3].

Finally, to investigate the plasmonic potential of bismuth, thin polycrystalline bismuth films were sputtered onto silicon nitride membranes. Thereafter, bowtie and bar plasmonic antennas of varying sizes were fabricated using focused ion beam lithography [7,8]. While the fabricated bismuth antennas exhibit lower plasmon resonance intensity than gold ones, the nearly identical plasmon energies across the entire range of tested antenna sizes demonstrate bismuth's potential as a viable alternative in plasmonic applications (see Figure 1). Moreover, the experimentally verified wider interval of bismuth plasmon energies allows applications at shorter wavelengths as well. The plasmonic performance of bismuth antennas has been validated, highlighting their potential as a viable substitute for gold [4].

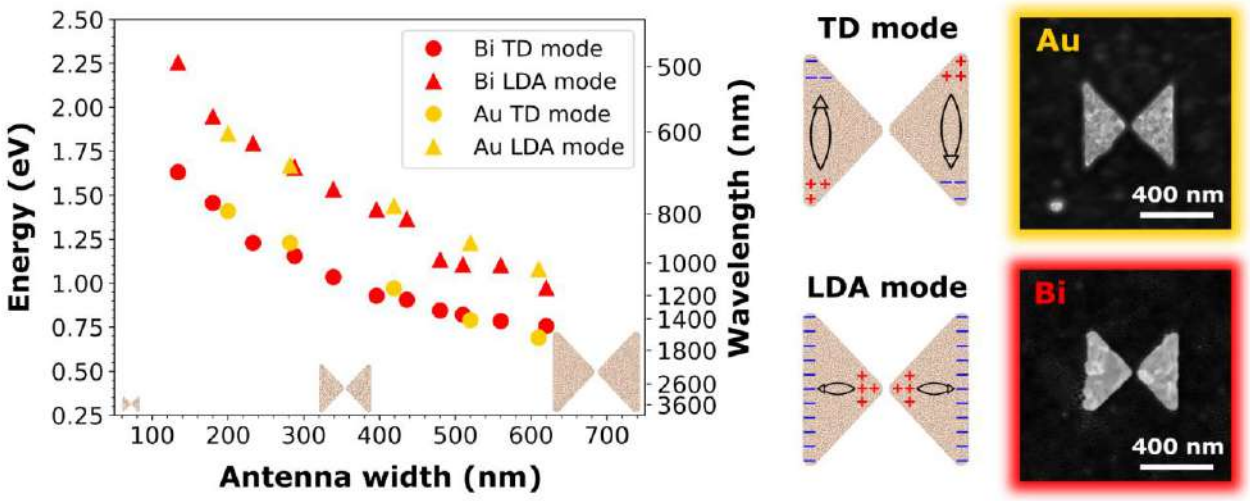

Figure 1: Energy of transverse dipole (TD) and longitudinal antibonding dipole (LDA) mode as a function of the reciprocal antenna width for bismuth and gold antennas. Based on the observed overlap of the two dependencies, bismuth can serve as a cheaper plasmonic alternative to gold. The data for gold bowtie antennas originates from Ref. [9].

Abstract: Nanomechanical resonators are powerful biosensing tools. While the mass and mechanical properties of individual human cells have been characterized in liquid, smaller entities, including bacteria, viruses, and proteins, have only been reliably analysed in vacuum. We demonstrate the characterization of single bacterial cells' mass and mechanical properties under ambient conditions.

In recent decades, nanomechanical resonators have become powerful tools for developing innovative biosensing technologies. Researchers have successfully characterized the mass and mechanical properties of individual human cells in liquid environment, as well as single bacteria, viruses and even proteins in vacuum [1]. This work presents a new technique for characterizing the mass and mechanical properties of single bacterial cells (*Staphylococcus epidermidis* and *Escherichia coli*) under ambient conditions. We deposit individual bacterial cells onto the sensor surface (100 nm-thick squared shaped microcantilevers made of silicon nitride, 40 μm side) with micrometric precision using an injection micropipette system. We monitor the frequency response of multiple mechanical modes of the sensor simultaneously, specifically, 1st and 2nd flexural modes, and 1st and 2nd torsional modes (Figure 1), to the adsorption of an individual bacterial cell. This enables disentangling the mass and stiffness effects induced by analyte adsorption, while also providing information about its morphology [2]. Finally, we demonstrate that our technique allows to distinguish between the two bacterial species, based on their mass, stiffness and morphology [3].

In the near future, we want evaluate this technique through its application to many other bacterial cell species and other microbiological entities, such as human cells or viruses. Additionally, we plan to extend this technique to liquid operation, the natural medium for biology. Our technique will provide new insights into the inherent properties of different microbiological entities and their biological processes, significantly impacting the biomedicine and clinical diagnosis.

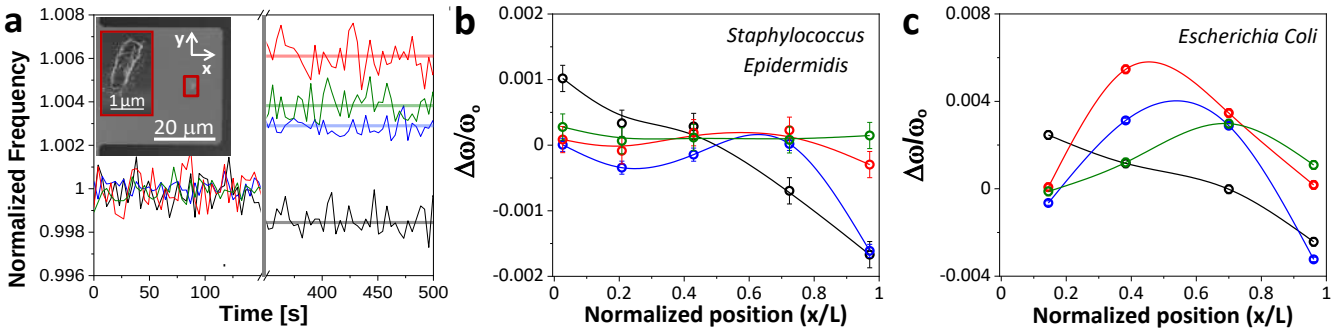

***Figure 1. a**. Normalized frequencies (ω/ω_o) of the sensor's 1st flexural (black), 1st torsional (red), 2nd flexural (blue) and 2nd torsional (green) modes before and after the adsorption of an individual Escherichia coli cell. The*

inset shows a scanning electron microscope image of a sensor after bacterium adsorption. Solid lines indicate the averaged normalized frequencies before and after the adsorption. ***b.*** *Relative frequency shifts of the sensor's mechanical modes induced by the adsorption of individual Staphylococcus epidermidis cells, adsorbed at positions centered along the y-axis and distributed along the longitudinal direction.* ***c.*** *Relative frequency shifts of the sensor's mechanical modes induced by the adsorption of individual Escherichia coli cells, adsorbed at positions centered along the y-axis and distributed along the longitudinal direction. Abstract: Mid-IR photo-induced force microscopy (PiF-IR) provides unprecedented spatial and high spectral resolution of the chemical composition in surfaces in the Materials and Life Sciences. We model the near-field-enhanced interaction of nanostructured materials with metallic atomic force microscopy tips enabling a qualitative evaluation of experimental results in PiF-IR and related methods.

The development of powerful mid-infrared (mid-IR) lasers in combination with sophisticated approaches in signal detection has opened the avenue for chemical characterization on the nanoscale complementing structural information provided by other methods, as for example, electron and fluorescence microscopy. In mid-IR photo-induced force microscopy (PiF-IR, also named mid-IR PiFM) tunable and pulsed quantum cascade lasers (QCLs) illuminate the region between a sharp metallic atomic force microscopy probe (AFM-tip) and the sample of interest. The conservative component $F_c(z)$ of the static tip-sample interaction force $F_{ts}(z)$ in the non-contact regime is the attractive van der Waals interaction force [1–3]. The near-field enhanced absorption in the tip-sample region induces a thermal expansion of the materials at their resonant IR frequencies resulting in a modulation of the van der Waals interaction due to material density reduction. PiF-IR is operated in dynamic non-contact AFM mode at small oscillation amplitudes of 1-2 nm, which enables to detect the force gradient $\partial F_{ts}/\partial z$ by employing a heterodyne detection scheme (sideband mode) [1, 3]. This sideband detection scheme provides access to the characterization of the chemical composition of materials surfaces with an unprecedented spatial resolution of ≈ 5 nm [4].

In a study applying PiF-IR to differently polarized F-Actin, a major structural protein in vertebrate cells, nanoscale chemical variations associated with the protein organization were found and compared to the significant local variations obtained from PiF-IR scans of mouse liver tissue at three different IR frequencies [4]. Our preliminary results from the investigation of *Bacillus subtilis* cells incubated with a β-Lactam antibiotic affecting the cell wall reveal the heterogeneous response of individual bacteria cells to the antibiotics by showing variations in the protein and glycan content of the cell surfaces (Figure 1a). For fully exploiting the potential of PiF-IR and related tip-enhanced infrared spectroscopic imaging methods for applications in the Life and Materials Sciences, further understanding of the signal generation in nanostructured samples is required.

In a comprehensive approach, we modeled the non-linear impact of material characteristics and surface shape on the tip-sample interaction, the photo-induced electric field (the schematics for our setup are depicted in the 3D topography image of the bacteria cells in Figure 1b), the heat generation and the associated thermal expansion under different illumination conditions including light polarization, as well as, the feedback to the dynamic tip

motion due to the expansion [3]. The comparison of the results from a simulated setup with our experimental investigation of a spherical polymer nanoparticle (NP, see Figure 1c, d) shows good agreement [3] contributing new insights into the understanding of PiF-IR contrasts obtained from nanostructured materials. In the here studied case of isotropically absorbing materials, an enhanced signal is found on the nanostructure perpendicular to the propagation vector k_0 of the illuminating field E_0, which oscillates in-plane with the oblique incidence onto the tip-sample region [3], see the enhanced signal on the NP in the experimentally obtained PiF contrast in respect to the illuminating field depicted by red arrows in Figure 1d).

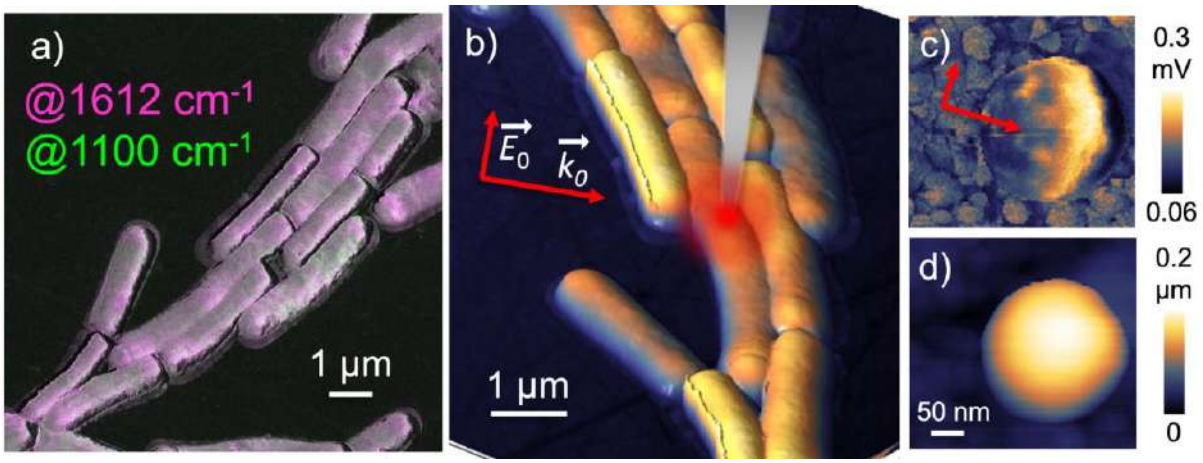

Figure 1. Photo-induced for microscopy: a) Merged RGB image PiF contrast of Bacillus subtilis cells succeedingly scanned @1100 cm^{-1} (green, glycans) and @16120 cm^{-1} (pink, peptides); b) schematics of near-field enhancement in our setup on 3D image of simultaneously acquired topography; c) PiF contrast of a spherical PMMA nanoparticle with radius 50 nm and d) simultaneously acquired height image.

Such signal enhancement parallel to the field oscillation vector is also visible in a study applying peak force infrared (PFIR) on grains of an isotropically absorbing material [5], which confirms the relevance of our results for a qualitative interpretation of data obtained using tip-enhanced infrared illumination on nanostructured materials. Further work, including other geometries and also anisotropically absorbing materials is required for a quantitative analysis of such contrasts obtained on nanostructured materials.

Hyperuniform Disordered Materials for Solar and Solar-Thermal Absorbers

M. Florescu[1*]

[1]Optoelectronics Research Centre, University of Southampton, Southampton SO17 1BJ, United Kingdom

[*]corresponding author: m.florescu@soton.ac.uk

Abstract: Hyperuniform disordered structures demonstrate great potential to enhance light absorption in solar cell and solar-thermal absorber architectures and due to unique light trapping mechanisms capable of attaining absorption enhancements up 85% over the visible spectrum and record solar cell efficiency in ultra-thin film solar cells.

Keywords: hyperuniform disorder, correlated disorder, solar cell, solar-thermal absorbers

In recent decades, advancements in nanoscience and nanotechnology have enabled precise control over nanostructures, playing a crucial role in enhancing solar energy capture, conversion, and storage. State-of-the-art fabrication techniques now offer extensive design flexibility, facilitating the development of complex and aperiodic geometries, such as hyperuniform, quasi-periodic, fractal, and seemingly random patterns. When appropriately designed, these structures can outperform conventional approaches while demonstrating increased resilience to fabrication imperfections. However, the absence of simple and systematic design methodologies has thus far hindered their full exploitation.

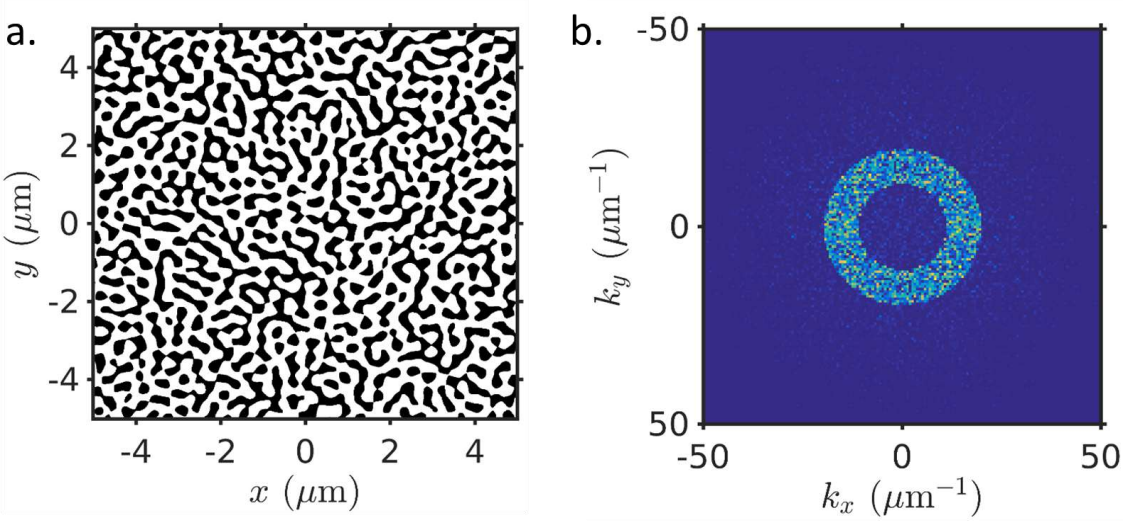

Figure 1. (a) Nearly-hyperuniform distribution of dielectric material generated under periodic boundary conditions. (b) Diffraction spectrum of the structure in (a) with most of the diffraction power concentrated in a circular shell of predefined boundaries.

Here, we employ novel hyperuniform and nearly-hyperuniform disordered architectures [1], [2], [3], [4] for selective absorbers to achieve an optimal control over the absorption of the solar spectrum. Utilizing an inverse Fourier-space design approach, we identify optimal absorber designs based on their Fourier components to achieve two key objectives: enhancing the efficiency and angular acceptance of solar cell absorbers while optimizing the trade-off between undesirable out-of-plane scattering losses and beneficial in-plane light trapping.

This approach aims to push absorption performance toward its ultimate theoretical limit.

The hyperuniform patterning is implemented as a textured layer atop a 1-micron-thick silicon slab, designed to optimize the coupling of incident solar radiation to the slab's supported optical modes [5]. Within the targeted spectral range of 400 to 1050 nm, silicon exhibits strong dispersion, leading to significant curvature of the silicon light cone and substantial variations in absorption. At shorter wavelengths, absorption remains high even with suboptimal coupling to incident radiation. However, at longer wavelengths, efficient coupling to the quasi-waveguided modes of the silicon slab becomes critical to counteract the inherently lower absorption of silicon. Our focus is on optimizing coupling to modes with wavevectors in the range of [10, 20] μm^{-1}, which facilitate access to the spectral region where silicon absorption is weaker [6]. The absorption spectra of hyperuniform disordered structures exhibit several notable characteristics. Most significantly, the spinodal structure achieves the highest overall absorption efficiency, reaching 85%, representing a substantial improvement over the untextured anti-reflective coating. Notably, despite their differing morphologies, the optimized structures share a common feature: filling fractions consistently within the 50–60% range. Additionally, the oscillations observed in the absorption spectrum of the unpatterned silicon slab are attributed to Fabry-Pérot resonances, which have previously been leveraged to enhance absorption in thin-film solar cells.

In conclusion, we have investigated the application of hyperuniform disordered texturing to enhance solar radiation absorption. The efficiency of solar energy harvesting is governed by key physical mechanisms, including diffraction induced by surface patterning and coupling to the relevant guided modes of the crystalline silicon (c-Si) slab. Our findings demonstrate that an absorption enhancement of up to 85% of incident solar radiation can be achieved within the broadband range of 400–1050 nm on a 1 μm-thick silicon membrane. This approach can be extended to other solar energy harvesting applications, such as solar-thermal absorbers for solar thermionic systems [6–9], where concentrated sunlight is utilized to generate electricity with high efficiency and minimal cost. In this context, solar radiation absorption would occur within a specially designed metasurface, composed of optimally engineered metal-dielectric-metal resonators arranged in a hyperuniform pattern to enhance coupling to the resonant modes.

Developing quantitative multiscale models for nonlinear molecular plasmonics

M. Sukharev

Arizona State University, USA
maxim.sukharev@asu.edu

Abstract: The research program established in my group integrates computational electrodynamics in the nonlinear optical regime with the quantum dynamics of large molecular systems. This talk overviews our recent advances in the field of nonlinear nano-optics and molecular plasmonics highlighting newly developed computational method, namely molecular mapping technique.

Nonlinear plasmonics has been a subject of increasing interest in the past few decades. With significant advancements in experimental capabilities enabling the localization of light into sub-diffraction volumes, numerous nonlinear optical phenomena, once predominantly studied in macroscopic systems, are now being explored at the nanoscale. A wide variety of metal nanoparticles (MNPs) shapes and arrays of nanoholes have been employed to investigate phenomena such as second harmonic generation, four-wave mixing, and many other nonlinear processes. For instance, we have recently demonstrated that the second harmonic generation can be used as a very sensitive optical tool for detecting spatial variations in MNPs shapes at the nanoscale level.

While significant attention has been paid to the harmonic generation using plasmonic nanostructures, reports on the reverse process of difference frequency generation (DFG) have been limited. With the help of a theoretical model and FDTD simulations based on the hydrodynamic-Maxwell model, we examine the effect of DFG in an array of L-shaped MNPs characterized by intrinsic plasmonic nonlinearity. The outcomes of the calculations reveal the spectral interplay of the gain and loss in the vicinity of the fundamental frequency of the localized surface-plasmon resonances. Our results suggest that the parametric amplification regime becomes feasible on a scale of hundreds of nanometers and parametric downconversion on the scale of tens of nanometers, opening exciting new opportunities for developing building blocks of photonic metasurfaces.

I will discuss the effect of resonant optical cavities on nonlinear multiphoton transitions in molecules. Our self-consistent quantum model provides fundamental insights into the complex dynamics of strongly coupled molecule-cavity systems. The observed modifications in molecular relaxation pathways, particularly the persistent alignment and collective dephasing effects, demonstrate the profound influence of cavity coupling on molecular quantum states. The cavity-induced rotational pumping mechanism represents a novel approach for controlling molecular orientation, with potential applications in ultrafast molecular switches and Schrödinger–Maxwell information processing. The discovery of relaxation stabilization through collective dephasing suggests new strategies for preserving quantum coherence in molecular systems. Furthermore, the predicted alterations in circular dichroism spectra of chiral metasurfaces under strong coupling open avenues for engineering enhanced light-matter interactions in nanophotonic devices and chiral sensing applications. These findings advance our understanding of molecular polaritonics and provide a theoretical framework for designing next-generation quantum optical devices and molecular control techniques.

Metasurface with gap and collective surface plasmon modes

A.O. Pinchuk[1*], and O.A. Yeshchenko[2]

[1]Center for Plasmonics, Nanophotonics, and Metamaterials, University of Colorado Colorado Springs, CO, 80918 USA, [2]Physics Department, Taras Shevchenko National University of Kyiv, Kyiv, 01601, Ukraine

A tunable metasurface, constructed from a monolayer of gold nanoparticles on a glass substrate positioned in close proximity to a thin aluminum film, was studied both numerically and experimentally. Three distinct peaks, dependent on angle and polarization, were observed in the metasurface's extinction spectra. Using the Finite-Difference Time-Domain (FDTD) method, we confirmed the positions of both the collective surface plasmon and the gap modes. We found that changing the polarization of the incident light results in a wavelength shift of these spectral peaks.

A strong coupling between gap and collective surface plasmon polariton modes was recently reported in a system consisting of a monolayer of gold nanoparticles on a glass substrate, separated from a thin aluminum film by a shellac polymer spacer of varying thickness. [1-3] Two optical extinction bands were identified: a long-wavelength gap mode and a short-wavelength collective surface plasmon mode. Both modes' positions and amplitudes strongly depend on the shellac dielectric spacer thickness. Changing this thickness shifts the two modes, eventually causing them to degenerate into a single mode as the spacer thickness increases. [1-3] These findings revealed a complex interplay between the gap and collective surface plasmon polariton modes. Although detailed numerical and experimental studies were conducted for various plasmonic metasurface geometries, all these investigations were performed with normal incidence of the probing light beam. No reports have examined the polarization dependence of extinction spectra for monolayers of gold nanoparticles in close proximity to a thin metal film.

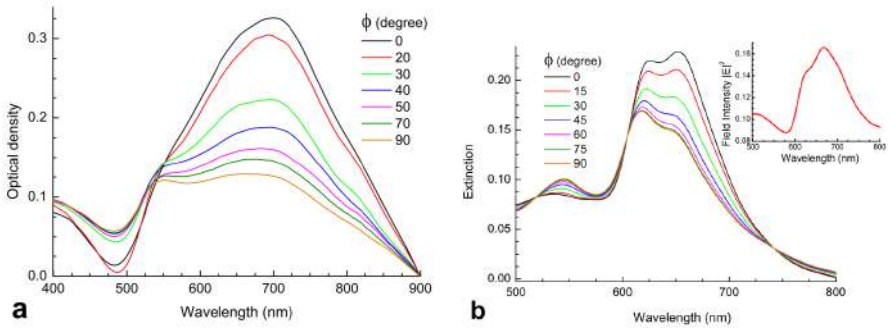

Figure 1. Experimental (a) and numerical (b) extinction spectra of the metasurface as a function of polarization angle φ of the incident probe beam for a sample with a shellac thickness of 10 nm. The angle of incidence of the light beam relative to the normal of the surface is $\theta = 60°$. The polarization angle of the incident light beam is gradually changed from 0° (s-polarization) to 90° (p-polarization). The inset picture (b) shows the results of the FDTD calculations of the intensity of the electric field in the middle of the shellac spacer as a function of the wavelength.

Here we examine a plasmonic metasurface composed of a monolayer of gold nanoparticles in close proximity to a thin aluminum film. A shellac dielectric spacer controls the distance (gap size) between the gold nanoparticles and the aluminum thin film. A similar structure, consisting of gold nanoparticle monolayers separated from an aluminum film by shellac spacers of varying thickness, was

recently studied under normal incidence of the probing beam.[1] Two modes were identified under this normal excitation: a gap mode and a collective SPR (Surface Plasmon Resonance) mode. Both the collective surface plasmon and the gap mode were excited when the spacer thickness was less than 30 nm. For spacer thicknesses larger than 30 nm, the two modes degenerated into one hybrid surface plasmon-gap mode.[1-3]

In the present work, we study the effects of different polarizations and incident angles of the probe beam on similar metasurfaces. Figure 1 shows both the experimental results (a) and FDTD numerical calculations (b) of the metasurface's extinction spectrum as a function of probe beam polarization when the angle of incidence relative to the surface normal is $\theta = 60°$. The polarization angle of the incident beam gradually changes from $\varphi = 0°$ for s-polarization to $\varphi = 90°$ for p-polarization. The experimental results for s-polarized incident light ($\varphi = 0°$) exhibit three peaks around 550 nm, 620 nm, and 650 nm. We attribute the peak near 550 nm to the collective SPR in the monolayer of gold nanoparticles. This collective SPR wavelength is close to the localized SPR wavelength in individual spherical gold nanoparticles (90 nm size) embedded in a dielectric with refractive index n=1.5. The broader gap mode peak is located around 700 nm. The FDTD calculations reveal a SPR collective mode near 550 nm and narrower two-peak gap modes near 610-650 nm, as seen in Fig.1(b). As the incident beam polarization gradually changes from $\varphi = 0°$ to $\varphi = 90°$, the collective SPR peak position remains around 550 nm. Simultaneously, the low-energy gap modes decrease in amplitude and exhibit a distinct two-peak structure.

The FDTD numerical calculations show a two-peak structure of gap modes with narrower bandwidth peaks for the p-polarized light beam. The broader bandwidth of the collective SPR and gap modes observed experimentally may be explained by the relatively large size distribution of gold nanoparticles in the sample. The inset in Fig.1(b) shows the numerically calculated electric field intensity at the shellac level in the gap. Maximum intensity is observed at ~650 nm, corresponding to the optical density maximum where the gap mode is excited (Fig. 1(a,b)). This confirms that the peak at ~650 nm is attributable to the gap mode. While the collective SPR peak wavelength doesn't change significantly as polarization shifts from s-polarization to p-polarization, the gap mode amplitude decreases. This effect is more pronounced experimentally than in numerical calculations. The gap mode bandwidth increases as polarization changes from 0° to 90°. The wavelengths of both the collective SPR mode and gap modes are similar to those observed with normal incidence of the probing beam.

Nonlocal metasurfaces and thin film devices for all-optical image processing and phase contrast imaging

A. Roberts[1*]

[1] ARC Centre of Excellence for Transformative Meta-Optical Systems, School of Physics, University of Melbourne, Victoria 3010, Australia

[*]Corresponding author: ann.roberts@unimelb.edu.au

Abstract: Metasurfaces and tailored thin film devices can manipulate images and extract information from optical fields in the object plane, leading to a significant reduction in size compared to other optical approaches. Here recent progress in extending and utilizing the range of information obtainable using these devices will be presented.

It is well-known that optical systems can perform image processing in the Fourier plane, but currently computational methods are more commonly employed for tasks such as edge detection, object identification, and image enhancement. The latter approaches, however, rely on the capture of information with a digital camera discarding phase information, and the resources required scale as the amount of information being processed. Hence, there is an ongoing interest in being able to perform operations directly at the sensor level. Furthermore, Frits Zernike demonstrated that the inclusion of phase plates as spatial filters using Fourier methods permitted visualization of essentially transparent objects such as unstained biological cells [1]. While there are advanced computational methods to extract phase information from intensity images, these methods can be slow and computationally intensive and are orthogonal to the drive to the sensor-level processing. Well-established all-optical Fourier and other image processing and phase contrast imaging methods, however, usually require large and sometimes costly optics. With the push for more compact optical components and advances in nanooptics, there is an emerging interest in all-optical image processing taking advantage of the unique capabilities of metasurfaces [1-4] and thin film devices [5-6].

Traditional spatial frequency filtering involves introducing a mask into the focal plane of a lens taking advantage of its Fourier transforming property to independently manipulate contributions to the angular spectrum of the optical wavefield. This approach places a lower bound on the axial extent of the system due to the introduction of lenses and propagation distances. Nonlocal approaches, on the other hand, involve the direct manipulation of the spatial frequency content of the field by using a device that has a reflectance or transmittance sensitive to the angle of incidence of a plane wave. This directly modifies the amplitude and/or phase of a given angular spectrum component of the field. Not only does this present a more compact optical system but permits flexibility in positioning the device [7]. Concepts leveraging known light-matter interactions or inverse design methods can be used to develop metasurfaces with a tailored angular dispersion and, hence, perform a particular operation [2,3]. Specifically, there is considerable scope for the development of compact devices that can generate enhanced contrast images of transparent objects. Indeed, we have previously shown that an off-the-shelf notch filter [8] or a metal-insulator-metal Salisbury screen [9] can perform edge detection and phase contrast imaging of unstained biological samples in, respectively, transmission and reflection. We also used a resonant waveguide grating in transmission [10, 11] to generate phase contrast images of unstained HeLa

cells. Our recent research has focused on dynamically modifying the imaging modality without removing the metasurface by changing the polarization of the incident field [12] or using phase change materials [13].

This presentation will focus on recent results utilizing inverse design strategies [14] to produce spatial frequency selective metasurfaces, tailored thin film devices and the introduction of tunable materials to modify image processing operations. Wavelength and polarization multiplexed information extraction from an optical wavefield will also be discussed and applications to quantitative phase imaging presented.

Chern insulators: nonlinearity and switching

Justin T. Cole[1]
[1]University of Colorado, Colorado Springs, USA
jcole13@uccs.edu

Abstract

Most results on Chern insulators are based on linear theories. Here nonlinear Chern insulator models and the states they support are examined. Solitons and traveling waves are investigated. A secondary agenda examines switching within Chern insulator models. Namely, mechanisms for controlling the flow of light are to be discussed.

Active Conducting Polymer Plasmonics and Metasurfaces

M. P. Jonsson

Abstract

Our group recently introduced conducting polymers as a new type of active plasmonic materials, enabling chemically and electrically controlled metasurfaces.[1-3] I will present the background to this emerging area and discuss challenges and recent advances, including exploration of different polymers,[4,5] narrowing of resonances through nonlocal coupling,[6] and new possibilities based on hyperbolic polymers.[7,8]

Abstract: This study develops injectable ultrasonic sensors using bio-acoustic metamaterials, enabling wireless monitoring of pressure, temperature, and pH via wearable ultrasound devices. These biodegradable sensors eliminate surgical removal needs, offering minimally invasive implantation and multi-signal detection capabilities for advanced healthcare monitoring.

The seamless integration of humans and machines lies at the heart of the next technological frontier, enabling transformative applications capable of enhancing our sensory capabilities, health monitoring, and overall quality of life. I have cultivated a multidisciplinary approach, delving into the design theory, manufacturing, and biomedical engineering applications of acoustic bio-metamaterials. Drawing upon foundational research, bio-acoustic metamaterials aimed at tackling the challenges inherent in transmitting information and energy across the skin barrier, with a specific focus on healthcare and sensory augmentation. For example, addressing the need for non-invasive, wireless monitoring solutions, I have pioneered the development of metagel-ultrasonic sensors (Figure 1). These sensors can be injected into the body via a needle, eliminating the need for open surgery. Compatible with handheld or wearable ultrasound devices, they facilitate precise, continuous, and wireless monitoring of various internal signals, including pressure, temperature, and pH. After the intended monitoring period, the metagel sensor naturally degrades, obviating the requirement for surgical removal. Offering advantages in implantation size, multi-signal decoupling, and biodegradability over existing wireless implantable sensors, this research holds promise for driving the development of safe, compact, wireless implantable sensors. It stands to inspire further investigations and potentially supplant the current paradigm of percutaneous wired sensors in clinical settings.

Abstract: We demonstrate two tailored resonant metasurfaces for enhancing third-order nonlinear optics, namely, a surface lattice resonance aluminum metasurface for wavelength-tunable Q-switched fiber laser, and a quasi-bound state in the continuum amorphous silicon metasurface to amplify two-photon absorption effect.

Resonant metasurfaces provide promising solutions to overcome the limitations of conventional nonlinear materials by enhancing the interaction between light and matter and amplifying optical nonlinearity. Here, we propose and demonstrate two tailored-resonant metasurface platforms: (1) a surface lattice resonance (SLR) aluminum (Al) metasurface, functioning as a saturable absorber (SA) integrated within a fiber laser cavity, which enables wavelength-tunable (1020-1048 nm) Q-switched pulse generation.[1] (2) a quasi-bound state in the continuum (q-BIC) amorphous silicon (a-Si) metasurface, featuring a theoretical Q-factor up to 930, which exhibits a giant nonlinear two-photon absorption (TPA) effect with nonsaturation TPA coefficient β_0= 173.2 cm/MW and TPA saturation intensity I_{sat}= 93.0 MW/cm^2.[2] Both platforms enhance third-order nonlinear absorption responses, offering significant potential applications in nonlinear optics and ultrafast optics.

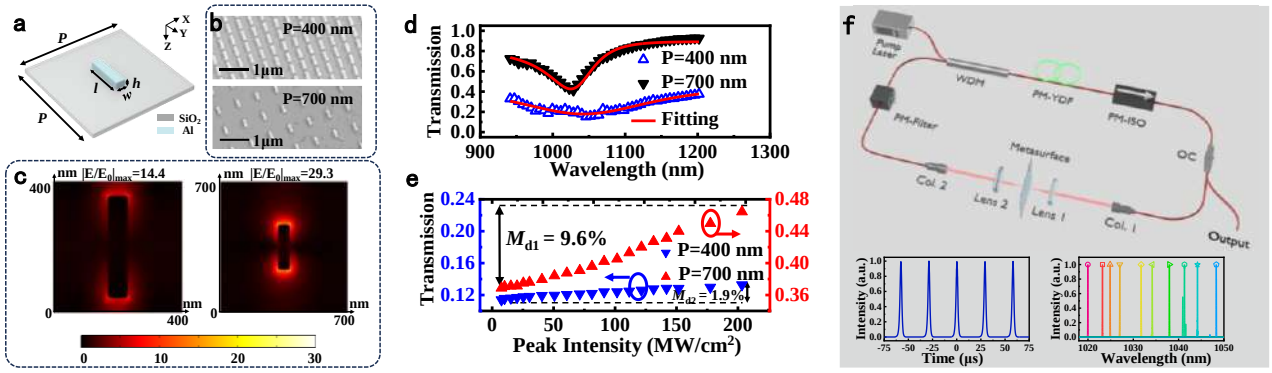

Fig. 1. The SLR aluminum metasurface and its application in a pulse fiber laser. (a) Schematic of the Al unit cell. (b) SEM images of the fabricated metasurfaces. (c) Electric near-field distributions at resonance wavelength 1035 nm at the X-Y plane of the half height of Al nanostructures. (d) Linear transmission spectra and (e) Nonlinear transmission measurements that exhibit the considerable saturation absorption of Al metasurfaces in experiment. 1035 nm fs laser is used for nonlinear measurement. (f) Setup of the Q-switched ytterbium-doped polarization-maintaining fiber laser. Typical pulse train (bottom right inset) and tunable spectra (bottom left inset) of Q-switching operation.

We fabricated two Al metasurfaces with different periods *P*, each consisting of periodic single-nanorod arrays. The unit cell and SEM images are shown in Fig. 1a and 1b, respectively. In order to achieve resonance within the desired wavelength range (~ 1 μm), metasurfaces are excited by Y-polarized normal incidence. As displayed in Fig. 1c and 1d, due to the coupling between the Rayleigh anomaly (RA, $\lambda_{RA}=n_{sub} \times P$) and localized surface plasmon resonance (LSPR), the metasurface with *P*=700 nm (supporting SLR mode) exhibits a narrower linewidth and a more prominent near-field enhancement compared to the metasurface with *P*=400 nm (supporting LSPR mode). This indicates a greater ability to amplify nonlinear optical responses. As a result, the SLR metasurface

(modulation depth M_d=9.6%) shows a more significant saturation absorption than the LSPR metasurface (M_d=1.89%) under a low incident fluence (25 μJ/cm^2) (Fig. 1e). Then, we have further achieved wavelength-tunable (1020-1048nm) Q-switched pulse generation by incorporating the SLR-based Al metasurface as a passive SA in a polarization-maintaining ytterbium-doped fiber laser (Fig. 1f).

The q-BIC metasurface consists of Π-like a-Si nanostructures with symmetric defects that trigger the transition from BIC to the q-BIC mode (Fig. 2a and the set of Fig. 2b). As shown in Fig. 2b, the Q-factor of the q-BIC mode increases as the asymmetry parameter α decreases. However, too small α will bring challenges to practical nanofabrication. Fig. 2c depicts the simulated (top panel) and experimental (bottom panel) transmission spectra, respectively. The metasurface exhibits a sharp q-BIC resonance (Q about 930 theoretically) with asymmetric Fano line shape and excellent near-field enhancement when are excited by X-polarized normal incidence. In contrast, when excited by Y-polarized normal incidence, the metasurface does not exhibit any resonance behavior in this wavelength range. As illustrated in Fig. 2d (black dots), the metasurface demonstrates a typical TPA response by X-polarized incident light. We fit the experimental data using the homogeneously broadened model of TPA saturation theory, which indicates a nonsaturation TPA coefficient β=173.2 cm/MW and a TPA saturation intensity I_{sat}=93.0 MW/cm^2. As a comparison, the TPA almost vanishes at Y-polarized incidence, confirming that the noticeable nonlinear response originates from the strong local near-field enabled by the excited q-BIC resonance.

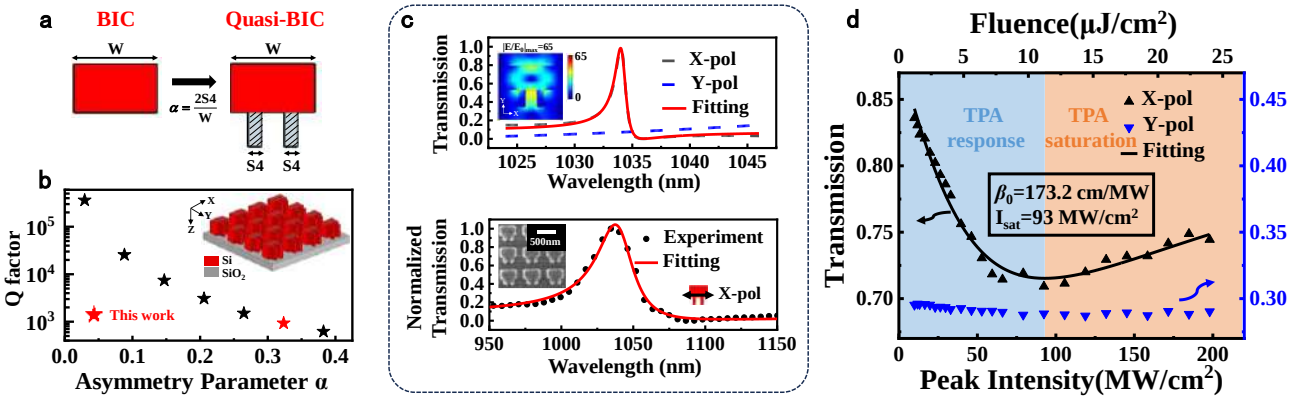

Fig. 2. The q-BIC silicon metasurface and its giant TPA effect. (a) Diagram of the meta-atom for transition from the BIC mode to the q-BIC mode. (b) Dependence of the Q factor on the asymmetry parameter α. The α is about 0.32 in experiment. Inset: schematic of the q-BIC metasurface. (c) Linear transmission spectra in simulation (top) and in experiment (bottom), respectively. Inset: electric near-field distributions for incident X-pol light (top panel) at 1035 nm wavelength and SEM image of the fabricated q-BIC metasurface (bottom panel). (d) Nonlinear experimental results using 1035 nm fs laser. The black solid curve is the fitting of the TPA saturation.

Our proposed resonant metasurface platforms are committed to achieving high Q-factor and low losses, offering exciting and flexible methods to enhance nonlinear optical effects.

Abstract: Phosphors have enabled modern full-color display technologies as well as solid-state lighting. In this talk, a paradigm-shifting novel approach is introduced to improve the color-conversion efficiency of phosphor: *structural engineering* under the principles of nanophotonics. Two structural platforms to be discussed are lateral photonic crystal and vertical resonant cavity.

The importance of phosphor has been revived ever since it enabled solid-state lighting in conjunction with blue LEDs. Phosphors are now playing a key role in full color display devices and systems as well. Conventionally, phosphor development has been mainly accomplished via developing new materials, which is culminated by the emergence of colloidal quantum dots (CQDs). Yet another possible route, which has been proposed and demonstrated by the author's group, is to reconfigure phosphor material into a nanophotonic structure such that its resonance is tuned to excitation wavelength for the phosphor material, resulting in a great improvement in color-conversion efficiency due to resonant absorption of excitation photons.

So far, we have successfully demonstrated two nanophotonic platforms in this purpose: lateral photonic crystal (PhC) and vertical resonant cavity (RC). The PhC phosphor, which utilizes a Γ-point band-edge mode, consists of a passive PhC platform and a phosphor material (such as CQDs) incorporated into the PhC backbone structure. In the RC phosphor, on the other hand, a thin CQD film is inserted in a cavity layer sandwiched between two distributed Bragg reflectors. Although amply different in structures, the both platforms exhibit a significantly enhanced CQD fluorescence when compared with reference phosphor having an equal amount of CQDs but no resonant structure. Continuous efforts are being exerted to improve the fabrication, performance, and functions of the structurally engineered phosphors.

Abstract: We investigate the growth dynamics of AuPd nanoparticles produced by electron evaporation through *in situ* optical spectroscopy. Our results shows that the optical response is dominated by the plasmonic properties of gold and is greatly influenced by the buffer structuring, the deposition angle and the amount of Pd in NPs.

For several decades, bimetallic nanoparticles (NPs), also called nanoalloys, have been the subject of unceasing investigations as they combine specific characteristics of the matter at the nanoscale with interesting properties of alloys as compared to their constituents. Such a combination can induce remarkable physical and chemical properties far different from their bulk counterpart, thereby leading to various applications in optics, magnetism or catalysis.[1]

In addition to size and shape effects, the relative composition of both species as the chemical arrangement are supplemental parameters allowing the tailoring of novel properties that may develop in such systems. However, their (chemical, geometric, electronic) structure may evolve under specific environments, especially under oxidizing or reducing conditions.[2] Among properties emerging in the nanometer range, the Localized Plasmon Resonance (LSPR) is an optical resonance leading to a strong absorption band and a local field amplification, which features are fully dependent on the structural parameters (size, morphology, chemical configuration) and the surrounding medium (nature and composition) of the NPs. In other words, the LSPR can be used as a probe of both the chemical structure and the composition of the local environment of plasmonic nanostructures.[3,4]

We recently developed an experimental setup for the physical vapor deposition (electron evaporation) of one to five different metals at various incidence angles. The uniqueness of this setup lies in the possibility of monitoring in real time the growth of the nanostructures through the measurement of their optical transmittance or reflectance. This allows probing the evolution of their chemical structure through the analysis of their optical response, and then access to their growth dynamics.

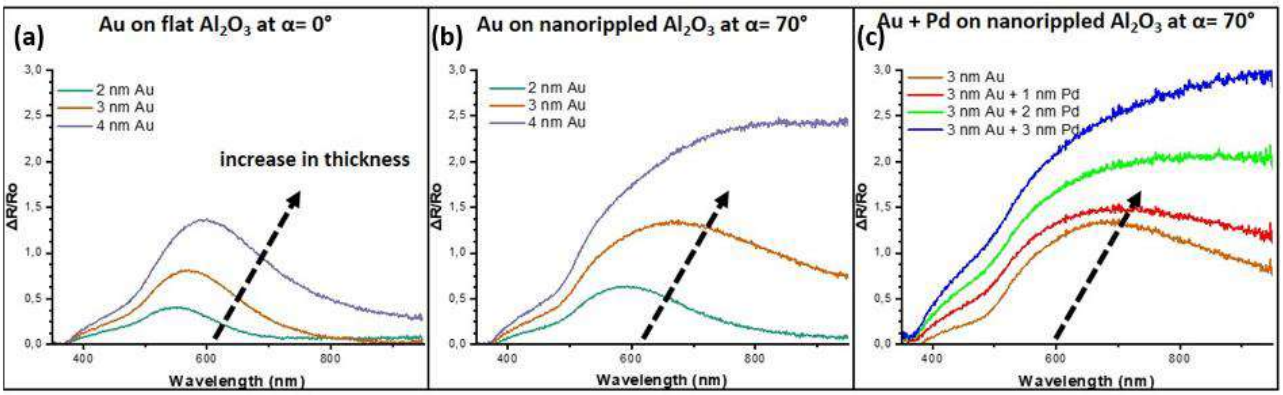

Figure 1: Optical reflectance of thin films measured in situ during their growth. (a) gold deposited at normal incidence (α=0°) on Al_2O_3 buffer. (b) gold deposited at oblique incidence (α=70°) on nanorippled Al_20_3 buffer. (c). 3 nm of gold followed by 3 nm of Palladium deposited on nanorippled Al_2O_3 buffer.

Here, we investigate the structure and the optical properties of Au_XPd_{1-X} bimetallic NPs. Au present a LSPR in the visible spectral range, while Pd NPs are very efficient catalysts, in particular for the rapid dissociation of hydrogen. Combining Au LSPR to Pd reactivity might then lead to a new generation of optical hydrogen sensors.[5,6] We synthesized AuPd NPs through a sequential deposition (gold followed by palladium) at normal and oblique angles (denoted as α) on flat and nanorippled Al_2O_3 surfaces. The optical response acquired during the growth of Au nanoparticles is dominated by its LSPR, which broadens and shifts towards near-IR range as the amount of Au increases, traducing deep structural modifications during the growth (fig 1.a). These LSPR changes are more pronounced when the flat buffer is replaced by nanoripples (fig 1.b) and when Pd is deposited onto Au NPs (fig. 1.c). The i*n situ* optical characterization of large assembly of NPs is supported by Transmission Electron Microscopy (TEM) observations. These results stress the importance of the deposition conditions on the adopted configurations. It also shows the promising perspective of monitoring the growth and the evolution of the optical response to tune the LSPR features (especially its spectral position) for specific applications by adjusting the quantity of deposited elements and the growth parameters.

Abstract: Determining the electric field vectors of surface plasmon polaritons (SPPs) in space and time is a challenging endeavor. It is accomplished with nanometer resolution in a time-resolved photoemission microscopy experiment. After reconstruction of the time-dependent electromagnetic field vectors, local topological properties of the SPPs are derived.

During the last years, the experimental determination of the electromagnetic vector fields of surface plasmon polaritons (SPPs) has become possible, and fundamental properties like the spin-momentum locking of SPPs have been demonstrated.[1] To investigate more complicated SPP field configurations that require a particular polarization for excitation, the concepts of these early vector reconstruction concepts had to be extended. By now, the experimental reconstruction of SPP fields with particular properties is possible.[2] This 'vector polarimetry' is based on the combination of nonlinear photoemission microscopy with femtosecond laser pulses in a time-resolved interferometric pump-probe experiment. The experimental concept is as follows: Femtosecond laser pulses from a Ti:Sapphire oscillator are separated into two pulses at the first beam-splitter of a Pancharatnam's phase stabilized Mach-Zehnder Interferometer. In both arms of the interferometer the polarization can be adjusted independently using $\lambda/2$ waveplates. Moreover, the polarization of both arms can jointly be adjusted by a combination of a $\lambda/2$ and a $\lambda/4$ waveplate that are placed behind the exit of the interferometer. The fs laser pulses are guided into the photoemission microscope (PEEM) where they impinge on the sample in a normal incidence geometry. A complete description of the contrast mechanism was provided by Dreher et al.[3] In brief, a SPP is excited by the pump pulse at a groove where the necessary momentum for an optical excitation is provided. The specific spatiotemporal structure of the excited SPP is controlled by the shape of the groove and the polarization of the pump pulse. The propagating SPP is then subsequently probed several times at different temporal delays with probe pulses of different polarization. The pump-probe contrast in the PEEM images depends predominantly on the longitudinal field component of the SPP, and using Fourier-techniques, the longitudinal electric field vector of the SPP can be triangulated.[1] The transverse component of the electric field vector can be calculated from the divergence-free nature of the evanescent SPP field in the vacuum: $\boldsymbol{\nabla} \cdot \mathbf{E}(\mathbf{r}, \mathrm{t}) = 0$. Since the temporal dependence of the electric field vectors is known after this calculation, the magnetic field vectors can be derived using the induction law where $\mathbf{H}(\mathbf{r}, \mathrm{t}) = -\int dt\, \boldsymbol{\nabla} \times \mathbf{E}(\mathbf{r}, \mathrm{t})$.

Figure 1 shows examples from a benchmarking experiment, building on the work by Dai et al.[4] An Archimedean spiral was cut into a single-crystalline Au island on a SiO_2 support using a focused ion beam. The gap in the spiral equals to two SPP wavelengths, i.e., with circularly polarized pump pulses, SPPs with an orbital angular momentum of J=1 or J=3 could be excited, depending on the handedness of the polarization.[5] Exciting this structure with linearly polarized light thus leads to an interference between the two possible orbital angular momentum modes. Panel b of Fig. 1 shows the experimentally determined electric field vectors at a pump-probe

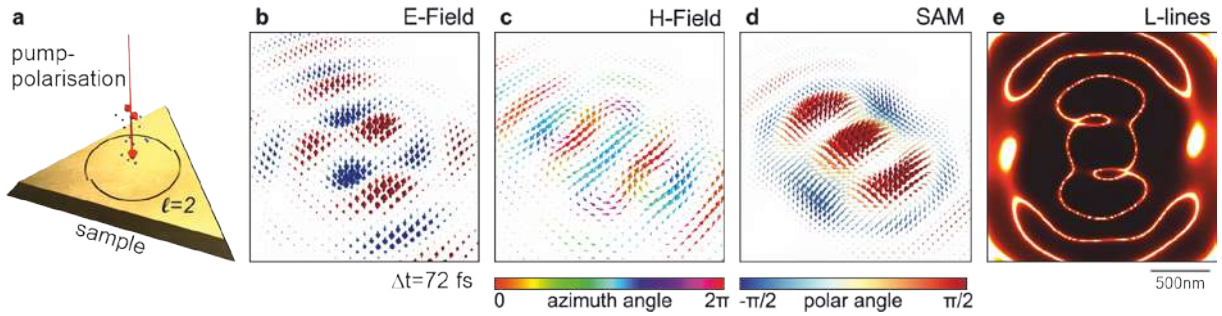

Figure 1: Results from a polarimetric reconstruction. (a) Sample design and excitation. (b) experimentally determined electric field vectors at delay time of 72 fs, (c) derived magnetic field vectors, (d) spin angular momentum vectors, (e) L-line plot, marking the regions where the transverse component of the spin angular momentum vanishes.

delay of 72 fs. The red arrows indicate electric field vectors in the vacuum that point away from the surface, blue arrows indicate regions that point into the surface. The field configuration rotates as a function of delay-time with optical frequencies.[5] Figure 1c shows the derived magnetic field for this delay-time that lies entirely in the surface plane and rotates as well. Since both the electric and magnetic field vectors are known, it is possible to calculate further field properties, such as the spin angular momentum (SAM) $\mathbf{S}(\mathbf{r},t) = \mathrm{Im}(\varepsilon\mathbf{E}^*(\mathbf{r},t) \times \mathbf{E}(\mathbf{r},t) + \mu\mathbf{H}(\mathbf{r},t)^* \times \mathbf{H}(\mathbf{r},t))/2\omega$ which does not rotate any longer, but is stable in time. The SAM for the excitation situation in Fig. 1a is shown in Fig. 1d. The prominent three red maxima are isolated regions where $\mathbf{S}$ is pointing away from the surface, that are surrounded by a region where $\mathbf{S}$ is pointing toward the surface. For infinitely long laser pulses this alternating behavior of red and blue regions would become an infinite series, however, the duration of the used laser pulses of $\approx$15 fs limits the observable region to the center of the spiral. As $\mathbf{S}$ must lie in the surface plane (or vanish altogether) for a transition between spin-upwards and spin-downwards regions, it is interesting to mark the regions where $\mathbf{S}_z = 0$. These regions form closed bands (L-lines). The experimentally determined L-lines are shown in Fig. 1e. The central L-line encircles the three red areas of $\mathbf{S}$ and allows identification of three Merons in the inner region of the spin structure.

In conclusion, we have developed a novel PEEM based technique, 'vector polarimetry' that allows to determine electric and magnetic field vectors of SPPs with thus far unprecedented temporal and spatial resolution. The accuracy of the reconstruction enables the experimental determination of topological properties, such as the SAM landscape, L-lines and Chern densities. The method is applicable to a wide range of SPP field configurations, including situations that are truly not periodic in space.[6] Vector polarimetry is thus clearly expected to play an important role in the future analysis of topological plasmonic structures.

Abstract: Two-dimensional metal-halide perovskite microcrystals with homogeneous and regular rectangular shape are fabricated by a solution-based process. These light-emitting semiconductor crystals can act as photonic cavities and feature strong light-matter interaction. Extending the solution growth employing various materials allows to obtain heterostructures defining regions with different band gap.

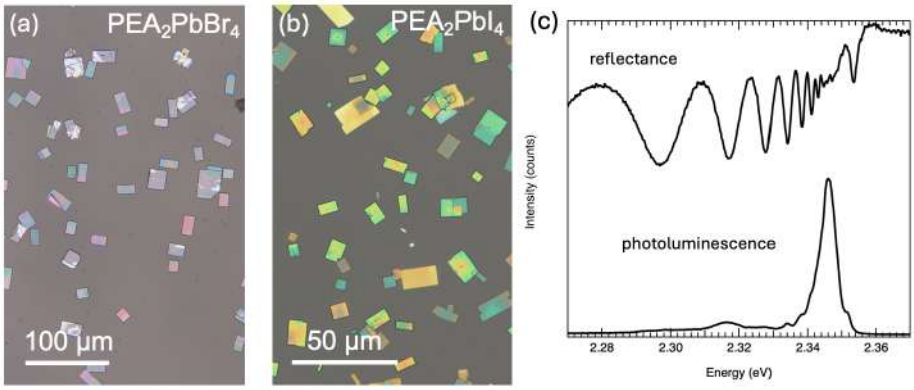

Figure 1. (a-b) Optical microscope images of 2D perovskite single crystals. (c) Reflectance and emission recorded from a single crystal, with evidence of Fabry-Perot resonances in reflection.

Two-dimensional organic/inorganic metal-halide perovskites (2DLHPs) are currently in the spotlight for their appealing optical properties and large structural and functional variety. Their layered structure in which a semiconducting octahedra lattice is sandwiched between dielectric organic layers renders them as natural quantum wells with strong quantum and dielectric confinement.[1] The possibility to tailor their properties via composition and architecture makes these materials highly promising for photonic and optoelectronic applications. Currently, 2DLHPs are mainly fabricated as powders, thin films or crystals with low control on their shape, thickness, and homogeneity on a larger scale.

We first demonstrate a solvent-antisolvent recrystallization method to fabricate 2DLHPs microcrystals (MCs) with highly regular rectangular shape, flat and nearly step-free surfaces (Figure 1a-b). We achieve this by dissolving pre-synthesized 2DLHP powders[2] and fine-tuning of the recrystallization parameters in terms of solvent/antisolvent choice, temperature, and concentration of the different components. With this we obtain single crystals with sizes in the tens and hundreds of µm range and good control on their lateral dimensions and thickness. [3] Our approach can be applied to various substrates, including glass, silicon oxide, and gold, as well as on functionalized or pre-patterned areas. The high crystalline quality and high refractive index of the resulting MCs is appealing for optical resonators where the crystal itself can act as the cavity (Figure 1c).

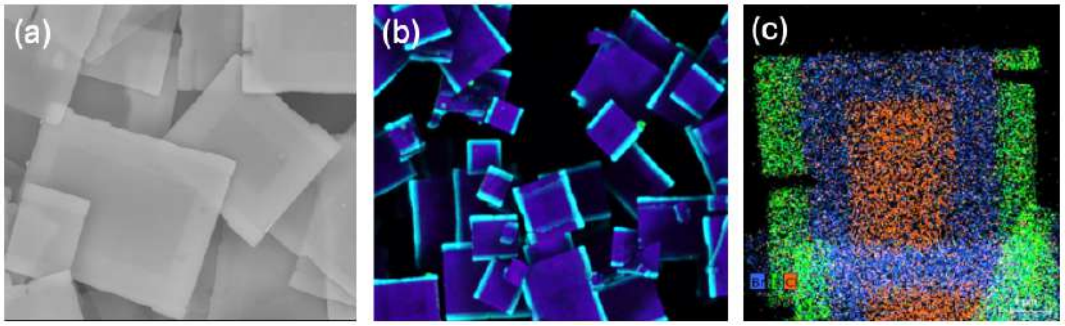

Figure 2. Triple-halide heterostructures in 2D perovskite single crystals. (a) Scanning electron microscopy image, (b) emission recorded with a confocal fluorescence microscope (λ_{ex}=400 nm), (c) overlay of the elemental mapping via energy-dispersive X-ray spectroscopy (EDX) showing Cl as orange, Br as blue, and I as green color.

Lateral heterostructures in semiconductor materials, and the ability to tailor the band gap in different regions of single crystals, are highly interesting for optoelectronics since they provide control on charge localisation and diffusion. Heterostructures have been fabricated by a solution-based sequential crystallization approach,[4] and by anion exchange processes in solid-gas phase processes with HBr or butylammonium halide vapor.[5, 6] We recently developed a solution-based anion exchange synthesis of lateral heterostructures with bromide and iodide as different halides.[3] We extended our solution based approach to grow heterostructures with high-quality crystalline interfaces, and phases of up to three different halides in a single microcrystal (Figure 2).

Development of three-dimensional bulk metamaterials suppliable as meta-atomic grains

Yoshiaki Kanamori[1*]

[1] Department of Robotics, Graduate School of Engineering, Tohoku University, Japan
[*]corresponding author: ykanamori@tohoku.ac.jp

Abstract: With the aim of realizing terahertz optical elements that can be formed into any shapes and have arbitrary refractive indices, our group has succeeded in developing a technology to manufacture grains containing meta-atoms and in putting them into a mold to produce three-dimensional bulk metamaterials.

In the terahertz region, the choice of optical materials is limited, making it difficult to realize a wide variety of optical elements. Therefore, the development of new materials that are easy to process and have a wide range of refractive index characteristics is awaited. Metamaterials are artificial optical materials composed of ultrafine structures, and are attracting attention as innovative artificial structures that break the limits of conventional electromagnetic wave manipulation technology. So far, our research group has aimed to realize terahertz optical elements that can be formed into any shape and have arbitrary refractive indices. We have succeeded in controlling the refractive index around a frequency of 0.7 THz by implementing a three-dimensional bulk metamaterial using a meta-atomic grain with a side length of 100 μm that contains a single-layered split-ring resonator as the unit structure of the metamaterial [1].

Recently, we have developed a three-dimensional bulk metamaterial in which double-layered split-ring resonators are irregularly arranged three-dimensionally based on the amorphous structure of a solid, as shown in Fig.1 [2]. By using meta-atomic grains containing double-layered split-ring resonators shown in Fig.2, the density of the resonators per unit volume is increased compared to a single-layer structure, and we have confirmed that the refractive index changes by 2.314 per terahertz at a frequency of around 0.34 THz. This refractive index change rate is 1.25 times larger than that of the previously reported three-dimensional bulk metamaterial, and it was also demonstrated that it can be adjusted by the density of the arrangement of the meta-atomic grains.

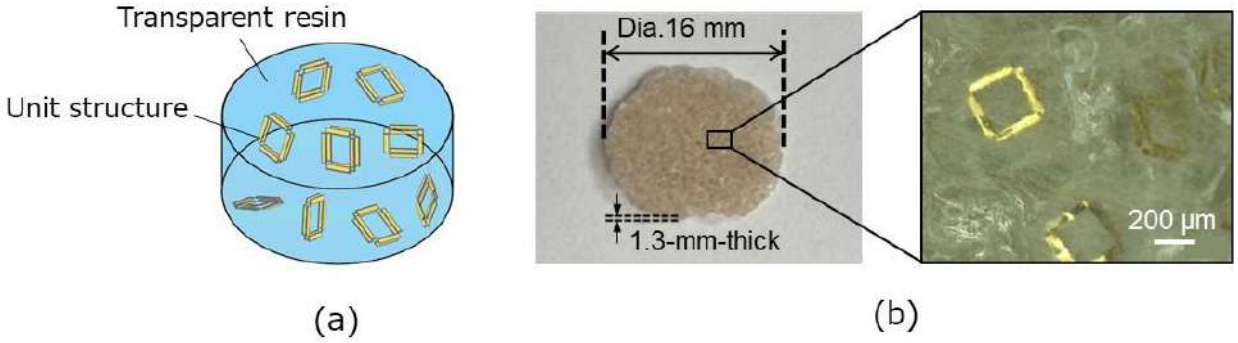

Figure 1: A three-dimensional bulk metamaterial. (a) Conceptual diagram and (b) fabricated three-dimensional bulk metamaterial.

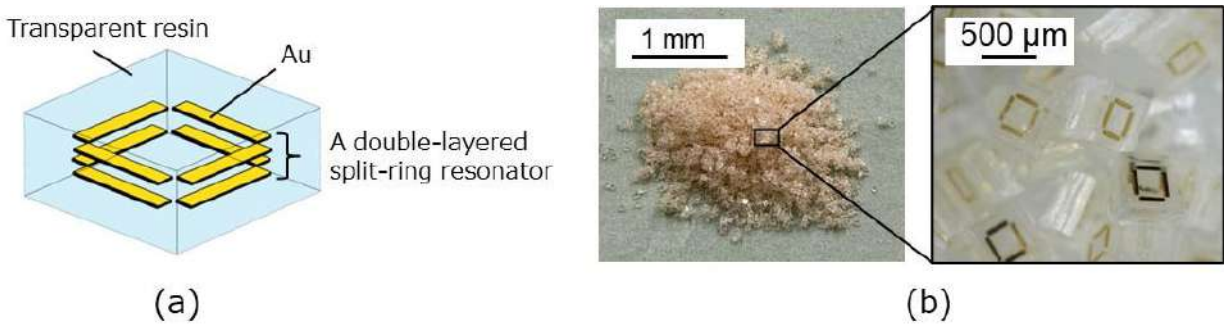

Figure 2: Meta-atomic grains. (a) Conceptual diagram and (b) fabricated meta-atomic grains.

Furthermore, we developed a dielectric three-dimensional bulk metamaterial (Si microparticle dispersion) [3]. The structure is such that Si microparticles are uniformly dispersed in a transparent resin with three-dimensional random orientation, achieving isotropic optical properties. We achieved an effective refractive index in the range of 1.53 to 1.96 at frequencies of 0.1 to 0.2 THz, which includes the 6G communication band. This effective refractive index can be freely controlled by the Si concentration in the Si microparticle dispersion.

Abstract: We report our latest works on large-diameter infrared silicon metalenses manufactured using production-ready Deep UV scanning lithography.

With the adoption of artificial metasurfaces, the metalenses are developed through phase-shifts control by different nano-features [1]. Although metalenses have been widely demonstrated through e-beam lithography as a lab solution, it is still challenging to use Deep UV lithography to make metalenses with suitability of mass production. Recently, we have demonstrated that large-area and wafer-scale metal oxide metasurface can be reliably manufactured using DUV lithography [2]. In this work, we demonstrate large-diameter Si-based metalenses, based on our novel designs and fabrication. With full CMOS compatibility, these metalens were fabricated using DUV lithography on 8-inch silicon substrates with individual metalens diameters ranging from 12 mm to above 25 mm (over a single DUV exposure field). Figure 1 shows the photo of a wafer with large-diameter metalenses over a 200 mm substrate (a), micrograph of the metalens center (b) and Zoom-in SEM image of the exact center with four exposure stitching. We will demonstrate the novel capabilities of our metalenses, which have been developed in the past years, and their real-world IR imaging capability with their integration into IR cameras.

Abstract: Accurate detection of single tumor cells in liquid biopsies and tumor tissues in brain is crucial for diagnostics and surgery, respectively. We present a label-free plasmonic biosensor for tumor discrimination in complex biological samples, based on the extraordinary optical transmission from nanoholes arrays in gold films.

The identification of single live tumor cells in liquid biopsies is essential for developing personalized treatments[1], while accurate identification of tumor margins in the brain is critical for effective glioblastoma surgery[2]. A simple, fast, and label-free optical technique to distinguish tumor cells and tissues from healthy ones would be highly valuable in clinical practice. This work presents a nanostructured plasmonic-based optical biosensor designed to meet these requirements in a minimally invasive way.

As a proof of concept, we applied nanohole arrays for optical label-free biosensing, based on the extraordinary optical transmission phenomenon. This biosensor offers a promising platform for developing fast, sensitive, and reliable detection systems suitable for both biomedical research and potential clinical applications.

We have used an optical microscopy setup to measure extraordinary optical transmission through the plasmonic biosensor after contact with biological samples[3]. The biosensor features nanoholes (diameter: 220 nm) arranged in a square array (periodicity: 550 nm) within a gold film (thickness: 60 nm). Spectral shifts in the transmission response correlate with changes in refractive index when cells or tissues interact with the sensor surface. We have observed refractive index differences between tumor and healthy cells and tissues, ranging from 0.002 to 0.3 RIU[1,2,4].

We first applied the label-free plasmonic biosensor to discriminate between single live cancer cells and normal cells. The optical setup isolates the spectral response of single cells in contact with the nanohole array, exploiting the localized interaction between the cell membrane and the plasmonic field. This approach demonstrated high sensitivity and specificity (80% to 100%) in distinguishing colorectal cancer cells from normal peripheral blood mononuclear cells and fibroblasts[1]. Notably, the system identified the actin cortex, a cytoskeletal structure located just beneath the cell membrane, as the main factor influencing the spectral response[1]. This highlights the biosensor's ability to detect physical and biochemical alterations at the cell surface.

The plasmonic biosensor was further used to monitor two dynamic cancer hallmarks: cell-matrix adhesion and cell division. Spectral shifts induced by interactions between cancer cells and extracellular matrix proteins were detected in real time, allowing the monitoring of cell adhesion processes during their first hour of contact with the biosensor[4]. Furthermore, by synchronizing colorectal cancer cells at different stages of the cell cycle, the biosensor successfully discriminated resting cells (G0/G1) from dividing cells (G2)[4]. These results highlight how changes in the actin cortex during adhesion and division directly influence the spectral response, demonstrating the biosensor's versatility in studying diverse cancer-related processes.

The label-free plasmonic biosensor was also tested in a pre-clinical context, using ex-vivo surgical specimens to discriminate glioblastoma tissue from peritumoral brain tissue. By comparing extraordinary optical transmission spectral shifts induced by tumor and non-tumor tissues in contact with the nanohole array, the biosensor achieved 81% sensitivity and 80% specificity[2]. These results demonstrate the biosensor's potential as a rapid, label-free intraoperative tool for neurosurgeons to improve tumor margin identification during surgery.

Overall, this work illustrates how nanohole array biosensing based on the extraordinary optical transmission phenomenon can enable label-free detection of cancer cells and tissues[1,2]. Key advantages include simplicity, speed, and versatility, making this approach a strong candidate for clinical translation. Beyond its diagnostic potential, this biosensor has proven valuable for studying cancer cell processes, from adhesion and migration to proliferation[4], further reinforcing its role as a powerful tool for both biomedical research and clinical applications.

Near-Infrared Photodetector Enhancement via Plasmonic Diffraction

Soh Uenoyama

Abstract: Near-infrared photodetectors have gained attention due to their attractive applications. However, the photo-absorption efficiency of Si-based photodetectors is relatively weak. In this talk, we demonstrate a plasmonic-diffraction approach that increases the effective photo-absorption length, resulting in a 2.0× enhancement in photocurrent at a specific wavelength and polarization.

Near-infrared (NIR) photodetectors have gained significant attention due to their attractive applications in Light Detection and Ranging (LiDAR), gas sensing, and facial recognition. However, compared to the visible range, the photo-absorption length at NIR wavelengths is considerably longer, resulting in poor photodetection efficiency.

A common approach to enhance photo-sensitivity is to increase the epitaxial layer thickness to absorb as many photons as possible. However, electrons excited near the bottom of the layer have difficulty reaching the photocurrent, resulted in the degrade of the photodetection efficiency.

Recently, nanophotonic approaches such as metalenses [1,2], nano-hole arrays [3], and black silicon [4] have gained significant attention for enhancing the photosensitivity of photodetectors. In this study, we focus on plasmonic diffraction phenomena [5,6]. In this approach, the period of the metal nano-grating is carefully designed to diffract incident light with a large diffraction angle toward the Si substrate at the target wavelength. Furthermore, optimizing the geometry of the metal nano-grating allows selective transmission at a specific wavelength and polarization, making it highly effective for active-sensing applications such as LiDAR. For this study, considering LiDAR applications, we selected 905 nm as the target wavelength.

Figure. 1 shows the photocurrent enhancement as a function of the incident wavelength (λ = 650 – 1000 nm). The red and black line plots correspond to TM-polarization and TE-polarization, respectively. Note that TM-polarization and TE-polarization refer to light polarized parallel and perpendicular to the period direction of the gold nano-grating, respectively. Photocurrent enhancement was defined as the ratio of photocurrent values with and without the gold nano-grating. As a result, gold nano-grating demonstrated a significant photocurrent enhancement (2.0×) under TM-polarization, particularly at a limited wavelength around the target wavelength (λ = 905 nm). In contrast, under TE-polarization, the photocurrent enhancement was suppressed.

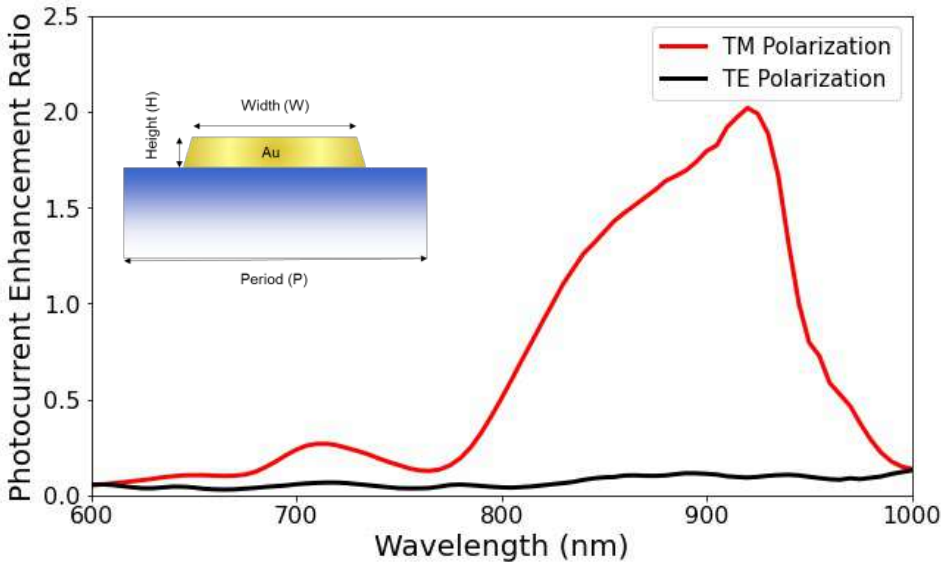

Figure.1. Photocurrent enhancement ratio as a function of the incident wavelength (**λ = 600 – 1000 nm**). The inset illustrates the geometry of the gold nano-grating, where the period (**P**), height (**H**), and width (**W**) are **520 nm, 200 nm, and 440 nm**, respectively.

Abstract: The dynamic tunability of the optical response in plasmonic systems through optical, mechanical, and electrical stimuli is pivotal for advancing reconfigurable nanophotonic applications. In this work, we present an innovative approach to achieve tunable plasmonic properties using ultrafast laser pulses by integrating phase-change materials (PCMs) with plasmonic nanostructures.

Plasmonic systems traditionally rely on fixed geometries and material properties, limiting post-fabrication tunability.[1] In this talk, we present active heterostructures where metallic nanoparticles (Au and Ga) are coupled to low-loss phase-change materials (PCMs), enabling dynamic control over the localized surface plasmon resonance (LSPR). By leveraging the reversible phase transitions of the PCM layer, we demonstrate spectral tuning of the optical response through low-energy thermal and laser-induced switching between amorphous and crystalline states.[2,3]

In the second part, we extend this concept to a metamaterial composed of VO_2 nanocrystals,[4] where we demonstrate ultrafast switching of plasmonic modes. Using pump-probe spectroscopic techniques, we reveal how light-driven phase transitions in VO_2 can modulate plasmonic excitations on picosecond timescales. These results highlight the potential of phase-change materials in reconfigurable nanophotonics and active plasmonic devices.

Abstract: A plasmonic biosensor based on a nanopatterned metasurface is presented for the recognition and differentiation of Shiga toxins (Stx1a, Stx2a, Stx2a-cl). Using Surface-Enhanced Raman Spectroscopy (SERS) and principal component analysis (PCA), the system enables highly sensitive, label-free identification, offering a promising tool for improved diagnostics of STEC infections.

Shiga toxin-producing Escherichia coli (STEC) are zoonotic pathogens causing severe diseases, including hemolytic uremic syndrome (HUS), the leading cause of acute renal failure in children, which can be fatal in some cases [1]. The primary virulence factors of STEC that contribute to HUS onset are two main types of cytotoxins: Shiga toxins 1 (Stx1) and 2 (Stx2). Currently, no effective therapies exist for STEC infection, and available diagnostic methods are often complex and sometimes inconclusive. Plasmonic biosensors are powerful platforms for detecting various types of analytes. Surface-Enhanced Raman spectroscopy (SERS) enables label-free, highly sensitive, and selective detection [2]. In this study, we designed, characterized, and tested SERS substrates based on a novel nanopattern fabricated using a top-down approach for the recognition and differentiation of Stx1, Stx2, and a cleaved version of the latter (Stx2a-cl). The sensors consist of an engineered planar plasmonic metasurface that we previously developed, studied and characterized [3, 4]. It features a hexagonal array of asymmetric nanocavities (NCs) fabricated on a gold thin film via electron beam lithography. The NCs are formed by the fusion of three equilateral triangles: two aligned on one side and the third centered on the opposite side, with an overall size of approximately 450 × 430 μm^2. A scanning electron microscopy (SEM) image of the metasurface is shown in Figure 1a. The plasmonic metasurface was tested to define the SERS fingerprint spectra of the three Stx variants under investigation. Equal concentrations of the three toxins (45 nM in water) were deposited onto three identical nanopatterned metasurfaces by direct adsorption. Measurements were performed on each nanopattern, yielding repeatable spectra with well-resolved peaks. Figure 1b shows the average, normalized SERS spectra obtained for Stx1a (blue line), Stx2a (red line) and its cleaved form Stx2a-cl (green line). The three spectra exhibit a complex distribution of vibrational modes corresponding to the molecular structures of the toxins. Overall, the three fingerprints appear highly similar, with only subtle differences. To further analyze these spectral variations, principal component analysis (PCA) was employed to extract key spectral features.

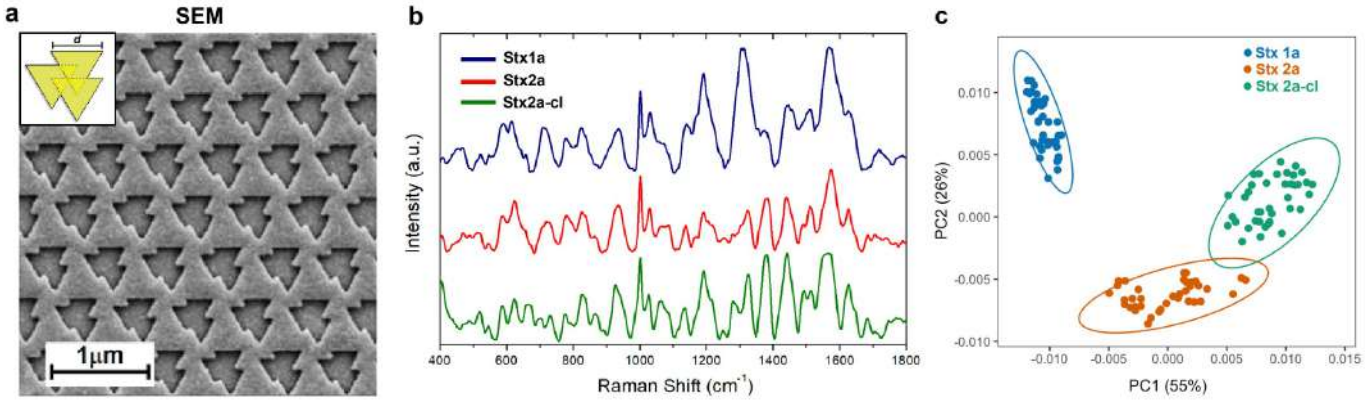

Figure 1. SERS analysis of the three Stx taken into consideration: (a) SEM image of the plasmonic metasurface employed, (b) average SERS fingerprint of the Stx1a (blue line), Stx2a (red line) and Stx2a-cl (green line), and (c) PCA analysis associated with the SERS measurements of the Stx1a (blue points), Stx2a (red points) and Stx2a-cl (green points).

Figure 2b shows the data projected in a two-dimensional space defined by the first two principal components (PC1 and PC2), with Stx1a (blue points), Stx2a (red points), and Stx2a-cl (green points) corresponding to the SERS measurements. As shown in the plot, the three toxins are clearly distinguishable, forming well-separated clusters. Notably, the relative distances between the clusters reflect the actual chemical differences among the toxins: the distinction between Stx1a and Stx2a is pronounced, while Stx2a and Stx2a-cl show only subtle differences, with partial overlap. This successful separation can be attributed to the variance explained by PC1 (55%) and PC2 (26%), which together account for over 80% of the total variance, a threshold commonly used for adequate differentiation of analytes. These findings demonstrate that SERS, combined with PCA, is a valuable tool for distinguishing different Stx variants in water, enabling specific analyte recognition without the need for antibody probes.

Boosting the magnetic response of a composite nanostructure in the near-visible region with a Fano resonance

Maximilian Grimmer[1*] and Monika Fleischer[1]

[1] Institute for Applied Physics and Center LISA[+], Eberhard Karls University of Tübingen, Auf der Morgenstelle 10, 72076 Tübingen, Germany

[*]maximilian-karl.grimmer@student.uni-tuebingen.de

Abstract: We investigate the optical properties of a plasmonic nanostructure, focusing on its magnetic response. Using the geometry of a composite split-ring resonator, it is possible to create a magnetic response at wavelengths close to the visible regime, which can be increased by modifying the geometry and enabling a Fano resonance.

Metallic nanostructures have optical properties that greatly differ from those of their respective bulk materials. At the nanoscale, the electric field component of light can affect the entire volume of the structure, as well as its conducting electrons. These electrons move in response to the electric field, leading to a charge separation within the nanostructure that oscillates with the frequency of the incident light. Plasmonics is the corresponding research field that investigates these oscillations. Nanoparticles made from (noble) metals can have a plasmonic resonance in the visible and the near-infrared range, causing a high scattering cross-section and strong electric near-field enhancement at the surface of the nanoparticle [1].

Plasmonics offer an easy way to create a structure with a strong electric response to light at optical frequencies. It is, however, more difficult to create a structure that shows a *magnetic* response to light at optical frequencies as well. The magnetic response of all natural materials decreases towards higher frequencies, dropping off in the GHz range for most materials. Landau and Lifschitz have shown that the magnetization and the magnetic permeability become irrelevant towards higher frequencies, with the relative magnetic permeability μ_r of all natural materials being 1 at optical frequencies [2]. It is nevertheless possible to engineer a material with a magnetic response at higher frequencies by utilizing not the magnetic but the electric response of the material. By designing the nanostructure so that the plasmonic current flows in a circular loop, a magnetic dipole is induced. The split-ring resonator (SRR) is a commonly used geometry to achieve such a magnetic response. It consists of a single nanoring with a gap. This structure with its resonance can be modeled as a coil with the inductance L (the nanoring) and a capacitor with the capacitance C (the nanogap), with a resonance frequency

$$\omega_0 = 1/\sqrt{L * C} \quad (1)$$

SRRs and their magnetic resonance have already been investigated for many applications, such as metamaterials, cloaking, sensing, and super-chiral near fields. However, saturation effects limit the maximum resonance frequency to the near-infrared range [3].

The purpose of our work is to shift the magnetic resonance towards higher frequencies and to increase the magnetic response to enable applications at such higher frequencies. For this aim, we propose a variation of the SRR geometry with two additional gaps. These gaps serve as additional capacitors connected in series, lowering the total capacitance and blue-shifting the magnetic resonance towards the visible range by more than 350 nm. We also demonstrate a novel way to boost the magnetic response of the structure by adding a nanorod below the central element of the SRR. The ensuing mode coupling leads to an interference phenomenon known as Fano resonance [4], resulting in a spectral dip that leads to an additional scattering peak. The new magnetic resonance shows a higher magnetic near-field enhancement than the resonance of the SRR; its excitation is calculated to boost the overall magnetic response of this structure by 70%. Such an increase in the magnetic response may improve the

performance of many applications of the SRRs at higher frequencies.
Both structures are investigated using numerical simulations as well as experimental fabrication and optical measurements. The two proposed nanostructures have both a geometry consisting of multiple elements that are separated by a gap of 10 nm and lower. Fabrication of these composite nanostructures is challenging and was done with a two-step process, where the basic structure is created using electron beam lithography, while the small gaps were milled into the structure using focused Helium-ion beam milling [5]. This approach is well-suited to create challenging nanostructures with small gap sizes, which can hardly be achieved with conventional electron beam lithography.

Electric field induced second order nonlinearity in amorphous As_2S_3, SiO_x and SiN_x

Abstract: Applying an electric field to As_2S_3, and silicon rich SiO_x and SiN_x leads to the formation of a field dependent quasi-$\chi^{(2)}$ and field induced second harmonic generation in transmission. Both PECVD-grown SiO_x and SiN_x also exhibit a field free $\chi^{(2)}$ leading to enhanced SHG by a waveguide surface grating.

When a strong static electric field E_{DC} is applied to a material and an intense Light wave ($E(\omega)$) is incident at the same time, the third order dipolar contribution is calculated via: $P^{(3)} \sim \chi^{(3)} \cdot \left(E_{DC} + E(\omega)\right)^3$. Multiplying out the cubic bracket gives then rise to the different third order nonlinear phenomena like third harmonic generation or intensity dependent refractive index. One term, which is usually overlooked is the generation of a frequency doubled polarization – the so called electric field induced second harmonic generation (EFISH) [1]:

$$P_{EFISH}^{2\omega} = \underbrace{\chi^{(3)}\, E_{dc}(0)}_{\text{quasi-}\chi^{(2)}} E(\omega)\, E(\omega) \qquad (1)$$

In this the product $\chi^{(3)} \cdot E_{DC}$ can be considered as a quasi-$\chi^{(2)}$. This means, that by applying a strong electric field on any material symmetry breaking occurs and an electric field induced quasi-$\chi^{(2)}$ can be generated, allowing the usual second order nonlinear processes like sum- or difference frequency generation. To observe this process and determine the achievable quasi-$\chi^{(2)}$ values we performed EFISH-measurements in transmission, first, using thin films of the chalcogenide glass As_2S_3 sandwiched between two semitransparent Cr-electrodes, which could be used to apply voltages up to 1000V across the As_2S_3-film (Fig. 1a) [2]. The observed parabolic relationship between

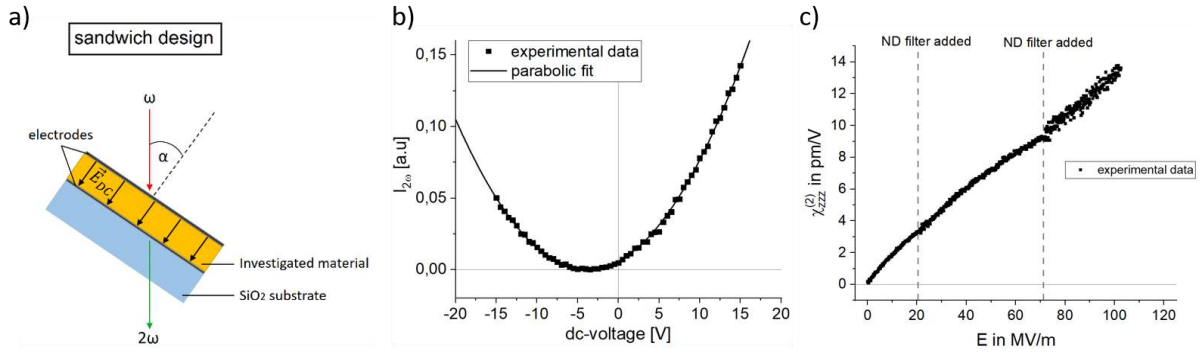

Fig. 1: EFISH-measurement in transmission a) Experimental setup applying TM (p-)-polarised light b) observed parabolic dependence between SHG-intensity and applied DC-voltage, c) Deduced field dependent quasi-$\chi^{(2)}$

the detected SHG and the applied DC-voltage confirms the assumed EFISH effect (Fig. 1b), since the detected

SHG-intensity depends on the squared second order polarization from (1). Applying DC-fields up to the break-down field of 100 MV/m resulted in quasi-$\chi^{(2)}$ values of about 13pm/V exceeding the $\chi^{(2)}$-values of classic nonlinear crystals like KDP or BBO. Furthermore, this field induced quasi- $\chi^{(2)}$ is not bound to a specific crystallographic direction but follows from the tensor product $\chi^{(3)} \cdot E_{DC}$. In amorphous films with isotropic $\chi^{(3)}$ we determined the $\chi^{(2)}_{zzz}$ component to be the strongest $\chi^{(2)}$ component generated by the z-oriented DC-field.

Besides As_2S_3-films we also investigated amorphous silicon rich SiO_x and SiN_x-films and measured their EFISH signals. For part of the films the measurement geometry was changed and lateral contacts were applied (Fig. 2a). This induced a strong in-plane quasi-$\chi^{(2)}_{xxx}$ component, so that also for TE (s-) polarized light EFISH could be measured (Fig. 2b). The measured $\chi^{(2)}$-values profited from the large $\chi^{(3)}$ which occurs in silicon rich SiNx. Surprisingly this was also the case for silicon rich Oxide (SiO_x), whose $\chi^{(3)}$ reached values of $10^{-18} m^2/V^2$ and was therefore comparable to the known high third order susceptibilities in ultra-Si-rich SiNx [2].

Finally, we could also observe a sizeable built-in (field-free) bulk -$\chi^{(2)}$ normal to the surface for the PECVD-grown SiN_x and SiO_x-films. In an attempt to further boost the impact of this field-free bulk -$\chi^{(2)}$ we etched a grating on top of a SiNx-waveguide and measured the SHG in transmission at near normal incidence. The period of the grating was adjusted in such a way that summetry and polarization protected bound states in continuum (BIC) appear at normal incidence giving still rise to increased Q-factors at small lateral k-vectors (small incidence angles.) Overall this geometry resulted in a 4 order of magnitude increase of the SHG-signal compared to unstructured films.

These results demonstrate, that the field induced quasi-$\chi^{(2)}$ can be introduced in photonic circuits based on dielectric/insulating materials. The possibility to switch the quasi-$\chi^{(2)}$ on or off- or modulating its strength just by changing the applied static electric field, allows for a large degree of flexibility and design freedom.

Abstract: This study focuses on developing mid-infrared superconducting nanowire single-photon detector (SNSPD) arrays. Using optimised NbN films, the research analyses electrical, optical, and temporal performance, alongside pixel performance uniformity. The study explores potential applications in the single-photon regime, including imaging, laser ranging, medical imaging, and astronomy.

Counting individual photons in the mid-infrared range is crucial for applications in quantum optics, quantum-enhanced imaging, depth sensing, and astronomy. Superconducting nanowire single-photon detectors (SNSPDs) are efficient, low-noise devices ideal for detecting low photon levels [1]. These detectors offer near-perfect quantum efficiency at telecom wavelengths, can detect photons up to 29 µm in the mid-IR range [2], and have a timing jitter as low as 3 ps. Advances in superconducting materials and manufacturing processes have enabled scaling from single pixels to multiplexed SNSPD arrays.

This study focuses on developing 36-pixel mid-infrared SNSPD arrays. The core element of the SNSPDs is the ultrathin superconducting film patterned into the nano-strip 30 to 200 nm wide. Figure 1(a) shows the optical image of the array, while Figure 1(b) presents a Scanning Electron Microscope (SEM) image of a single pixel. The SNSPD is cooled to cryogenic temperatures (typically below 2K) and biased just below its critical current value. When a photon is absorbed in the nanowire, it creates a resistive domain in the film, generating a voltage pulse in the read-out circuit. After a brief recovery period, the superconductivity is restored, allowing the detector to register another photon. Magnetron sputtering, commonly used for deposition of thin superconducting films of NbN, has limitations in uniformity, hindering large-area device development. However, multi-pixel SNSPDs require films with spatially uniform parameters such as thickness, superconducting transition temperature, and critical current density. A newer technique, Atomic Layer Deposition (ALD), enables the production of high-quality thin films of NbN, TiN, and NbTiN [3]. The ALD method offers greater uniformity in pixel performance compared to sputtering, making it ideal for SNSPD arrays. The devices in this study are based on optimised ultrathin NbN films grown using both sputtering

a)

b)

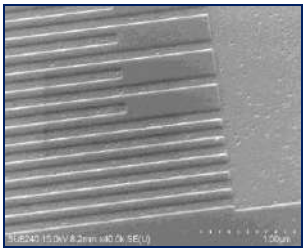

Figure 1: (a) Photograph of the 36-pixel SNSPD chip. (b) SEM image of the SNSPD pixel.

and ALD techniques.

This study presents a thorough analysis of the electrical, optical, and temporal performance of individual pixels, along with an assessment of pixel uniformity across arrays with varying pixel spacing. Figure 2 shows the uniformity of superconducting critical current values across the SNSPD array based on 8 nm thick sputtered NbN film. To characterise the devices, a setup using tunable optical parametric oscillator (OPO) sources was employed, delivering picosecond pulses in the 1.5 – 10 μm spectral range. Additionally, proof-of-concept tests for ranging and imaging are included to showcase the potential applications of SNSPD arrays. The present study is aimed towards the prospective applications such as detecting of faint mid-infrared sources, long-range communication, laser ranging, medical imaging and astronomy.

E-mail: HO.Ya-Lun@nims.go.jp

Abstract: The freestanding dielectric membrane metasurface, with a thickness of 36 nm, has been demonstrated to achieve a bound state in the continuum (BIC) mode, exhibiting spontaneous emission with a high Q-factor over 2037 in the visible regime.

Embedded within the radiation continuum, photonic bound states in continuum (BICs) represent exceptional nonradiative states where modes become fully trapped through destructive interference or symmetry protection mechanisms. This trapping phenomenon enhances light-matter interactions and can generate impressive Q factors[1]. Freestanding membrane structures offer ideal platforms for BIC implementation, confining light without substrate field leakage. These characteristics significantly amplify spontaneous emission rates and optical absorption, creating structures perfectly suited for applications demanding robust optical confinement and elevated Q-factors[2,3]. The thickness of a freestanding membrane plays a critical role in optimizing light-matter interactions, particularly when interfacing with atomically thin materials where even nanoscale dimensional changes can dramatically alter coupling efficiency and field confinement. The reduced thickness of the membranes decreases mode volume and positions the resonant mode field in closer proximity to atomically thin materials like monolayer transition metal dichalcogenides. This proximity substantially improves coupling efficiency between the photonic structure and these ultra-thin materials[3], a critical factor for maximizing light-matter interaction and enhancing spontaneous emission efficiency.

Figure 1(a) and (b) present simulated reflection spectra for two configurations: a SiN metasurface on a SiO_2 substrate and a free-standing SiN membrane metasurface, respectively. These metasurfaces featured triangular lattices of air holes (period P = 600 nm, hole diameter D = 300 nm). In both configurations, all modes exhibited a blueshift with decreasing thickness, attributable to reduced effective optical path. Figure 1(a) displays simulation results across varying thicknesses, as the thickness approaches 100 nm, coupling between the modes and substrate radiation channels becomes dominant, resulting in weakened field confinement that barely sustains the modes. Electric field distribution simulations were analyzed for distinguishing between BICs and GMs. Figure 1(b) presents reflectance spectra identifying specific BICs and GMs in the SiN membrane metasurface. Due to vertical symmetry and minimal leakage, all TE modes remained observable even as thickness approached zero, while only two TM modes disappeared below approximately 75 nm thickness due to their vertical resonance characteristics.

Spontaneous emission spectra for 163 nm and 36 nm thick SiN membrane metasurfaces (Figure 1(c)) demonstrate significantly enhanced emission peaks. As thickness decreased, a blueshift in peaks occurred, aligning with simulation data from Figure 1(b). The 36 nm device exhibited two sharp peaks corresponding to BIC modes at 561 nm and 572 nm with enhanced intensity and narrower linewidths. Notably, the BIC_4 peak at 598.44 nm achieved an exceptional Q-factor of 2037 in the visible spectrum.

In this work, we have successfully demonstrated the realization of BIC modes in ultra-thin free-standing SiN hole-array membrane with thicknesses down to 36 nm. Through systematic investigation of thickness-dependent optical properties, we observed that both TE- and TM-BIC modes persist in these ultra-thin photonic structures, maintaining high Q-factors as thickness decreases. Notably, we achieved an exceptional Q-factor of 9632 for a TE-BIC mode at a thickness of 163 nm, with substantial Q-factors of 2037 preserved even at thicknesses down to 36 nm. Our comparative study between free-standing membranes and substrate-supported structures revealed the critical role of substrate-induced field leakage in mode sustainability. The spectral positions of these modes exhibited predictable blue-shifts with decreasing thickness, allowing for precise wavelength tuning. This tunability, combined with the enhancement of spontaneous emission (up to 130-fold compared to plain SiN thin-film on Si), demonstrates the potential of these structures for various photonic applications. The achievement of high-Q BIC modes in ultra-thin hole-array membrane is particularly significant for sensing applications and applications involving atomically thin 2D materials.

Steering plasmonic optical losses using alkali metals

Jie Liang, Yuhan Yang, Lin Zhou*

College of Engineering and Applied Sciences, Nanjing University, China
*corresponding author: linzhou@nju.edu.cn

Abstract: Plasmonic losses has been regarded as one of the most crucial issues for nanophotonics and integrated optics. In this talk, the authors will present the recent advancements on a variety of material and/or meta-structure strategies on steering the optical losses based on alkali metals, from the fundamental optical properties to the potential applications.

Alkali metals, with their simple electronic structure, low free carrier density, and weak interband optical transition, are promising plasmonic materials expected to exhibit lower optical damping rates than conventional noble metals. Additionally, their potential as negative electrode materials in high-capacity, high-energy-density batteries offers a natural platform for low-powered dynamic plasmonics control.

I will first present the fundamental physical mechanisms behind the optical low-loss nature in alkali metals, along with new fabrication techniques aimed at further reducing these losses and advanced experimental methods for measuring the optical loss in alkali metals. Based on these foundational studies, I will then introduce the diverse applications enabled by low-loss alkali metal plasmonics, including plasmonic nanolasers, waveguides, optical filters, strong coupling applications such as optical sensing, and low-powered dynamic plasmonics leveraging battery energy storage properties.

A notable study based on high-performance sodium-based metasurfaces for optical filtration in the visible range is shown in Figure 1. By using a unique design with spatially decoupled concave surfaces and precise fabrication, the sodium based metasurfaces achieve narrow linewidths (~15 nm), high optical contrast (~93%), and a strong spectral match ratio. This work marks the first extension of sodium-based plasmonic devices from infrared to visible wavelengths, filling a gap in commercial optical filters.

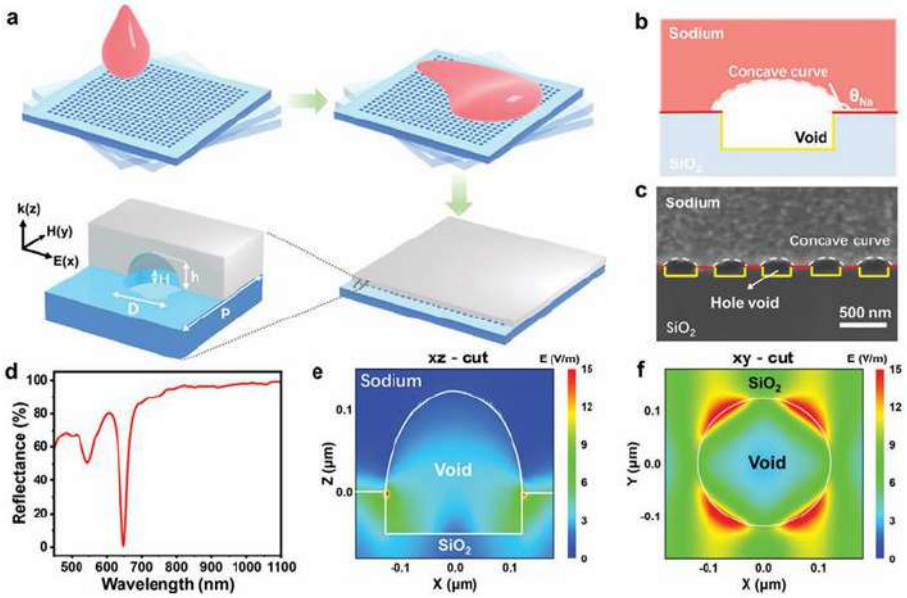

Figure 1. The low-loss sodium anti-dome metasurface. (a) Schematic of the templated spin-on-sodiophobic-glass fabrication process. (b) Schematic diagram of a single anti-dome curve patterned structure. (c) The cross-sectional SEM image of a representative sodium-based concave metasurface. (d-f) Representative simulated reflectance spectrum and electric field of an arbitrary sodium-based concave metasurface.

Another most representative example, the electric-driven dynamic plasmonics for low-powered display, is shown in Figure 2. It is well known that, display and power supply have been two essential and independent cornerstones of modern electronics. A low power or even self-powered display devices are highly desired but rather challenging thus far. Our recent work reported a lithium plasmon based low-powered dynamic color display with inherited dual functionalities, the plasmonic display and energy recycling unit (see Figure 2a), through electric-driven transformation of nanostructured lithium metals. In such an intriguing operation configuration, each display pixel can work as a micro-battery cell and most excitingly, each micro-pixel (micro-battery) can be powered by its adjacent counterpart, making the manipulation of dual functionalities (information and energy) more flexible (Figure 2b).

We acknowledge the financial supports from the National Key Research and Development Program of China (Nos. 2022YFA1404300, 2021YFA1400700).

Manipulation of light propagation in photonic crystals via non-Hermitian photonic band engineering

T. Inoue, M. Yoshida, and S. Noda

Kyoto University, Japan
*corresponding author: t_inoue@qoe.kuee.kyoto-u.ac.jp

Abstract: Non-Hermitian photonic systems are known to exhibit unique light propagation phenomena, where non-Hermiticity is typically introduced by material loss or gain. Here, we propose and experimentally demonstrate manipulation of light propagation solely based on radiation loss via non-Hermitian photonic band engineering of photonic crystals.

Non-Hermitian photonic systems are known to exhibit various unique optical phenomena near the exceptional point (EP) such as unidirectional reflectionless light propagation and enhanced sensing. Photonic crystal slabs are ideal platforms to embody such unique phenomena because they inherently involve non-Hermiticity caused by radiation loss even when material loss nor gain is introduced. Here, we demonstrate flexible manipulation of light propagation solely based on radiation loss via non-Hermitian photonic band engineering of photonic crystals. We first show that various types of non-Hermitian photonic band structures such as a conical dispersion with a single EP and multiple exceptional rings can be realized by controlling both Hermitian and non-Hermitian couplings inside the photonic crystal [1,2]. Then we experimentally demonstrate several unique light propagations using such non-Hermitian band engineering, including unidirectional radiation/reflection phenomena and arbitrary manipulation of vertical radiation profiles.

Figures 1(a) and 1(b) shows the schematic diagram of Hermitian and non-Hermitian wave couplings inside double-lattice photonic crystals [1,3]. Figure 1(a) denotes the Hermitian couplings without accompanying energy loss, which includes ±180° diffractions (κ_{1D}) and ±90° diffractions ($\kappa_{2D\pm}$), while Fig. 1(b) shows the non-Hermitian couplings via radiative waves, which accompany energy loss. Using these coupling coefficients, complex eigenfrequencies ($\delta + i\alpha$) at an in-plane wavevector (k_x, k_y) near the second-order Γ-point can be derived by solving the following coupled-wave equation [1]:

$$\left(\delta + \mathrm{i}\frac{\alpha}{2}\right)\begin{pmatrix} R_x \\ S_x \\ R_y \\ S_y \end{pmatrix} = \begin{pmatrix} \kappa_{11} + \mathrm{i}\mu + k_x & \kappa_{1\mathrm{D}} + \mathrm{i}\mu e^{\mathrm{i}\theta_{\mathrm{pc}}} & \kappa_{2\mathrm{D}+} & \kappa_{2\mathrm{D}-} \\ \kappa_{1\mathrm{D}}^* + \mathrm{i}\mu e^{-\mathrm{i}\theta_{\mathrm{pc}}} & \kappa_{11} + \mathrm{i}\mu - k_x & \kappa_{2\mathrm{D}-}^* & \kappa_{2\mathrm{D}+} \\ \kappa_{2\mathrm{D}+} & \kappa_{2\mathrm{D}-} & \kappa_{11} + \mathrm{i}\mu + k_y & \kappa_{1\mathrm{D}} + \mathrm{i}\mu e^{\mathrm{i}\theta_{\mathrm{pc}}} \\ \kappa_{2\mathrm{D}-}^* & \kappa_{2\mathrm{D}+} & \kappa_{1\mathrm{D}}^* + \mathrm{i}\mu e^{-\mathrm{i}\theta_{\mathrm{pc}}} & \kappa_{11} + \mathrm{i}\mu - k_y \end{pmatrix}\begin{pmatrix} R_x \\ S_x \\ R_y \\ S_y \end{pmatrix} \quad (1)$$

Figures 1(c)-1(f) show several examples of the calculated non-Hermitian photonic band structures, where two out of four bands (band A, C) are plotted for simplicity. Type I dispersion [Fig. 1(c)] has a small photonic band gap between the two bands while radiation loss of the lower band rapidly increases away from the Γ point, which is suitable for the realization of ultra-large-area photonic-crystal surface-emitting lasers [1,4]. When the 180° and 90° couplings are effectively cancelled out (more rigorously, $\mathrm{Re}[(\kappa_{1\mathrm{D}} + \kappa_{2\mathrm{D}-})e^{-\mathrm{i}\theta_{\mathrm{pc}}}]=0$), Type II dispersion [Fig. 1(d)] or Type III dispersion [Fig. 1(e)] appears, where the former has a degenerate flat band surrounded by EPs, while the latter has a conical dispersion with a single EP [2]. In a more specific case where there is a large anisotropy in ±90° couplings, Type IV dispersion with multiple exceptional rings can be also realized.

Using these non-Hermitian photonic band structures, we can realize various counterintuitive light propagation phenomena in photonic crystals. Figures 2(a) and 2(b) show two such examples in one-dimensional photonic-

crystal waveguides, where ±90° diffractions do not occur ($\kappa_{2D\pm}$=0). In Fig. 2(a), we employ photonic crystals with Type III dispersion, and demonstrate a unidirectional waveguide which shows perfect radiation when light is incident from the left side, and shows perfect reflection when light is incident from the other side [2]. In Fig. 2(b), we employ photonic crystals with Type II dispersion, and demonstrate vertically radiative waveguides that have arbitrary radiation profiles (e.g. uniform or step-like profiles) with suppressed backward reflection. The details of these experiments and other possible applications will be reported at the conference.

Abstract: Optical chirality (OC) is traditionally linked to spin angular momentum of light. Recent studies suggest that chiral dichroism (ChD) in chiral materials may also be governed by an alternative form of chirality associated with orbital angular momentum of light (orbital OC). We investigate ChD in a single twisted gold nanorod dimer using circularly polarized optical vortex beams, revealing wavelength-dependent ChD behavior at the beam center, indicative of orbital OC.

The chirality of a material can only be identified through asymmetric interactions with other chiral objects or chiral fields [1]. Circularly polarized (CP) lights, carrying spin angular momentum (SAM: $s = \pm 1$), are well-known chiral optical fields, and their interaction with chiral materials have been extensively studied. Chiral materials exhibit circular dichroism (CD), where their absorption differs between left- and right-handed CP light. This effect primarily arises from lower-order excitation modes, such as electric and magnetic dipole modes. In 2010, it was revealed that the magnitude of CD arising from lower-order excitation modes of isotropic chiral materials depends on a physical parameter known as optical chirality (OC), or spin OC, which characterizes the chirality of the excitation light based on its optical SAM [2]. This discovery opened up new research directions, enabling the control of chiral light-matter interactions through the design of tailored optical fields.

Recently, optical vortices (OVs), carrying orbital angular momentum (OAM: $l = 0, \pm 1, \pm 2, \ldots$), have gained attention as another form of chiral optical field. The chirality of materials has also been detected using OVs through vortex dichroism (VD), where they exhibit different optical responses to left- and right-handed linearly polarized OVs [3]. Since OVs can excite higher-order modes such as electric quadrupole modes [4], VD signals are suggested to reflect the geometric characteristics of chiral materials more strongly than CD. If the analogy between spin OC and CD extends to VD resulting from higher-order chiral excitations, this suggests the existence of a new physical parameter, orbital OC, which characterizes chirality based on optical OAM. However, in most previous studies, chiral materials larger than the wavelength of excitation light were used, leading to the simultaneous excitation of multiple modes. This spectral overlap has made it challenging to determine which specific modes contribute to the VD signal, preventing the establishment of a definitive link between VD and orbital OC.

To address this issue, we employ a subwavelength-scale twisted gold nanorod dimer (TND) (Figure 1, left) as a nanoscale chiral probe, which enables clear spectral separation of electric dipole and quadrupole modes. This minimizes mode overlap and allows for a more precise analysis of the relationship between excitation modes and optical SAM and OAM of the excitation light in its chiral optical response. To systematically investigate the contributions of optical SAM and OAM in chiral optical responses of the TND, we utilize CP OVs as excitation light. CP OVs inherently carry both optical SAM and OAM, making them well-suited for distinguishing the respective roles of these angular momentum components in chiral light-matter interactions. However, the dichroic

response of chiral materials to CP OVs does not fit conventional CD or VD classifications. To address this, we introduce chiral dichroism (ChD) as a generalized framework that encompasses both CD and VD. Here, $g_{\mathrm{ChD}}(s, l) \equiv 2(I_{+s,+l} - I_{-s,-l})/(I_{+s,+l} + I_{-s,-l})$ defines the ChD signal, where $I_{\pm s,\pm l}$ denotes the transmission intensities for CP OVs with $(\pm s, \pm l)$.

We developed a ChD microscopic spectroscopy system to measure ChD in the TND. Since OVs exhibit a doughnut-shaped intensity profile, the relative position between the beam and the sample is critical for analyzing ChD signals, necessitating microscopic imaging. Additionally, spectral acquisition is required to understand the relationship between ChD and excitation modes. Our system integrates a high-speed CP OV modulation optical setup [5] within an optical microscope, enabling rapid switching of CP OV handedness at ~50 kHz while also allowing wavelength tuning of the excitation light. This setup facilitates precise spatially resolved ChD imaging while simultaneously acquiring spectral data, enabling a comprehensive analysis of structured light interactions with chiral materials.

To systematically examine ChD under different excitation conditions, we conduct two sets of experiments. The first employs a CP Gaussian beam ($s = \pm 1$, $l = 0$) as a baseline measurement to establish a reference ChD (CD) response. Under this condition, a wavelength-independent positive ChD signal is observed, reflecting the spatial structure of the Gaussian beam (Figure 1, top right). In contrast, when using a CP OV beam ($s = \pm 1$, $l = \pm 1$), the ChD signal exhibits two distinct characteristics (Figure 1, bottom right). First, a wavelength-independent positive ChD signal is observed, mirroring the doughnut-shaped intensity profile of the OV beam. Second, at the beam center, where spin OC is expected to be zero, the ChD signal displays a wavelength-dependent sign reversal. Specifically, at 800 nm, the ChD signal is positive; at 825 nm, it vanishes; and at 850 nm, it becomes negative. The observed wavelength-dependent sign reversal at the beam center suggests that ChD in OVs cannot be fully explained by spin OC alone, indicating the necessity of an alternative physical parameter, orbital OC. This finding highlights the importance of OAM in chiral light-matter interactions and demonstrates the potential of structured light as a tool for enhancing and tailoring chiral optical responses in nanophotonic systems.

Susceptibility invariance and disorder-induced statistical properties in time-varying media

Bo Zhou[1], Enzong Wu[1] and Zuojia Wang[1*]

[1] Zhejiang University, China
[*]corresponding author: zuojiawang@zju.edu.cn

Abstract: We present theoretical and analytical frameworks for perpendicular-moving metasurfaces, where susceptibility invariance and duality-matching conditions are derived via generalized sheet transition conditions and Lorentz transformations. We also discuss the emergent wave dynamics in disordered time-varying cavities, where temporal reflections lead to non-normal electromagnetic field distributions, contrasting classical spatial localization.

Space-time systems (space-time media, usually focus on space-time metamaterials), whose physical parameters change over time, are becoming extremely attractive, as they may allow complete control of electromagnetic waves in time and space. They are categorized into two main types: modulated systems (by time-varying media) and moving systems (by space-varying media). Here, we present some progression in understanding wave-matter interactions within time-varying systems, combining insights from two interconnected studies on relativistic electrodynamics and statistical electrodynamics in time-varying systems.

First, we present theoretical and analytical frameworks for perpendicular-moving metasurfaces, where susceptibility invariance and duality-matching conditions are derived via generalized sheet transition conditions and Lorentz transformations [1]. Under these frameworks, we derive the boundary conditions of moving metasurface and reveal the relativistic constraints for the intriguing invariant phenomenon of susceptibility parameters (specific susceptibility parameters remain invariant during motion). We further verify the effectiveness of invariance phenomenon in bianisotropic media. These findings could provide foundational guidance for the analysis and design of space-time metasurface.

Second, we develop a model to analyze the statistical properties of the transient electric field strengths in one-dimensional locally disordered time-varying cavities [2]. We demonstrate that temporal disorders within the cavity can lead to an approximate normal distribution of the field strengths at any spatial point. But over extended temporal scales, this approximate normal distribution will disappear. By incorporating the framework of disordered space-time crystals and invoking Lyapunov's theorem, we identify that the time-varying nature of the cavity triggers an exponential surge in energy over extended periods, thereby resulting in a deviation from the normal distribution. Then we employ the generalized central limit theorem to prove that the field strength will ultimately evolve into a non-normal Lévy skew alpha-stable distribution. These statistical characteristics offer insights into the spatiotemporal dynamics of wave phenomena and hold potential implications for predicting extreme events occurring within enclosed spaces.

By unifying these perspectives, the report underscores the unique opportunities and challenges of time-

varying systems, including unavoidable reflections in parameter-discontinuous media and the role of temporal symmetry breaking in hyperbolic propagation. These findings provide foundational guidance for developing advanced nanophotonic devices, such as dynamically reconfigurable metasurfaces and temporal disorder-engineered sensors.

Abstract: We present a novel approach to a tunable array of fiber-integrated single-photon sources. By developing a versatile fiber platform that integrates multiple cavity-coupled quantum dot devices using a pick-and-place technique, we achieve high-efficiency, scalable, and tunable quantum light sources for telecom-based quantum networks and protocols.

Single-photon sources serve as a fundamental building block for a wide range of quantum technologies that rely on photonic qubits, including photonic quantum simulators, secure quantum communication, and large-scale quantum networks. Beyond single-photon sources, the ability to generate highly indistinguishable single photons arrays is crucial for advancing quantum protocols and increasing the capacity of quantum channels. While significant progress has been made in developing solid-state quantum emitters with high performance, integrating these sources into scalable and practical optical platforms remains a key challenge in realizing real-world quantum applications.

In this work, we present a novel approach to developing a tunable array of fiber-integrated single-photon sources, offering a scalable and reliable solution for multi-channel quantum light generation. Our system is based on a hole-based circular Bragg grating cavity, which enables efficient vertical beaming of single photons that match the mode profile of a single-mode optical fiber [1]. This ensures optimal photon collection efficiency and enhances the practicality of fiber-based quantum photonic systems. To achieve high scalability and precision, we employ a pick-and-place technique to selectively integrate multiple quantum dot (QD) devices onto a V-groove fiber platform. This method allows for the precise alignment and positioning of quantum emitters, overcoming fabrication constraints associated with conventional approaches. Furthermore, our uniquely designed etched fiber ensures that the membrane cavity remains air-suspended, preserving its optical characteristics before and after integrationTherefore, this post-characterization and selective integration allows us the high-yield of multi-channel devices.

For cryogenic operation of multi-channel fiber-integrated systems, we developed metal patterning on the fiber platform, which serves a dual purpose. First, it facilitates efficient cooling of the integrated quantum dot devices to cryogenic temperatures, ensuring stable and high-purity single-photon emission. Second, it enables the application of electric fields to the quantum dots, allowing for tunable emission wavelengths and controlled operation of the photon sources [2]. These integrated functionalities significantly enhance the versatility of our platform, making it a promising candidate for on-demand, reconfigurable quantum light sources.

Our fiber-integrated quantum platform exhibits key advantages, including high single-photon coupling efficiency, scalability, and tunability. By leveraging these features, we demonstrate the potential for realizing compact, high-yield

single-photon arrays directly on fiber-based chips, specifically at telecom wavelengths. This advancement paves the way for the practical deployment of quantum photonic systems in fiber networks, facilitating their integration into future quantum communication and computing architectures.

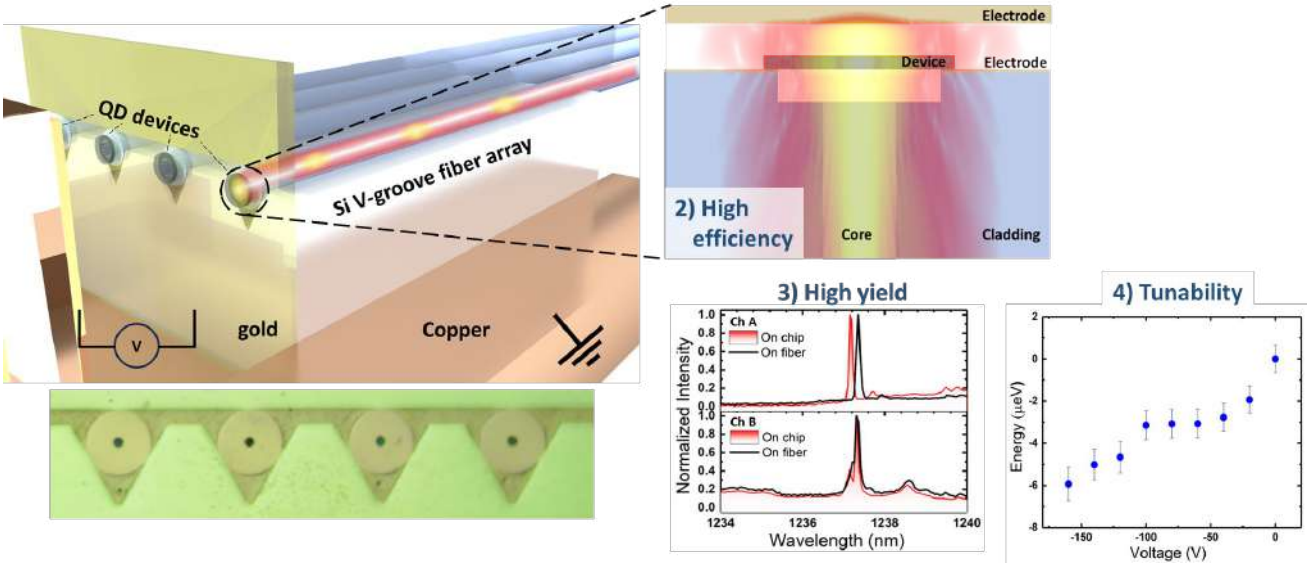

Fig. 1. Schematic illustration of the multi-functional fiber-integrated platform. The insets display a photo of cavity-coupled quantum dots integrated onto a V-groove fiber facet, a numerical simulation of field propagation from the integrated cavity, the emission spectrum before and after integration, and wavelength tuning by applying voltage.

Second-order coherence of Bose-Einstein condensation in plasmonic lattices

E. A. Mamonov[1*], S. Eyvazi[1], L. Freter[1], and P. Törmä[1]

Abstract: Plasmonic lattices accompanied with active media are versatile platform for many applications such as lasing or Bose-Einstein condensation (BEC). Here we present our studies of second-order coherence of BEC in plasmonic lattices. We analyze the behavior of $g^{(2)}(\tau = 0)$ function in the three stages of emission: lasing, incomplete thermalization and condensation.

Plasmonic lattices of different configurations combined with emissive materials offer unique opportunities to study fascinating phenomena such as lasing with topologically nontrivial properties [1, 2] and Bose-Einstein condensation (BEC) [3, 4]. BEC in strong coupling regime in plasmonic lattices undergoes three consecutive stages as the pump fluence increases: polariton lasing, incomplete stimulated thermalization and condensation, making it distinctive from many other systems both in strong and weak coupling regimes [5].

Unlike second-order coherence, first-order coherence properties of different types of BE condensates have already been studied more extensively [6,7] although the former highly depends on a quantum state of an emitter and can bring additional information on the processes occurring before and during the condensation.

Here we study BEC in a plasmonic lattice of gold nanocylinders with a diameter of 100 nm and a periodicity of 570 nm supporting surface lattice resonance (SLR) excitation; its frequency at Γ point is a band edge for BEC. As an active media IR-792 dye was used which provided BEC in strong coupling regime.

To study second-order coherence properties of BEC, we measured pulse-to-pulse intensity fluctuation resolving it spectrally and in momentum space. Under certain assumptions about emission's spatial and temporal modes structure, this measurement gives the value of the second-order correlation function $g^{(2)}(\tau = 0)$.We show that the $g^{(2)}$ values decrease with increasing pump fluence and discuss the peculiarities of the function's behavior during the transition to BEC.

Abstract: The information content of a scattered field increases orders of magnitude with topologically structured (as opposed to unstructured) light, and plasmonic effects can enhance/redirect information flow. On this basis, picometric precision and accuracy can be achieved in optical metrology and imaging.

Complex optical fields can contain structure at deeply subwavelength scales – including point-like singularities, zones of energy back-flow, and strong phase and intensity gradients. The scattering of light from an object can thus depend strongly on exactly where its features are located within such a field. On this basis, precision and accuracy reaching the atomic scale (100-200 pm; $<\lambda/5000$) have recently been demonstrated in single-shot optical measurements of nano-object positions and dimensions, based on deep-learning analyses of their far-field diffraction patterns in topologically structured light (doi: 10.1038/s41563-023-01543-y).

Here, we explain how such performance – reaching far beyond the conventional diffraction limit – is possible, through a Fisher Information analysis of the technique, showing that the scattered field from an object located near a singularity can have information content orders of magnitude higher than the scattered field from a plane wave. We further show how plasmonic effects can resonantly enhance and redirect the flow of Fisher information (very differently from the flow of energy), directly impacting the limits of measurement precision and accuracy; and we illustrate how the concepts can be extended from the constrained problem of retrieving single/few dimensional parameter measurements to the greater challenge of imaging arbitrary nano-objects.

Negative frequency generation and temporal diffraction in graphene at THz frequencies

E. Hendry

School of Physics and Astronomy, University of Exeter, Stocker Road, Exeter, EX4 4QL, UK
e.hendry@exeter.ac.uk

Abstract: Temporal modulation of graphene using ultrafast pulses can be incredibly fast compared to the period of a transmitted THz field. We demonstrate that this gives rise to distinct signatures in the transmission spectrum arising from generation of negative frequency components. We then discuss several temporal diffraction experiments using graphene modulation.

Fast modulation of the optical properties of materials has recently been shown to produce strikingly different electrodynamics from passive materials, giving rise to effects such as temporal diffraction and associated generation of new frequency components of a field. In the first demonstrations of this concept in [1], new frequencies were generated using ITO modulators at optical frequencies, where the modulation time (the time taken to switch the optical transmission) was considerably slower than the characteristic period of the electromagnetic wave. Here, we show that graphene, a highly efficient modulator for THz fields, is capable of modulating transmission on a timescale that is substantially faster than the period of the THz wave. This leads to an extremely large bandwidth for the generated frequencies covering the entire THz spectral band, even crossing the origin to generate negative frequencies. We see in experiment distinct oscillatory features (see figure) in transmission spectra of a modulated narrow band THz source (centred at 0.5 THz) arising from interference with negative frequency components of the field. Finally, we present our first experimental results displaying temporal diffraction arising from stimulation using multiple pulses, starting with the traditional temporal analogue of a Youngs double slit experiment [1], which give diffraction fringes covering the entire THz spectral band from 0 to 2 THz.

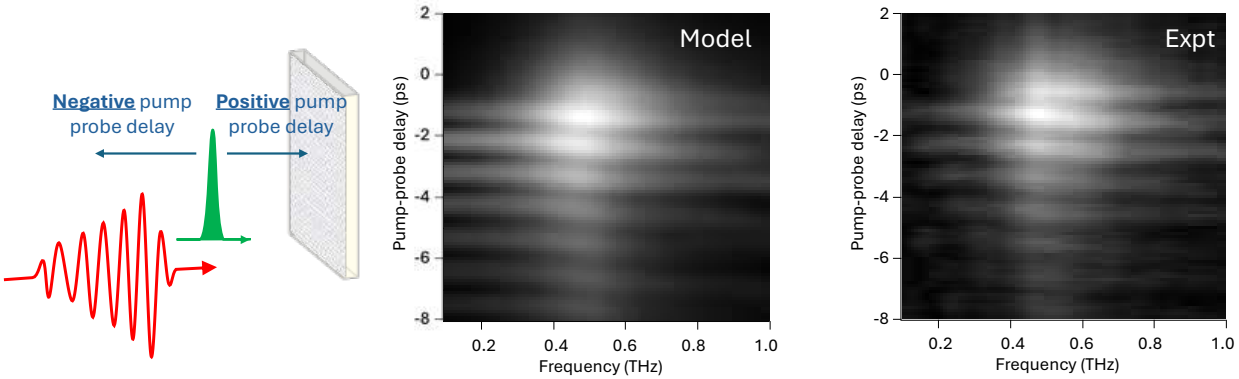

Figure: Modelling and experiment showing spectra of the change in transmission in a temporal diffraction experiment using a single stimulation pulse and a narrow band THz source centred at 0.5 THz. We observe new frequencies in transmission, which are not present in the incident field, spanning the entire THz band. Moreover, the oscillatory features in both model and experiment arise from interference with generated negative frequency components of the field.

Abstract: We evidence a phenomenon of self-hybridization of the resonances sustained by aluminum nanorods, owing to the strong coupling of the localized plasmonic resonances with interband transitions occurring within the metal. Anomalously high rates of hot electron generation are associated with these hybridized states.

Strong coupling is typically observed between two distinct entities or between an entity and its environment (e.g., an atom and a cavity). However, it can also occur between two distinct excitations within the same object, a phenomenon that has been less extensively investigated. In this work, we present evidence of strong coupling between localized surface plasmon resonances and the interband transition in aluminum nanorods. This coupling is evidenced by optical spectroscopy and electron energy loss spectroscopy (EELS), supported by numerical simulations. The strong coupling involves multiple orders of plasmon modes, including dark modes. The corresponding Rabi energy, which defines the energy splitting between the two polaritonic branches, is determined in each case. Notably, the use of EELS allowed us to experimentally map the hybrid modes with nanoscale resolution, giving further evidence of the strong coupling.

Furthermore, a dedicated numerical model [1] is employed to demonstrate that strong coupling in the near-infrared region facilitates efficient hot electron generation, exploiting the hybrid nature of the modes. The plasmonic component provides a high absorption cross-section, while the interband transition ensures efficient hot electron generation. The associated interband HE efficiency is predicted to reach about 40%. Importantly, this phenomenon is triggered by red and near infrared light, a spectral range that is particularly well suited to solar light-based applications, such as hot carrier-based photodetection.

Abstract: Thermoplasmonic detection is an emerging application within the rapidly expanding and promising field of thermoplasmonics. While the heat generated by gold nanoparticles has been utilized in biomedical applications such as photothermal therapy, the impact of nanoscale photothermal processes remains a topic of ongoing discussion.

In this context, this work aims to provide a better understanding on the thermoplasmonic mechanism leading to efficient and sensitive detection by evaluating the performances as thermoplasmonic generators of colloidal gold nanobipyramids (AuBPs) in solution and immobilized onto a paper nanoplatform. For this purpose, firstly AuBPs with different aspect ratios were synthesized in aqueous solution and their intrinsic light-to-heat performances were assessed by their exposure to the 808 nm laser line. Thus, photothermal efficiencies (η) up to 64 % were determined for the colloidal nanoparticles close to the resonance condition related to the excitation wavelength. Next, 4-mercaptobenzoic acid was grafted onto their surface through its thiol group. As a consequence of the 4-MBA functionalization, η was decreased by 5 to 8 %. Additionally, after their immobilization of Whatman No. 1 filter paper through immersion, their optical properties and intrinsic thermoplasmonic activity were preserved. As 4-MBA – a small molecule, was added onto the plasmonic paper, the photothermal conversion performances were significantly decreased causing an increase in the cooling time constant. Furthermore, a more complex molecule was tested, specifically thiol-polyethylene glycol-amine – as a thermo-sensitive polymer, proving temperature-induced phase transitions in materials can be also highlighted by modifications is the light-to-heat conversion performances of the immobilized nanoparticles. Thus, the obtained results contribute to the consolidation of the versatile thermoplasmonic detection technique and represent a steppingstone in the development of simple plasmonic nanoplatforms for thermoplasmonic-driven applications.

Abstract: We present AlInP as an attractive alternative to common nonlinear materials used in nanophotonic structures and devices, especially in the visible spectral range. As a demonstration, we show enhanced second-harmonic generation from nanodisks fabricated in a wafer-bonded crystalline AlInP layer.

Resonant nanophotonic systems with enhanced second-order optical nonlinearity ($\chi^{(2)}$) are desired for many applications, including electro-optic modulation, generation of entangled photons, and frequency conversion.[1] Achieving a high quality (Q) factor and strong light confinement in a nanoresonator requires a material with high refractive index (n) and low absorption loss (k). On the other hand, efficient $\chi^{(2)}$ nonlinearity is usually provided by noncentrosymmetric crystalline materials. The choice of a suitable material is often dictated by a trade-off between n, k, $\chi^{(2)}$, and fabrication feasibility. For example, in the visible spectral range, some materials (e.g., GaAs) have high n and $\chi^{(2)}$, but are strongly absorbing, while other materials (e.g., $LiNbO_3$) are transparent, but show moderate n and $\chi^{(2)}$. There are also materials offering a decent combination of n, k, and $\chi^{(2)}$, like GaP, but nanofabrication involving these materials is not easy.[2] Therefore, there is a need for alternative $\chi^{(2)}$ materials that would enable efficient fabrication of high-Q resonant nanostructures, especially for operation in the visible spectral range. In search for such a material, we turned our attention to aluminum indium phosphide (AlInP).

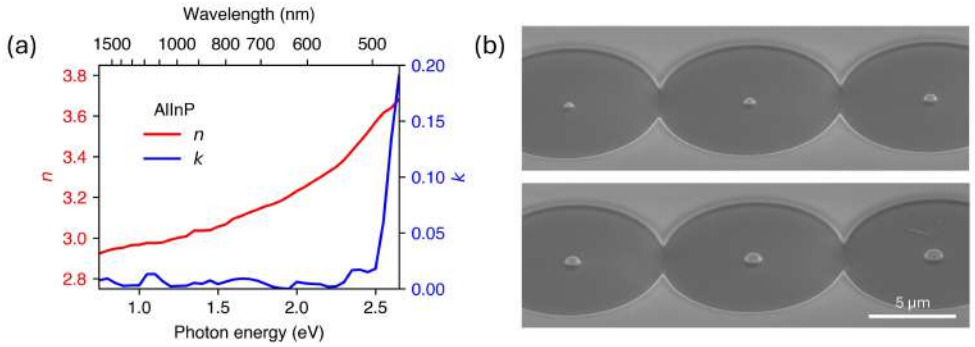

Figure 1. Demonstration of AlInP as an attractive material for resonant nanophotonics. (a) Real and imaginary parts of the refractive index (n and k, respectively) measured ellipsometrically for a 400 nm thick AlInP layer bonded to glass. (b) Scanning electron microscope (SEM) images of a AlInP layer patterned using FIB.

Despite extensive use of AlInP in solar cells, transistors, and light-emitting diodes, its potential for nonlinear nanophotonics has so far been largely overlooked.[3] Since AlInP is lattice-matched to GaAs, it can be grown on relatively inexpensive GaAs wafers, and then transferred onto a low-refractive-index substrate. Here, we used metal-organic vapor-phase epitaxy (MOVPE) and wafer bonding to obtain a thin crystalline AlInP layer on glass. The optical constants of this layer, measured by ellipsometry, are shown in Fig. 1(a), demonstrating $n > 3$ across

the visible and most of the near-infrared spectral range and high transparency down to the wavelength of 500 nm. The layer can easily be patterned with a focused ion beam (FIB), as presented in Fig. 1(b). Already these properties make AlInP an attractive alternative to GaP. We are currently developing a process based on electron-beam lithography (EBL) to enable high-throughput fabrication of AlInP nanostructures.

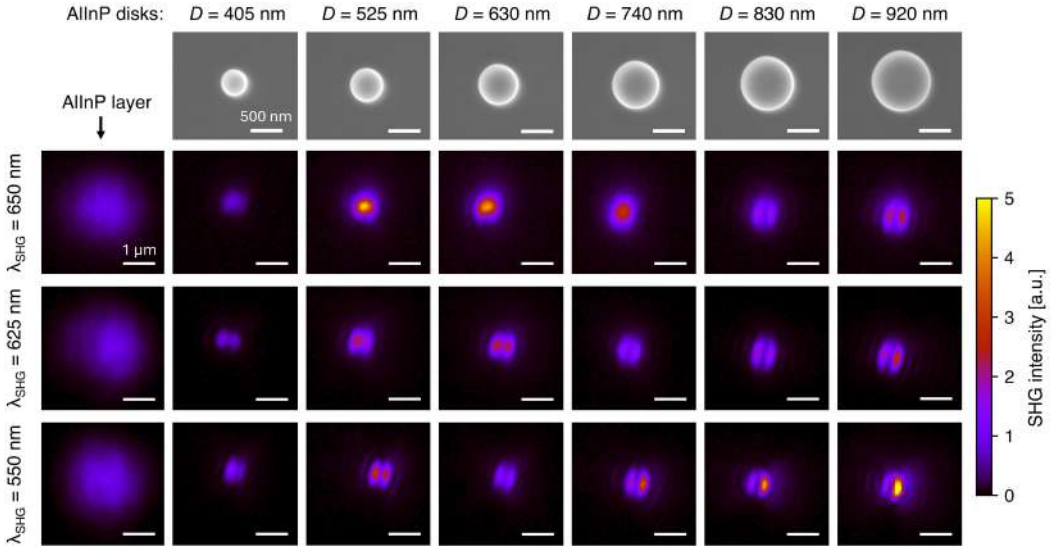

Figure 2. SEM images (top row) and optical microscopy images of SHG excited at different fundamental wavelengths in the range 1100-1300 nm (SHG wavelength 550-650 nm) from AlInP nanodisks of various diameters (*D* from 405 to 920 nm). The scale bars correspond to 500 nm in all the SEM images, and to 1 μm in all the SHG images. The incident beam is polarized horizontally (along the scale bars) with a possible out-of-plane component due to the tight focusing.

To showcase the potential of AlInP for nonlinear nanophotonics, we studied second-harmonic generation (SHG) in AlInP nanodisks excited by a focused femtosecond laser beam, as shown in Fig. 2. At the fundamental wavelength of 1300 nm (λ_{SHG} = 650 nm), nanodisks of diameters D = 525 and 630 nm provide a 5-fold resonant enhancement of SHG compared to a bare AlInP layer. A resonant enhancement is visible also in the largest disks at a shorter wavelength. The observed SHG patterns result from an interplay between the incident beam polarization, the $\chi^{(2)}$-tensor symmetry, and shaping the incident and SHG fields by Mie resonances. Further demonstrations of enhanced $\chi^{(2)}$ phenomena in AlInP-based Mie resonators, anapoles, and periodic metasurfaces supporting bound states in the continuum are a target of our ongoing research.

Abstract: Chiral molecules with opposite handedness can have strongly different biological functionalities. Identifying chirality is, however, limited by low sensitivity, restricting detection to high concentrations and large volumes. We propose a silicon nanophotonics-based sensing technique to enhance the sensitivity of chiral molecular detection.

Detecting the handedness of chiral molecules is critical in biochemistry, where the functionality of biomolecules such as proteins, amino acids, and carbohydrates can strongly differ between enantiomers. Circularly polarized light is commonly used to distinguish enantiomers based on their differential absorption for the two circular polarizations, *i.e.*, circular dichroism (CD). This transmission-based method requires measuring very small changes in absorption, which is inherently difficult due to the large background caused by negligible absorption at low concentrations. As a result, the sensitivity is reduced, requiring a high density of molecules and long measurement times. This makes the conventional method unsuitable for critical applications like detecting protein aggregates linked to various diseases.

Fluorescence-based chiral sensing bypasses some of the difficulties of CD by shifting the wavelength of the light that interacted with the chiral molecules, allowing for separating this signal from the background of the excitation source. However, fluorescence is weak and its polarization very low. Nanophotonics provides routes for enhancing chiral sensitivity [1], [2], [3]. Optical resonators function as antennas, facilitating a more efficient light-matter interaction between the analyte and the excitation light. This effect can be amplified by arranging the resonators in arrays with an appropriate pitch [4]. In addition to excitation enhancement, the fluorescence of the analytes can also be increased thanks to Purcell enhancement, which increases the radiative rate. Furthermore, the resonator array can improve the directionality, enabling more efficient detection of the emitted fluorescence. These combined enhancement processes significantly boost the detected fluorescence of chiral molecules. Additionally, for chiral sensing, the polarization component is also critical. Utilizing resonators made from high-refractive-index dielectrics allows for tuning of electric and magnetic resonances, enabling control over optical chirality density, which can even generate local super-chiral fields, enabling a CD greater than that produced by of a circularly polarized plane wave.

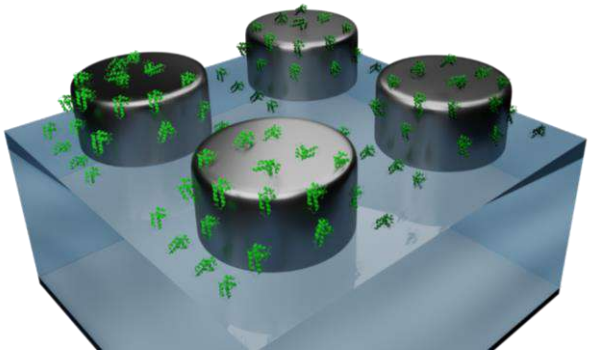

Figure 1. Chiral molecules on a silicon metasurface.

In this presentation, we introduce our recent experimental results on enhancing fluorescence-based chiral sensing using silicon metasurfaces. We fabricate crystalline silicon nanostructures displaying optical resonances in the visible. By combining them with chiral materials, we demonstrate enhanced circularly polarized fluorescence. To this end, we developed a custom-built polarization-sensitive microscope with polarization-modulation and photon-counting capabilities. Our microscope can measure smaller chiral analyte volumes than commercial systems.

Abstract: We theoretically investigate new chiroptical sensing techniques in nano-scale drug volumes by modelling the bi-anisotropic linear response of reparixin, ladarixin and levodropropizine solutions through molecular dynamics, time-dependent density functional theory and Perturbed Matrix Method, and by obtaining an analytical expression for the macroscopic optical parameters from first principles.

Enantiomers play a central role in pharmaceutics since they affect drug functionality, as in particular in pharmacodynamics, pharmacokinetics and toxicity [1]. Moreover, chiral sensing is essential for optimizing biological tissue penetration and to gain enhanced control of contrast agents, detection markers and biosensors.
Currently, optical sensing techniques, e.g., polarimetry and vibrational circular dichroism (VCD), offer the advantage of real-time analysis capabilities and potential lab-on-a-chip integration and wider nanomedicine applications.

Here, we explore the potential of nanophotonics-based devices for chiroptical sensing of drug solutions. We model drug solutions using molecular dynamics (MD) to find the conformational states of the molecules, time-dependent density functional theory (TD-DFT) to obtain the unperturbed eigenvalues of the vibrational and electronic molecular states, and, finally, Perturbed Matrix Method (PMM) to consider the perturbation due to the solvent to find the perturbed eigenvalues and their static and transition electric/magnetic dipole moments.
Moreover, we obtain the macroscopic optical parameters by perturbatively solving the density matrix equations within the dipole approximation and by averaging the obtained first/second-order hyper-polarizability tensors over the random molecular orientation through the Euler rotation matrix approach. Specifically, in Fig.1 one can see the dielectric permittivity ε_r, the magnetic permeability μ_r and the chiral parameter κ of three different chiral mixtures: reparixin (solid curves in Figs. 1a,b), that is an inhibitor of the CXCR2 function attenuating inflammatory responses [2,3] that has been adopted in clinical trials for the treatment of hospitalized patients with COVID-19 pneumonia [4], dissolved in $CH_3CN + H_2O$ (50:50 volume ratio), levodropropizine (dashed curves in Figs. 1a,b) dissolved in $C_6H_{14} + C_2H_5OH$ (40:60 volume ratio), and ladarixin (dotted curves in Figs. 1a,b) dissolved in water.
In all cases we study the chiral parameter κ (Figs. 1c-h) as a function of the wavelength and the relative concentration $\Delta n_{mol}/n_{mol} = [n^{(S)}_{mol} - n^{(R)}_{mol}]/n_{mol}$), where $n^{(R,S)}_{mol}$ indicate the number densities of R and S enantiomers, respectively and the number molecular density is $n_{mol}=n^{(R)}_{mol}+n^{(S)}_{mol} \approx 10^{-2}$ nm^{-3} (corresponding to a concentration of 5 mg/ml).
Finally, our results are relevant for the development of innovative integrated schemes for chiroptical sensing of drug solutions, such as plasmon-enhanced circular dichroism spectroscopy [5].

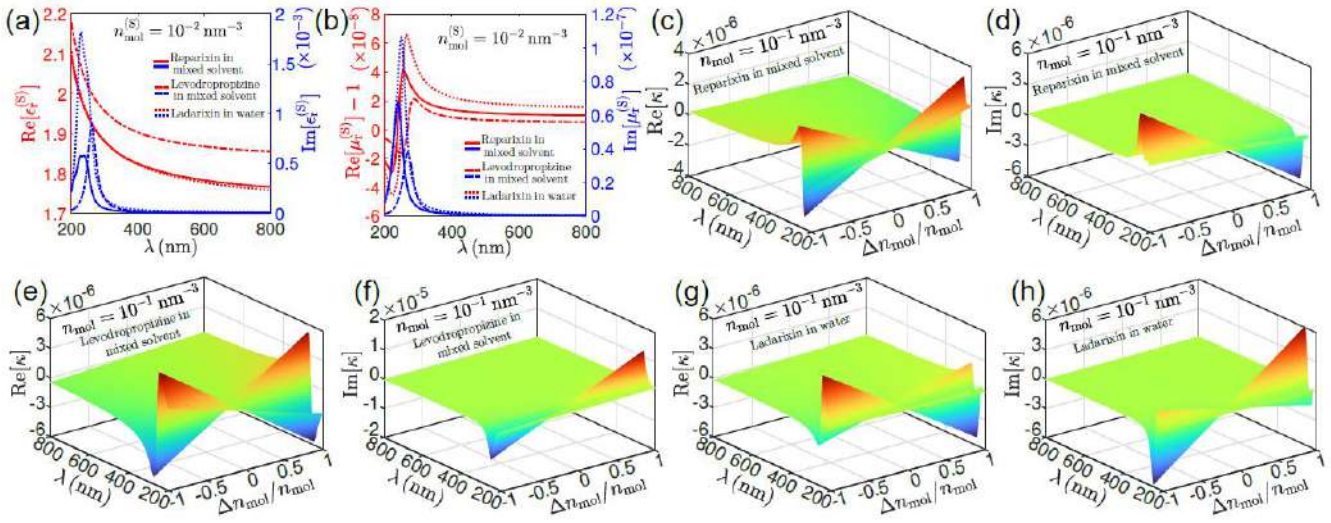

Fig. 1 Real (red curves) and imaginary (blue curves) parts of the **(a)** relative permittivity ϵ_r and **(b)** permeability μ_r of the S-type chiral enantiomer of the three pharmaceutical molecules (with concentration $n_{mol} = 10^{-2}$ nm^{-3}) in different solvents. Here, the left (red) and right (blue) axes represent the real and imaginary parts of ϵ_r and μ_r. The solid curves correspond to reparixin dissolved in $CH_3CN + H_2O$ (50:50 volume ratio), the dashed curves indicate levodropropizine dissolved in $C_6H_{14} + C_2H_5OH$ (40:60 volume ratio), and the dotted curves correspond to ladarixin dissolved in water. **(c,e,g)** Real and **(d,f,h)** imaginary parts of κ as a function of wavelength (λ) for relative concentration ($\Delta n_{mol}/n_{mol} = [n^{(S)}_{mol} - n^{(R)}_{mol}]/n_{mol}$) of an enantiomeric mixture of R and S enantiomers.

Abstract: This study presents a wafer-scale, self-assembly fabrication method of metallic helices by engineering the residual stresses and gradient strains in thin films to induce spontaneous folding and twisting. The fabricated nanohelices of sub-micrometer radii exhibit strong chiroptical responses in the infrared regime, enabling practical applications in chiroptical spectroscopies and chiral chemistry.

Chiral metasurface has emerged as a promising candidate to enhance the chiroptical activity towards spectroscopic and chiral chemistry applications. Recent theoretical and experimental works show that the chiroptical signals of chiral molecules are significantly amplified when they couple with chiral metastructures. Among various chiral metastructures reported so far, helices are particularly well-studied due to their intrinsic optical chirality, arising from their geometric configuration.[1-2] They are particularly valuable in maximizing light-matter interactions in applications such as chiral sensing or stereochemical reactions. However, despite their potential, the fabrication and optical characterization of metallic helices remain underexplored due to substantial technical challenges, particularly the tradeoff between precise structural control and process efficiency.

In this study, we present a self-assembly fabrication technique for nanohelices that offers precise feature control, wafer-scale production capability, and broad material compatibility. Our method involves the single-step transformation of metallic strips composed of multilayered thin films into helical geometries once released from the substrate. This transformation is driven by the nanoscale control of the residual stresses and gradient strains within the metallic strips, which spontaneously generate the necessary forces for folding and twisting. This technique facilitates the efficient fabrication of centimeter-scale samples, allowing for chiroptical characterization using standard commercial spectrometers. Experimental measurements and numerical simulations confirm strong chiroptical responses in the infrared (IR) region for helices with radii on the order of hundreds of nanometers.

The fabrication process begins with the preparation of micrometer-scale strips of multilayered metallic thin films on a Si substrate, using ultraviolet (UV) lithography, electron-beam evaporation, and lift-off techniques. The substrate is then coated with the electron-beam lithography (EBL) resist, and uniform nanoscale line-and-space patterns are written at a specific angle θ relative to the strip's axis. After development, selective wet etching is performed to partially remove the top metal layer. Upon removal of the EBL resist, microstrips with nanogroove patterns are formed. The substrate then undergoes isotropic reactive ion etching to eliminate the underlying silicon. As the Si beneath the strips is fully removed, the strips detach from the substrate. Residual stresses in the nanogrooves create a periodic strain gradient, causing the strips to fold and twist spontaneously into nanohelices.

Figure 1(a-b) shows the scanning electron microscope (SEM) images of nanohelices aligned in parallel to the Si substrate fabricated from aluminum (Al)/titanium (Ti)/aluminum (Al) and gold (Au)/nickel (Ni)/aluminum (Al)

trilayer films, respectively. We have succeeded in fabricating helices with diameter ranging from 800 nm to several μms. Based on the helical geometry, the pitch P between adjacent rings is related to radius R of helix by $P = \frac{2\pi R}{\tan\theta}$. The radius R can be expressed as $R \approx \frac{l}{|\alpha|}$, where l is the periodicity of the nanogroove patterns and α is the folding angle induced at each nanogroove. These relationships indicate that structural parameters such as R and P can be precisely tuned by adjusting the nanogroove periodicity l, the folding angle α, and the alignment angle θ of the groove patterns.

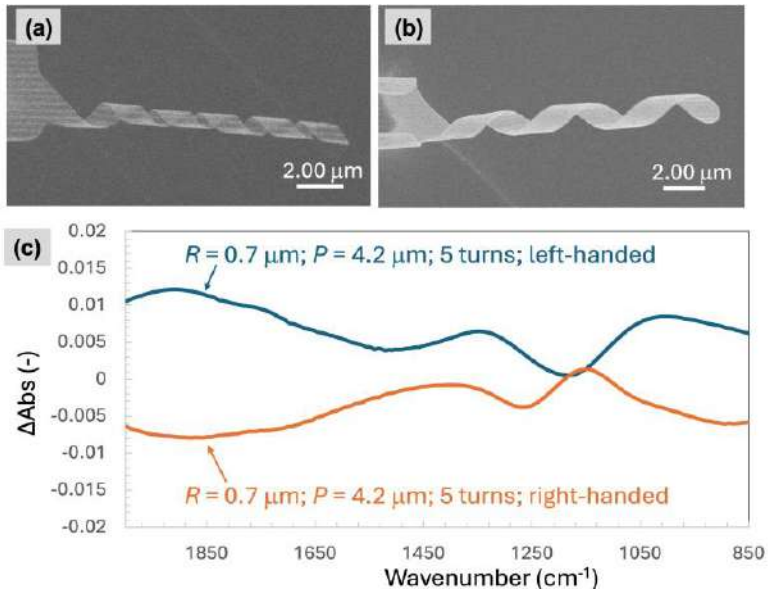

Figure 1. SEM images of helices fabricated from (a) Al/Ti/Al and (b) Ni/Au/Al thin films. (c) IR-CD spectra of pairs of helices.

A key advancement of this technique is its ability to achieve wafer-scale fabrication within a relatively short processing time. The realization of cm²-sized samples has enabled the characterization of the chiroptical properties of metallic helices using standard spectrometers, eliminating the need for previously required microscope-based setups. To verify the chiral responses of the fabricated helices, we measured the extinction spectrum differences for incident circularly polarized light of opposite handedness in the IR range of 850 – 2000 cm^{-1}, using a standard Fourier transform-based IR circular dichroism (IR-CD) spectrometer. The resulting IR-CD spectra, shown in Fig. 1(c) for two Al helices with opposite handedness, reveal distinct circular dichroism (CD) peaks and dips at identical frequencies. The right- and left-handed structures exhibit opposite signs with nearly equal amplitudes, demonstrating the mirror-symmetric behavior characteristic of chiral systems, which arises from the chiral eigenmodes of their intrinsic geometry.

We have developed a robust method for fabricating submicrometer metallic helices by engineering the stress and strain in metallic thin films through conventional lithography techniques. The ability to fabricate helical structures at the wafer scale, combined with tunable structural parameters and tailored optical properties, establishes this technique as a transformative chiral metasurface platform. It holds promise for practical applications in photonics, chiroptical spectroscopy, and stereochemistry, including chiral sensing, IR inspection, stereostructural characterization, and enantioselective chemical reactions.

Abstract: Lateral heterostructures of different Transition Metal Dichalcogenide monolayers provide new architectures leading to a wide range of novel photonic and optoelectronic applications. In recent studies, we have shown that such lateral heterostructures can be used to filter, focus, collimate, or trap neutral excitons, giving a base for excitonic devices.

Transition Metal Dichalcogenide monolayers (TMD-ML) have been the focus of extensive research in recent years thanks to their strong light-matter coupling and intriguing optical and excitonic properties.[1-2] A particular emphasis has been placed on the manipulation of neutral excitons at room temperature (RT) in these materials, which is a direct consequence of their tight binding energies and notably high mobilities.[3-4] Indeed, controlling the spatial motion of these quasi-particles has the potential to yield significant advancements in excitonic circuits, photonics, and optoelectronics. However, the neutral charge nature of the main excitons in TMD-MLs limits their interaction with external electric or magnetic fields, making their manipulation a challenging task. Several studies have focused on spatially manipulating excitons while localizing their emission using local strain gradient engineering of TMD-MLs deposited on nanoantennas.[5-6] Furthermore, combining two or more TMD-MLs with different optical properties for designing innovative vertical heterojunctions (VHs)[7-8] or lateral heterojunctions (LHs)[9-11] have been paying increasing attention, thanks to their unique excitonic properties, such as Moiré interlayer excitons and charge transfer excitons.

Recently, we demonstrated efficient unidirectional transport of excitonic flux from a higher bandgap TMD-ML to a lower gap TMD-ML at RT in high-quality type-II band alignment CVD-grown LHs[12]. Near-field optical spectroscopies based on tip-enhanced Raman scattering and photoluminescence (PL), providing a spatial resolution of about 30 nm, were performed on high-quality WSe_2-$MoSe_2$ LH, exhibiting an excitonic diode-like effect. Indeed, neutral excitons generated inside WSe_2 (large gap) were able to pass through the junction before recombining inside $MoSe_2$ (narrow gap), while the reverse case was not allowed. This phenomenon gives rise to a Kapitza resistance-like effect,[13] which manifests as a strong discontinuity in the excitonic density at the interface between both materials. As a result, the high-gap material-related PL is quenched, while the low-gap material-related PL is enhanced near the junction. Furthermore, by using μ-PL imaging combined with numerical simulations based on statistical approach of randomly moving excitons through specific geometries of sharp WSe_2-

$MoSe_2$ LHs, we showed that various shapes formed by those interfaces enable advanced in-plane control of both excitonic distribution and fluxes over large distances[14]. Thus, a triangular shape LH allows both exciton focalization and flux collimation, consisting in the formation of parallel current lines extending a few micrometers away from the source. We also proved that sub-wavelength $MoSe_2$ triangles embedded in a WSe_2 matrix provide efficient systems for trapping and confining excitons in adjustable size spaces[14]. Our finding about sharp TMD-LHs opens new perspectives for the manipulation of neutral excitons in flat semiconducting 2D materials, hence for the design and production of new excitonic devices.

Abstract: We report a microcavity-assisted metasurface with a gradient-thickness DBR substrate that achieves 15 high-Q resonances across the visible to NIR spectrum, enabling efficient amplitude and phase modulation for advanced optical control.

Metasurfaces have revolutionized optical modulation at subwavelength scales, yet their performance has largely been confined to single-wavelength or narrowband operation. This work introduces a novel microcavity-assisted metasurface [1, 2] that enables multi-wavelength wavefront control by incorporating a distributed Bragg reflector (DBR) substrate with precisely engineered meta-atoms. The proposed design supports multiple high-Q resonances spanning from the visible to near-infrared spectrum, achieving remarkable efficiency and uniformity across different wavelengths. Our experimental results confirm the generation of up to 15 resonant peaks with enhanced optical performance, enabling flexible amplitude and phase manipulation. Additionally, we demonstrate the integration of this metasurface into advanced optical applications such as structured color generation, holographic imaging, and hyperspectral imaging. These findings offer new possibilities for the development of multifunctional metasurfaces, paving the way for applications in imaging, sensing, and next-generation display technologies.

Abstract: We demonstrate an all-optical reservoir computing device with a nonlinear amplifying loop mirror for high-speed ML tasks and optimization algorithms for microcomb design. These advancements enhance AI, telecommunications, and smart photonic optimization.

Introduction

Machine learning (ML) has emerged as a transformative tool for tackling complex computational tasks with minimal human intervention, driving the need for faster and more efficient processing. Conventional electronic processors struggle with speed and energy limitations when handling large neural networks, prompting the exploration of photonic computing as an alternative[1-2]. By leveraging the inherent parallelism, bandwidth, and speed of light, photonic artificial intelligence (AI) hardware—such as optical neural networks and reservoir computing systems—promises to overcome these bottlenecks, reducing power consumption, increasing processing speed, and minimizing latency beyond electronic limits. At the same time, photonic technologies are advancing rapidly, enabling new possibilities for AI-driven optimization. For instance, chip-scale frequency combs ("microcombs") generated in nonlinear microring resonators provide vast potential for applications in metrology, communications, and sensing. Meanwhile, ML techniques are reshaping photonic system design, offering robust solutions for optimizing experimental parameters in nonlinear optical systems. The synergy between photonics and AI is thus paving the way for next-generation computing platforms that integrate light-based computation with intelligent data processing. Here, first, we show an all-optical reservoir computing[3] (RC) device based on a nonlinear amplifying loop mirror (NALM), capable of executing multiple ML tasks in parallel via wavelength-division multiplexing (WDM). This device exhibits high accuracy in chaotic time-series prediction while minimizing latency, addressing the limitations of traditional electronic AI accelerators. Second, we demonstrate an ML-based optimization framework employing genetic algorithms (GAs) for stable microcomb generation within microring resonators (MRRs). By optimizing pump parameters, laser detuning, and system feedback, this approach enables repeatable microcomb formation with long-term stability and high spectral coherence.

NALM-based photonic reservoir computing

Optical time-delayed reservoir computing (RC) emerges among others for its ability to form a recurrent network with fading memory while maintaining a minimal hardware footprint. Our proposed photonic RC system consists of a Sagnac interferometer with a NALM as the processing unit, with tunable gain and transmission. This architecture supports a wide range of coherent nonlinear dynamics, both with and without continuous-wave (CW)

injection. By leveraging a wide range of coherent nonlinear dynamics, the processing unit classifies continuous-valued input signals, even when they exhibit significant complexity and nonlinearity. By leveraging WDM, multiple input channels are injected into the system, enabling parallel execution of Mackey-Glass chaotic time-series prediction. As a result, we reach a processing speed of approximately 27 MHz, achieving an error rate of 1%, as shown in Fig.1 (a), after applying a ML training algorithm, i.e., the ridge regression. This scalable approach significantly enhances AI processing capabilities for new photonic intelligent applications.

Optimization algorithms for microcomb designing

Microcombs, generated in microring resonators (MRRs), arise due to the nonlinear interactions of the injected optical field with the material composing their structure. When pumped with enough power, Kerr-induced parametric effects, such as four-wave mixing, allow the generation of broadband microcombs covering the entire telecom C-Band. However, their spectral properties are highly sensitive to pump conditions and detuning, making stable generation challenging. To address this, we implement an optimization scheme based on a genetic algorithm (GA), which performs in a manner analogous to natural selection in evolutionary theory and autonomously identifies optimal experimental parameters for microcomb formation. The fitness function considers key spectral features such as comb line spacing, intracavity power, and spectral envelope uniformity. Through iterative evolution, the GA minimizes spectral deviations, as shown in Fig. 1 (b), achieving power-per-line stability exceeding one day and coherence values of ~86% for three-photon lifetimes. This model-free approach ensures robustness across different microcomb generation regimes, facilitating practical applications in high-capacity optical communications, neuromorphic computing, and quantum photonics.

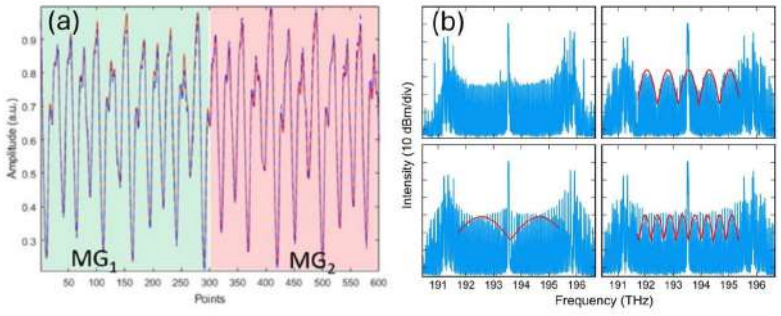

Figure 1. Experimental results. (a) Optical machine learning classification of two MG time series signals using the NALM-based processing unit. (b) Microcombs' spectral design using our GA[4].

Conclusions

Our work underscores the bidirectional synergy between photonics and ML. Optical RC offers a high-speed, energy-efficient solution for AI tasks, while ML-driven optimization enables robust and stable photonic applications design. These advancements pave the way for next-generation photonic processors and intelligent optical systems, driving new possibilities in AI, telecommunications, and beyond.

Abstract: We present a novel nanomotor design that enables 3-dimensional control of motion. A moderate cone angle Bessel beam with azimuthal polarization, acting on a glass chassis, allows for stable optical pulling; while asymmetric plasmonic dimers embedded within this chassis provide lateral movements upon plane wave illumination.

Momentum transfer in light-matter interactions generates optical forces, which play a crucial role in advancing micro- and nanotechnology, particularly in lab-on-a-chip devices [1]. Traditionally, gradient optical forces from optical tweezers have been employed to drive components such as pumps and valves, but these forces are limited by the size, shape, and material properties of the actuated objects. To overcome these limitations, recent research has proposed nanomotors utilizing scattering forces from asymmetric plasmonic nanoantennas or dielectric metasurfaces [2,3]. While showing successful results in enabling movement within two-dimensional planes, controlling longitudinal motion has remained a persistent challenge [4]. In contrast to the relatively trivial and well-known pushing effect obtained from scattering, optical pulling forces, first recognized in the last decade, require precise illuminating and scattering conditions [5].

This optical pulling effect has been theoretically achieved by the exploitation of several schemes, such as large cone angle Bessel beams, plane wave pairs, hyperbolic materials or chiral light-matter interactions [6]. However, most of these strategies propose unrealistic experimental conditions, making the practical realization of the effect challenging. A promising solution to this problem was proposed by Li et al. in 2019, using a dielectric cylinder that collimates Bessel beams by acting as a waveguide, allowing optical pulling effects across long distances with low cone angle Bessel beams [7].

In this work, we present a novel nanomotor design that enables control over both transversal and longitudinal motion. The system utilizes a coupling mechanism between an azimuthally polarized Bessel beam and a dielectric glass cylinder, which serves also as a chassis for the nanomotor (Figure 1a). Asymmetric plasmonic dimers are embedded within the cylinder in a way that minimizes their interaction with the pulling beam. This scheme allows for lateral motion, driven by the scattering forces from the plasmonic dimers under plane wave illumination (Figure 1b,d), while Bessel beam incidence enables longitudinal motion through optical pulling forces on the cylinder. Our design unlocks a new degree of freedom in motion control, allowing for pulling, pushing, and lateral movement by adjusting the polarization or switching between plane waves and Bessel beams. Furthermore, the optical pulling force in our system is robust against rotational and translational disturbances (Figure 1c), including Brownian motion, enhancing its practical applicability for advanced optical manipulation applications.

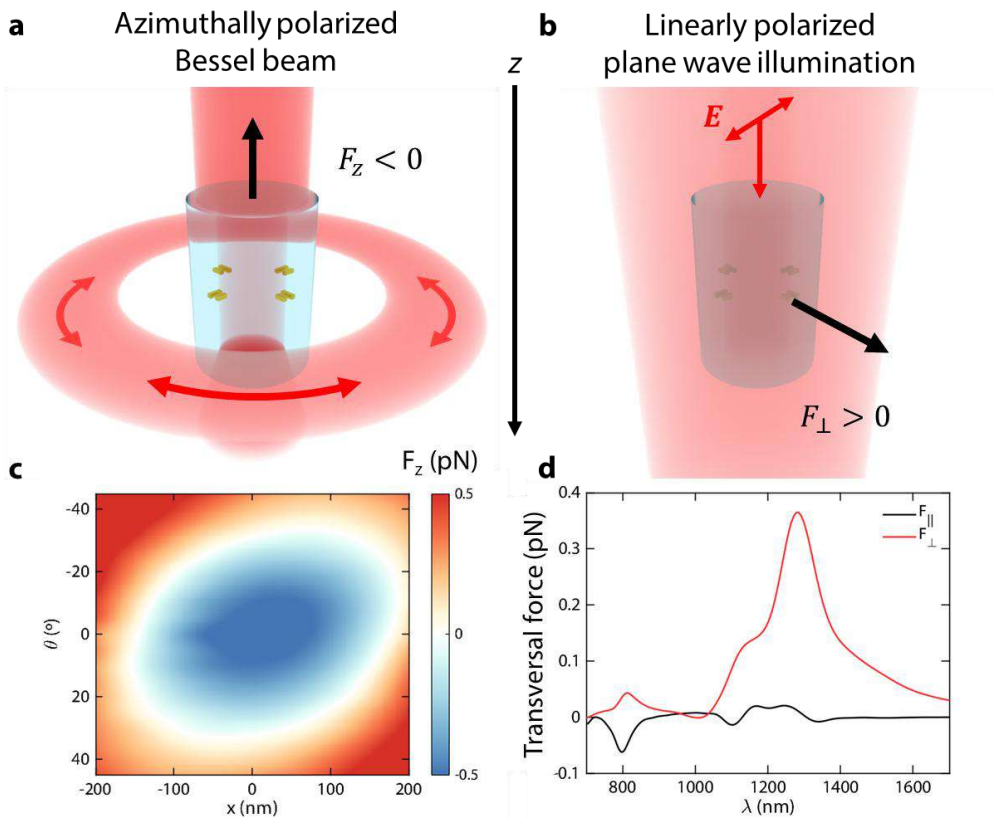

Figure 1. Depiction of the nanomotor design, acting in its optical pulling (a) and lateral movement (b) configurations. c) Longitudinal optical force with respect to angle and position. d) Lateral force components with respect to incident wavelength.

Abstract: Nonlinear effects are fundamental in spectroscopy and ultrafast physics but are limited in the XUV regime due to weak radiation-matter interaction. By means of femtosecond free-electron laser radiation, we report the first observation of the ENZ enhancement of self-action nonlinear effects in a the extreme ultraviolet.

The extreme ultraviolet (XUV) spectral range, thanks to the advent of pulsed sources, provides a window to a plethora of phenomena that cannot be observed in other spectral ranges, opening novel avenues for our understanding of ultrafast relaxation and non-equilibrium processes. Indeed, with the development of high harmonic generation (HHG) table-top sources, new spectroscopy schemes have enabled experimental implementations, such as nonlinear spectroscopy, coherent multidimensional spectroscopy, and time-resolved XUV transient absorption. The limited power of such sources hampers the observation of extreme nonlinear effects in a table-top framework, restricting their application mainly to spectroscopic techniques. However, by means of femtosecond free electron laser (FEL) pulses, it is possible to reach enough power to probe NL effects in the XUV regime (peak intensity > 200 TW/cm^2) [1]. Moreover, such NL effects can be enhanced owing to the tremendous field enhancement that epsilon-near-zero (ENZ) materials can provide.

Here, we report the first experimental observation of the ENZ enhancement of a third order nonlinear effect, namely self-phase modulation (SPM), in the XUV range. Specifically, the femtosecond FEL pulse [2] is characterized by a wavelength λ=44nm, and impinges on a 300nm tick Al foil. The near-zero effective-index (NZI) condition (eq. 1),

$$\mathrm{Re}\sqrt{\epsilon_{\mathrm{Al}}(\lambda) - \sin^2\theta_{\mathrm{NZI}}(\lambda)} = 0 \quad , \tag{1}$$

can be reach by tuning the impinging angle θ. In this regime, broadband Ferrell-Berreman (FB) modes in the Al thin foils occurs, leading to an enhancement of SPM. Particularly, during the ultrafast interaction between the femtosecond FEL pulse, the electron in Al undergoes ultrafast heating, followed by a relaxation process via electron-phonon collisions. This complex dynamics is theoretically taken into account by modeling a spatio-temporal electronic temperature, which causes a modulation of the refractive index.

In conclusion, we report the first observation of ENZ enhancement of self-induced spectral modulation in the XUV spectral range. In our extended theoretical model [3], we describe the enhancement of nonlinear effects that can occur at the epsilon-near-zero (ENZ) wavelength for a nanometric bilayer of poor metal, where plasmons play a crucial role in light-matter interaction.

Labyrinthine Magnetic Domains in Epitaxial Magnetooptical Garnet Films for Synchrotron Analysis and Optical Modulator Applications

Taichi Goto[1]

[1]Research Institute of Electrical Communication, Tohoku University, Japan
*corresponding author: taichi.goto.a6@tohoku.ac.jp

Abstract: Ce-substituted yttrium iron garnet grown epitaxially on garnet substrates exhibits labyrinthine magnetic domains. We analyzed these domains in detail using synchrotron radiation facilities and applied them to modulation devices utilizing magneto-optical effects.

Magnetooptical devices including Q-switched lasers [1], spatial light modulators, optical isolators, and magnetic holographic memory systems have attracted considerable attention due to their unique operational characteristics. The dynamic manipulation of magnetic domains offers promising approaches for next-generation optical modulation technologies with advantages in switching speed and energy efficiency.

In this study, we investigate cerium-substituted yttrium iron garnet (Ce:YIG) films epitaxially grown on gadolinium gallium garnet (GGG) and substituted GGG (SGGG) substrates using RF ion beam sputtering [2]. The deposition process was optimized with substrates maintained at 810°C and rotated at 4.3 rpm for uniform film growth across 10 mm × 10 mm substrates. The resulting Ce:YIG films measured ~130 nm in thickness, characterized through stylus profilometry and cross-sectional transmission electron microscopy. Compositional analysis via energy-dispersive spectroscopy revealed a stoichiometry of $Ce_{0.9}Y_{2.1}Fe_5O_{12-\delta}$, where δ represents oxygen deficiency.

We employed synchrotron radiation facilities to visualize magnetic domain structures with exceptional clarity, revealing distinct labyrinthine patterns with well-defined boundaries suitable for detailed quantitative analysis. The relationship between film thickness, magnetooptical response, perpendicular magnetic anisotropy, and magnetic domain width presents significant engineering challenges. Specifically, while increased film thickness enhances magnetooptical effects, it simultaneously reduces perpendicular magnetic anisotropy due to strain relaxation at the film-substrate interface, causing magnetization to reorient toward an in-plane configuration and resulting in the disappearance of desirable domain structures.

To understand domain dynamics, we conducted micromagnetic simulations using a 20 × 20 × 2 mm model discretized into 80 × 80 × 80 nm cells (4.77×10^6 total cells). Material parameters included 40 mT saturation magnetization, 7 pJ/m exchange coupling constant, and 2.5×10^4 A/m anisotropic field. These calculations were executed using Fujitsu's EXAMAG software on a high-performance system with Intel Xeon Gold 6132 processors (128 cores, 960 GB memory), completing in approximately 30 minutes.

Simulation results provided critical insights into magnetization dynamics and domain wall motion under various applied fields, revealing rapid domain reconfiguration in response to external magnetic fields—a characteristic essential for high-speed modulation devices. The agreement between experimental observations and simulation results validates both our material synthesis approach and computational methodology.

This work provides foundational knowledge regarding the growth, characterization, and theoretical understanding of Ce:YIG films with labyrinthine magnetic domains, contributing to the development of high-performance magnetooptical devices for optical communication systems, information processing

technologies, and specialized photonic applications requiring rapid light modulation capabilities.

Quasi-Babinet principle in dielectric resonators and Mie voids

M. Hamidi[1], K. Koshelev[2*], S. Gladyshev[1], A. C. Valero[1], M. Hentschel[3]

Abstract: We establish a quasi-Babinet principle for dielectric systems, linking dielectric Mie voids and their complementary structures. Among its various implications, this principle notably connects their resonant properties, and our work establishes simple design rules for constructing dielectric resonators with complex functionalities from their complementary counterparts.

Advancing resonant nanophotonics requires novel building blocks. Recently, cavities in high-index dielectrics have been shown to resonantly confine light inside a lower-index region [1]. These so-called Mie voids represent a counterpart to solid high-index dielectric Mie resonators, offering novel functionality such as resonant behavior in the ultraviolet spectral region [1]. In the simplest case, this structure can be assumed to be a spherical void in a high-index surrounding, which can be filled with a high-index particle. Such an analogy is shown in Fig. 1.

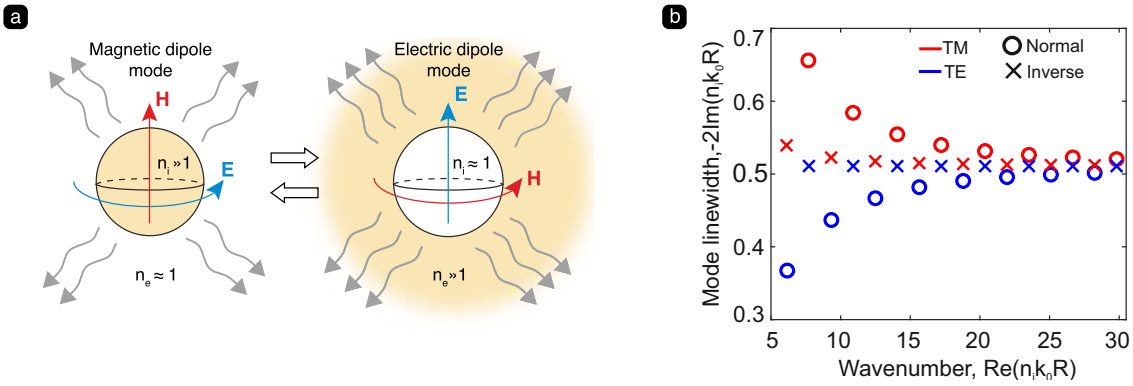

Figure 1: (a) High-index dielectric structure and low-index void in high-index dielectric host medium as its inverse system (b) Demonstration of the quasi-Babinet principle for a high-index dielectric sphere with $n_\mathrm{i} = 4$, $n_\mathrm{e} = 1$ and a spherical low-index void with $n_\mathrm{i} = 1$, $n_\mathrm{e} = 4$.

Looking at these two complementary structures reminds us of the well-known and highly useful Babinet's principle, a fundamental concept in electromagnetism that relates the scattering properties of thin perfect metallic conductors to complementary apertures in metal sheets [2]. Up to some extent, it applies as well to diffraction patterns from radiation passing through complementary metallic screens, exchanging transmission and reflection spectra [3]. However, it is not strictly applicable to dielectrics and volumetric systems. Here, we show that within certain boundaries, Babinet's principle can be generalized to dielectric and magnetodielectric systems, which we refer to as the quasi-Babinet principle and demonstrated for spherical and more generically shaped Mie resonators [4]. We reveal that for spherical nanoparticles, even

an analytic form of the quasi-Babinet principle can be established, connecting the electric and magnetic fields of a structure and its complementary counterpart, as well as their resonant frequencies and quality factors. The new principle holds quantitatively for voids (nanoparticles) with size larger than the wavelength, and approximately for subwavelength voids (nanoparticles). The quasi-Babinet principle remains approximately valid for nonspherical geometries, while it breaks down in the regions of high absorption and high dispersion.

Our work not only offers deeper physical insight into the working mechanism of these systems but also establishes simple design rules for constructing dielectric resonators with complex functionalities from their complementary counterparts. We anticipate the developed principle to pave the way toward smart engineering of nanoscale metadevices comprising applications in strong light-matter interaction, biosensing, and quantum information processing.

Abstract: Atomically thin semiconductors such as WS_2 can sustain spin-valley polarization and emit circularly polarized light. Using few-layer WS_2, we investigate the electrodynamic nature of valley-polarized emission using back focal plane imaging. We also demonstrate a Drexhage experiment to enhance and control valley-polarized emission.

Two-dimensional semiconductors hold great promise for nanoscale photonics and optoelectronics. Based on robust excitons at room temperature, they exhibit strong light absorption and emission, and they are easy to integrate into nanophotonic structures. One of their most promising properties is spin-valley polarization. In atomically thin semiconductors such as monolayer MoS_2 or WS_2, the spin and momentum direction of carriers can be locked. As a result, using circularly polarized light, we can populate carriers with a momentum direction that depends on the handedness of the optical excitation.[1] This degree of freedom, known as valley polarization, could be exploited to add a new dimension to information processing and optoelectronics. To fully take advantage of valley polarization for nanophotonics, it is necessary to better understand the conditions for it to occur, its electrodynamic nature, and the possibilities for enhancing it through optical means.

In this presentation, we characterize the microscopic electrodynamic character of valley polarization and valley coherence in few-layer WS_2 at room temperature. We employ back focal plane (BFP) imaging to record polarization-resolved angular radiation patterns. By analyzing the spin of the evanescent part of the angular spectrum, we identify circular and linear electric dipole characteristics in WS_2 excitons under circularly and linearly polarized excitations, respectively. Such evanescent optical spin is transferable to the far field using a glass substrate and has peculiar characteristics. Our investigation compares theory and experimental results for a dipolar source of photoluminescence in few-layer WS_2 semiconductors on a glass substrate. Utilizing polarization-resolved BFP imaging, we attribute valley-polarized emission to circularly polarized electric dipoles and valley-coherent emission to linearly polarized dipoles. Interestingly, it is possible to observe emission with linear polarization under certain angles for valley-polarized emission, and radiation with circular polarization for valley-coherent emission.

The ideal valley-polarized material should exhibit high emission quantum efficiency together with high polarization. However, currently available transition metal dichalcogenides suffer from either low efficiency or low polarization. In the second part of this presentation, we follow a nanophotonic route to enhance circularly polarized emission capable of enhancing both the emission intensity and the degree of polarization. We introduce a Drexhage experiment for valley polarization, where we control the distance between a WS_2 bilayer and a mirror using dielectric spacers. Our experiment achieves nearly complete control over valley-polarized emission at room temperature, with a degree of circular polarization varying from 0.1 to 0.75 at different distances. We characterize the lifetime of the polarized emitted photons and the angular radiation patterns. We interpret the results using a rate equation model and highlight the impact of distance and power-dependent polarization on valley dynamics, providing a new path to control valley polarization. Unlike complex arrays of nanostructures,[2] our Drexhage

experiment is a simple yet effective method to exert robust control over valley polarization by exploiting exciton dynamics. Our findings elucidate the spin-valley dynamics influenced by exciton-exciton annihilation.

Our results offer valuable insights into the dipolar nature of exciton emitters with valley polarization and their intrinsic evanescent fields. By understanding, controlling, and enhancing the circular polarization of light emitted by WS_2, our results open up new possibilities for spin-based nanophotonic and optoelectronic devices. Our findings have implications for applications such as polarization-controlled light on-chip and the development of valley-based technologies and integrated photonic devices.

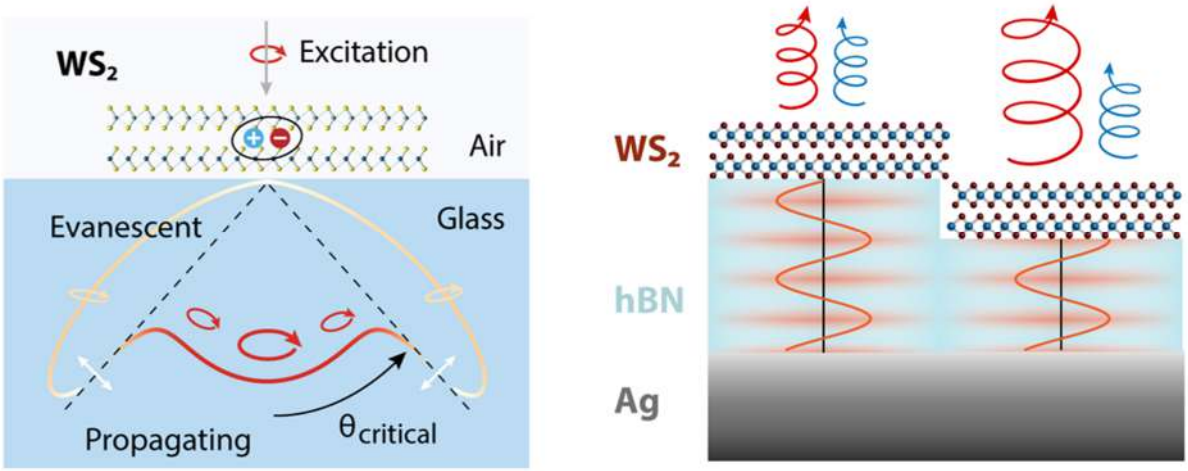

Figure 1. Polarization-resolved angular radiation patterns of few-layer WS_2 and enhanced valley-polarized emission near a mirror.

Abstract: We study how material-induced bianisotropy of hybrid nanostructures leads to resonant features in the optical response of both individual hybrid particles and metasurfaces composed of them. The excitation of quasi-bound states in the continuum in hybrid metasurfaces leading to spectral absorption bands is discussed.

Hybrid nanostructures promise to combine the beneficial properties of metallic nanostructures, such as strong confinement of electromagnetic energy, and dielectric nanostructures, such as high scattering directivity and low losses. Hybrid nanostructures, including their periodic arrays (metasurfaces), have already been extensively studied theoretically and experimentally [1]. The use of hybrid metasurfaces for refractive index sensing with high sensitivity was proposed in [2]. Reconfigurable hybrid metasurfaces incorporating phase transition material into meta-atoms [3] and hybrid metasurfaces with broken out-of-plane symmetry [4] have been recently proposed for efficient control of light properties.

In this work the features of optical properties of hybrid silicon-gold nanodisks are studied, demonstrating that internal material inhomogeneity can lead to a strong bianisotropic response of the particles associated with the distortion of their inversion symmetry. A method for obtaining information on the structure of the dipole polarizability tensor of hybrid particles based on the analysis of symmetry properties and the multipole composition of their eigenmodes is discussed. The spectral response of metasurfaces composed of such particles, in turn, can have narrow resonance features associated with resonant multipole coupling and excitation of quasi-bound states in the continuum (BICs). It is shown that these resonance features strongly depend on the polarization of incident waves and are accompanied by an increase in absorption and field enhancement in the plane of the metasurface. It is also shown that, using a special procedure for determining (tuning) the period of the metasurface, it is possible to implement switching control of the excitation of quasi-BICs of magnetic and electric types by changing the only polarization of the incident wave.

Thus, it was found that, unlike purely dielectric metasurfaces, quasi-BIC excitation in hybrid metasurfaces leads to the resonant absorption of light. Under the resonant absorption, strong electromagnetic fields are concentrated in the dielectric part of the hybrid metasurface particles, providing contribution into transmission and reflection. Multipole analysis of reflection showed that, depending on the polarization of the incident wave, its suppression can be associated with the anapole effect and the Kerker effect. In the case of hybrid structures, information about the distribution of near electromagnetic fields is of particular importance, as it reveals new possibilities for manipulating light energy on subwavelength scales by combining resonances of the plasmonic and dielectric parts. For the practical implementation of hybrid structures, it should be possible to use several methods specially developed for obtaining hybrid particles of various shapes [5,6].

Abstract:

Wavelength-selective light absorbers, emitters, or spectroscopic energy transducers for light, are widely utilized in our society by providing wide variety of applications in lighting, solar energy harvesting, remote sensing, and label free bio-sensing. With the combination of novel and efficient phosphor materials and simple micro- and nano-architectures, such as Fabri-Perot resonator[1,2] and whispering gallery resonatores[3], and polaritonic grating absorbers[4], one can engineer spectroscopic feature in wavelength conversion and light amplification which will be useful for lighting application and photonic encryption.

Fluorescent carbon dots/carbonized polymer dots (CDs/ CPDs) are promising materials that exhibit unique luminescence in the visible-to near-infrared wavelength region. These metal-free novel phosphor materials have gained significant interest because of their unique optical properties, photo stability, low cost, and low toxicity, thus being utilized in widespread applications in various fields, including optoelectronic devices. Owing to the limitations of rare-earth elements and heavy toxic effects of chalcogenides and perovskite quantum dots on the environment and biological systems, researchers have started focusing on CDs/CPDs to overcome the drawbacks of conventional phosphor materials.

In this talk, we introduce some of our recently developed light-emitting devices combining metal-free carbogenic phosphors and DBR based microcavity as well as microbeads for controlling the sharp resonant emission and chromaticity via wavelength-selective photoluminescence as well as lasing and infrared emission. By adopting Fabri-Perot structure with two dielectric multilayer-photonic mirrors, we could realize light amplification in the blue wavelength region. We could also observe whispering gallery mode from the CPDs in the visible to the red and finally in the near infrared region. These proposed devices in this study will open a new avenue for potential applications in chromaticity-tunable white light emitters, lasers[5], spectroscopic authentication, and single-microparticle-based chemical/bio sensing.

Abstract: gold-assisted exfoliation techniques yield large-area monolayers of 2D materials on gold films, but transferring them to final substrates remains challenging. This innovative approach enables the effortless exfoliation of millimeter-sized 2D materials onto arbitrary substrates, providing an efficient and refined solution for large-area transition metal dichalcogenide exfoliation.

Semiconducting transition metal dichalcogenides (TMDCs), such as MoS_2 and WS_2, have emerged as promising candidates for next-generation optoelectronic devices, owing to their remarkable electronic and optical properties. They exhibit room-temperature excitonic effects and, when thinned down to a three-atom-thick monolayer, exhibit direct-gap semiconducting band structure, making them an excellent playground for exploiting light-matter interaction at the nanoscale.

Many methods have been developed to fabricate monolayer flakes of TMDCs. Scotch-tape exfoliation from bulk crystals yields high-quality monolayers flakes, but their lateral size rarely exceeds few micrometers. Chemical vapor deposition techniques can yield large-area flakes, but they often suffer from homogeneity issues, and it is difficult to reproduce the same recipe on different deposition furnaces.

Recently, gold-assisted exfoliation has emerged as a reliable technique for peeling off large-area TMDC monolayers from bulk crystals. Indeed, the strong affinity between gold and chalcogens overcomes the van der Waals interlayer attraction, thus peeling off the outermost layer from the bulk TMDC. However, the use of a conducting substrate like gold often limits the subsequent application of the 2D semiconductor. Therefore, several strategies have been developed so far to eventually transfer the gold-exfoliated monolayer to another substrate [1]. These methods, however, require lengthy and complex procedures, involving multiple chemical treatments and strict substrate compatibility constraints.

Our work represents a significant improvement of the technique proposed by Liu et al. [2] and refined by Petrini et al. [3]. We adopt from these works the use of thermal release tape to pick up the gold film and bring it into contact with the bulk crystal. We simplify the process and extend its applicability, enabling both exfoliation and deterministic transfer of large-area monolayer TMDCs onto virtually any substrate. The key innovation in our method is the introduction of a sacrificial, mechanically constraining layer during the critical tape-release step. This enhancement enables controlled exfoliation, yielding high-quality flakes with minimal defects and large lateral dimensions, while requiring limited experimental effort and using common consumables.

In our work, we show the applicability of our novel exfoliation method to the production of millimeter-size MoS_2 monolayers on SiO_2/Si, fused silica, and PDMS substrates. We assess sample quality and morphology using XPS, Raman, and photoluminescence spectroscopy, and imaging spectroscopic ellipsometry. Figure 1 shows the thickness maps obtained by means of imaging spectroscopic ellipsometry, displaying large-area

monolayer flakes on various substrates. Finally, using samples produced on PDMS substrates, we demonstrate the possibility of systematically transferring the produced samples onto a desired target with micrometer control of the sample positioning. The deterministic transfer process allows us to achieve large-area even on fragile substrates, such as silicon nitride membranes for transmission electron microscopy.

This optimized gold-assisted method provides a simple and reproducible pathway to produce large-area 2D TMDs, opening new possibilities for their integration into advanced nanoelectronic and photonic systems.

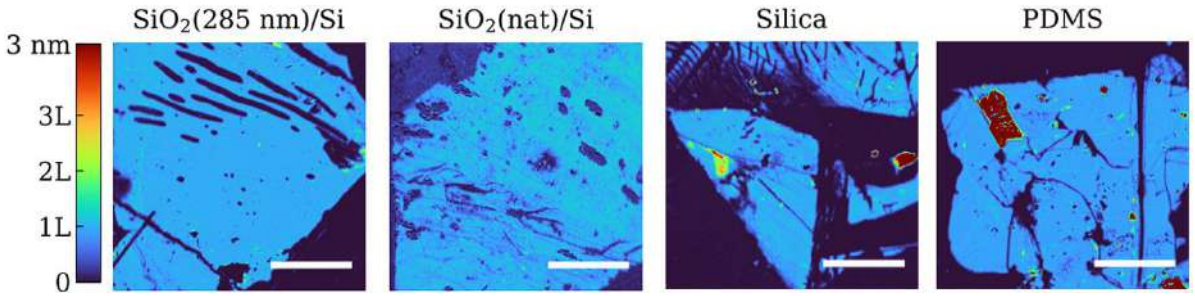

Figure 1. Thickness mapping by means of imaging spectroscopic ellipsometry of the exfoliated samples on various substrates. Large-area monolayer (1L) MoS_2 covers most of the image area. Scale bar: 300 μm.

Design of Broadband Multilayer Metamaterials Based on Genetic Algorithm and Neural Network

Kotaro Kajikawa
Institute of Science Tokyo, Japan
Corresponding author: kajikawa@ee.e.titech.ac.jp

Abstract: I report on the design of broadband multilayer metamaterials based on genetic algorithms (GA) or a combination of GA and neural networks (NN). With many unknown parameters, preparing a dataset for NN is impossible within a realistic time scale. Thus, GA is a good choice for the design.

It is essential to design metamaterials with the desired functions. Using machine learning, it is possible to find such structures. Machine learning is relatively accurate and fast when we use it for metamaterial design. Our research group has conducted structure searches using genetic algorithms (GA) and optical response calculations using neural networks (NN) [1]. Once a dataset is constructed, fast calculations using NN are possible, and inverse design becomes possible by combining it with methods for solving linear programming problems, such as the simplex method. On the other hand, it has been found that combining GA and NN makes it possible to perform fast GA calculations.

In my talk, I will discuss the design of broadband multilayer metamaterials. These metamaterials include optical cloaking, millimeter-wave absorbers, and sky radiators. We have found a cloaking structure covering the visible light region [2]. Most cloaking reported so far has operated in relatively narrow bands, but we have achieved this by appropriately designing a multilayer structure with around 30 layers. Similar broadband metamaterials also proved effective in the design of millimeter-wave absorbers, and we designed a thin (less than 0.5 mm-thick) with a simple metamaterial structure that covers the entire W-band (75-110 GHz) [3]. These methods can also be applied to the design of radiative cooling materials, and we designed highly efficient multilayer metamaterials.

This work was partly supported by JST CREST (MJCR22B4).

Surface Acoustic Wave Stimulated Brillouin Scattering

Moritz Merklein

The University of Sydney, Australia

Abstract: Stimulated Brillouin scattering (SBS) is a third-order nonlinear optical effect that describes the coherent coupling between acoustic and optical modes. SBS has a linewidth in the Megahertz to tens of Megahertz, is optically induced and frequency tunable, and hence ideal for optical signal processing applications such as filter, phase-shifter and delay schemes. Furthermore, the ability to generate strong SBS in integrated photonic circuits opens a pathway toward all-optical signal processing in a small footprint. Inducing SBS on a photonic chip comes with its own challenges, however, as the integrated waveguides need to guide optical and acoustic modes simultaneously to enable strong interaction. In this talk, I will introduce a new type of on-chip SBS interaction that harnesses surface acoustic waves (SAWs). Those acoustic waves are travelling along the surface of the waveguide rather than in the waveguide core. Surface acoustic wave stimulated Brillouin scattering (SAW-SBS) opens a path toward exploring new material platforms and applications arising from the exposure of the SAWs to the surroundings of the waveguide.

Permittivity-driven ultrafast photonic bound states in the continuum

A. Tittl[1]

[1]Nanoinstitute Munich, Faculty of Physics, Ludwig-Maximilians-Universität München, 80539 Munich, Germany
*corresponding author: Andreas.Tittl@physik.uni-muenchen.de

Abstract: Permittivity-driven bound states in the continuum enable all-dielectric metasurfaces that overcome geometrical symmetry-breaking limits. Recent demonstrations reveal high-Q resonances with exceptional spectral control, dynamic tunability with electro-optical polymers, and all-optical generation via ultrafast pulses, enabling promising applications in adaptive photonics and high-speed modulators.

All-dielectric metasurfaces supporting photonic bound states in the continuum (BICs) have emerged as a transformative platform for manipulating light-matter interactions at the nanoscale. They are able to confine light with exceptionally high quality (Q) factors and significant near-field enhancements, enabling a diverse array of applications, including ultrasensitive biospectroscopy, catalytic detection, enhanced photon emission, and strong polaritonic coupling, all of which benefit from the precise control over resonance properties that BICs provide. Traditionally, BIC-driven metasurfaces have achieved tailored resonance characteristics by breaking the geometrical symmetry of their unit cells, transitioning symmetry-protected BICs into quasi-BIC (qBIC) modes that couple to the far field. While effective, this method is constrained by challenges such as the precision required in nanofabrication, the smallest achievable asymmetry limited by atomic scales, and the inherent difficulties in achieving dynamic tunability post-fabrication.

Here, I will present our recent advancements in realizing permittivity-asymmetric BICs (ε-qBICs), an innovative approach that introduces permittivity variations within geometrically symmetric unit cells. This strategy overcomes the limitations of geometrical symmetry breaking, offering enhanced flexibility and new degrees of freedom for resonance control and nanoscale light manipulation. I will begin with the fundamentals of ε-qBICs, establishing that symmetry-protected qBICs can be induced by breaking the in-plane permittivity symmetry of a metasurface's unit cell, rather than its geometry [1]. Using theoretical analysis and eigenmode expansion, we derive a Fano-shaped transmittance formula, revealing that ε-qBICs emerge when permittivity asymmetry disrupts the conditions sustaining a true BIC. A key finding is the inverse-square dependence of the radiative Q-factor on the permittivity asymmetry parameter ($\Delta\varepsilon/\varepsilon$), validated through numerical simulations of a metasurface with paired resonators of differing permittivities. These findings highlight the complete equivalence of ε-qBICs to geometrically asymmetric qBICs in their optical response, near-field distributions, and Q-factor tunability. Importantly, permittivity modulations (which can be achieved, e.g., through minute refractive index changes via carrier doping or electro-optical effects) can access asymmetry regimes beyond the reach of geometrical fabrication limits, where angstrom-level accuracy would be needed to reach asymmetries below 10^{-4}. ε-qBICs in the near-infrared were demonstrated using a multi-material metasurface, where the unit cell consists of geometrically identical resonators with a give permittivity contrast between Si and TiO_2.

Building on static ε-qBICs, I will present their dynamic tunability using an electro-optically active polymer [2]. This study introduces environmental symmetry breaking by embedding identical TiO_2 nanorods in contrasting refractive index media: one in PMMA ($n \approx 1.5$) and the other in air or polyaniline (PANI). The integration of PANI, grown in-situ via electrochemical polymerization, enables electrically reconfigurable ε-qBICs. By applying voltages from -0.2 V to +0.6 V, the refractive index of PANI can be precisely tuned,

modulating the asymmetry parameter (Δn) and thus the resonance properties. Experimental results show a pronounced ON/OFF switching capability in transmittance spectra, as well as rapid switching speeds (rise time 12.2 ms, fall time 18 ms) and exceptional durability over 1000 cycles, attributed to PANI's stable electron redistribution properties. This approach enhances the metasurface's responsiveness to environmental perturbations, offering millisecond-timescale control over resonance position and linewidth, applicable to adaptive optical devices.

Subsequently, I will showcase the all-optical generation of ε-qBICs using ultrashort laser pulses [3]. We demonstrate the creation of transient ε-qBICs in an unstructured 45 nm amorphous silicon (a-Si) thin film by interfering two 180 fs laser pulses at an angle, creating a periodic permittivity modulation via carrier excitation in the bright fringes. Pump-probe experiments revealed a Fano-shaped resonance with >30% transmittance modulation, tunable across the near-infrared by varying the pump wavelength and interference angle. Resonances with high Q factors up to 80 and decay times in the ps range could be generated, and additional control over the resonance properties could be obtained via the pump power. Furthermore, we show that all-optical ε-qBICs can carry out photonic functionalities by demonstrating a >200% enhancement of third-harmonic generation (THG) at around 345 nm when the fundamental beam at 1020 nm aligns the ε-qBIC resonance wavelength. This lithography-free method provides spectral, linewidth, and temporal control, extending to ultrafast near-field enhancement applications.

Finally, I will present our latest research on the realization of temporal symmetry-breaking in BIC-driven metasurfaces via ultrafast optical pumping [4]. We introduce the new concept restored of symmetry-protected bound states in the continuum, which arise in metasurfaces with *geometrically asymmetric* unit cells, where the total dipole moment (composed of two antisymmetric dipoles) is precisely engineered to cancel out, effectively restoring photonic symmetry despite the structural asymmetry. Mie-resonant optical absorption within specific regions of the unit cell locally modifies the refractive index, disrupting the balance between the two dipole moments, which provides ultrafast control over the radiative loss channel of the metasurface and allows precise adjustment of the resonance linewidth, near-field enhancement, and resonance amplitude. We experimentally demonstrated resonance broadening (ΔQ = 100, a change of 25%), resonance sharpening (ΔQ = 150, a change of 150%), and resonance creation and annihilation on 300 fs timescales. These advancements significantly enhance the dynamic tunability of ε-qBICs and pave the way for transformative applications, such as high-speed optical modulators, ultrafast optical switches, and next-generation devices for optical computing and communication.

Overall, ε-qBICs provide a promising new paradigm for the design and functionality of all-dielectric metasurfaces and unlock new possibilities for static and dynamic light manipulation, with profound implications for next-generation photonic technologies.

Enhanced Sensing with Ultrastrong Coupling Condition

Wen-Hui (Sophia) Cheng[1,*], Alexis Angelo R. Garcia[1], Cheng-An Mao[1]
[1] National Cheng Kung University, Taiwan
[*]corresponding author: wcheng@gs.ncku.edu.tw

Abstract: Raman spectroscopy can detect molecules through their vibrational modes, and its efficiency is enhanced by localized electric field. The proposed ANA heterostructure, combining gold nanoparticles and nickel oxide, achieves ultrastrong coupling and significantly improves Raman sensing, demonstrating over 20-fold enhancement for tetracycline detection.

Raman spectroscopy has been effectively employed to detect molecules based on their specific vibrational modes. However, the efficiency of this process is often limited and significantly influenced by the local electric field. In confined metallic nanostructures, oscillations in the electric field can induce localized surface plasmon resonances (LSPR), which can substantially enhance the electric field. This enhancement results in a stronger Raman signal, a phenomenon known as surface-enhanced Raman scattering (SERS). To further improve light-matter interactions, we aim to achieve electromagnetic coupling between the LSPR in metals and the cavity modes in dielectric materials. We propose a heterostructure consisting of gold nanoparticles (Au-NPs), p-type nickel oxide (p-NiO), and an Au film—collectively referred to as the ANA structure. This design intends to establish strong coupling effects to enhance Raman sensing capabilities. We have designed and simulated this structure to optimize its optical benefits. The heterostructure has been experimentally realized through air-liquid interface self-assembly, successfully achieving the conditions for ultrastrong coupling with a Rabi splitting energy surpassing 650 meV. The emonstration of tetracycline molecules sensing using the ANA structure showed more than 20-fold improvement compared to the bare substrate. These findings underscore the promising potential of plasmonic hybrid platforms, which can be further refined for enhanced sensing applications.

Abstract: We present a self-illuminating plasmonic biosensor using quantum tunneling-driven light emission for label-free biomolecule detection. Integrating a plasmonic metasurface with a metal-insulator-metal tunnel junction removes the need for an external light source. Experiments confirm detection of nanoscale organic and biological coatings via refractive index changes, advancing compact biosensing platforms.

Introduction. Plasmonic nanostructures have gained substantial attention in optical sensing due to their ability to generate strong optical field enhancements and confine light at the subwavelength scale [1]. These properties have led to the development of biosensors with significantly improved detection capabilities compared to conventional optical sensors [2]. Traditional surface plasmon resonance (SPR) sensors rely on external light sources, requiring bulky optical components that limit their portability and ease of integration into miniaturized platforms.

To address these limitations, we propose a self-illuminating plasmonic biosensor that eliminates the need for external light sources. Our device utilizes a metal-insulator-metal (MIM) tunnel junction integrated with a plasmonic metasurface, enabling intrinsic light generation through inelastic electron tunneling [3-6]. The emitted light is coupled to plasmonic modes, resulting in enhanced sensitivity for biosensing applications.

Results. The plasmonic metasurface layer acts as a transducer, outcoupling plasmons excited by inelastic electron tunneling to far-field light emission. In addition to supporting optical plasmonic resonances, the conductive metasurface serves as electrical contact layer for charge transport. We optimized the sensor design and fabrication process to provide uniform emission over a large area under an applied voltage of 2.4 V, producing a total collected optical power of 40 pW, making it feasible for practical sensing applications. Angle-resolved spectroscopy revealed the presence of plasmonic lattice modes that strongly influence electroluminescence emission spectra. These modes convert plasmon-polaritons, excited through inelastic

electron tunneling, into photons at specific wavelengths and angles, dictated by their dispersion characteristics. Notably, the electric fields of these lattice modes are highly localized at the tops of the gold resonators, providing optical sensing capabilities. To evaluate the biosensing capability, we tested with several analytes including thin polymer layer and biofilms and showed its performance is already comparable to state-of-the-art passive nanoplasmonic biosensors.

Conclusion. By leveraging quantum tunneling and plasmonic nanoantennas, our sensor provides a compact and efficient platform for biochemical detection. This approach enables label-free biosensing with high spatial resolution, offering significant potential for integration into next-generation diagnostic devices. The demonstrated high sensitivity and stability make it a promising candidate for real-world applications in medical diagnostics and environmental monitoring.

Characteristics of optical chiral fields around nanostructures revealed by scanning near-field optical microscopy

Kohei Imura[1*]
[1]Department of Chemistry and Biochemistry, School of Advanced Science and Engineering, Waseda University, Japan
[*]corresponding author: imura@waseda.jp

Abstract: Optical chiral density is amplified near the gold and dielectric nanostructures. We investigate the optical chiral field near the nanostructure by using apertured near-field optical microscope and reveal that the unique spatial characteristics of the optical chiral field are induced depending on the elementary mode excited.

Nanomaterials exhibits unique optical properties due to light confinement capability. Optical fields are enhanced in the vicinity of the nanomaterials. For metal and dielectric nanoparticles, plasmons and Mie resonances are excited, respectively, and optical field is confined near the particle. These resonances provide strong light-matter interaction. Recently, localized near-fields induced in these materials are utilized for enhancement of chiral responses. Chiral signal of molecules is detected by the difference in absorbance between left- and right-circularly polarized light and is in general very small compared to the absorption signal. This originates partly from the fact that the spatial scale of the molecules is much smaller than that of the light. Spatial scale of the near-field in the nanomaterials becomes comparable to that of light, and therefore scale mismatch between the material and light is compensated. Since the optical near-field is enhanced in these materials, the plasmon and Mie resonances are promising for enhancing the optical chiral responses.

In order to amplify the chiral responses, understanding of the near-field is essential. Spatial scale of the localized field is smaller than the diffraction of light, nanoimaging techniques are indispensable for visualization. Near-field imaging technique overcome the diffraction limit and utilize for this purpose. We have been developing various near-field imaging techniques to visualize plasmon modes and plasmonic optical fields in gold nanoparticles.[1] For instance, by combining the aperture near-field apparatus with phase stepping method, near-field reflection spectroscopy is demonstrated.[2] This imaging technique is applicable to transparent sample as well as opaque one. By analyzing the transmission and reflection signals, absorption and scattering properties are able to be obtained at the same time.[3] These properties are crucial for deeper understanding control of the optical properties.[4,5] We also developed three-dimensional near-field imaging technique to visualize spatial extension of the near-field signal and revealed that the light confinement capability depends on the plasmon mode excited.[6,7] In this study, we have investigated the optical chirality near gold and Si nanostructures by using the three-dimensional near-field imaging. We also performed electromagnetic field simulation to reveal the physical origin of the observed near-field properties.

Gold nanoparticles were synthesized chemically. Si nanoparticles were prepared by laser ablation of the Si substrate. The particles were dispersed onto glass substrate for near-field imaging. Aperture near-field optical microscope is used for locally illuminating sample, and transmitted light was detected. For three-dimensional imaging, distance between the near-field probe tip to sample surface was regulated from 10 to several hundred nm. For chiral optical imaging, incident light is adjusted to be linearly polarized at the aperture of the near-field probe, and circularly polarized components in the transmission light are detected by using a quarter waveplate and a polarizer.

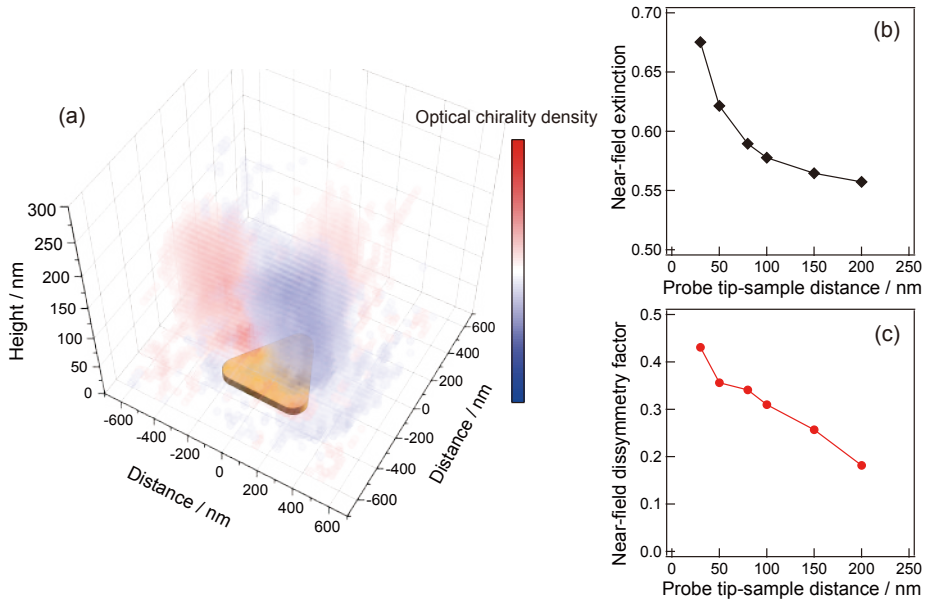

Figure 1. (a) Reconstructed three-dimensional chiral optical fields near the gold nanoplate. (b,c) Near-field probe tip-sample distance dependence of the near-field extinction and dissymmetry factor, respectively.

Figure 1(a) shows the three-dimensional chiral optical field near single gold nanoplate.[8] We found that the sign of the chiral signals varies at the left and right side of the plate. We also examine steric extension of the near-field extinction signal in Fig. 1(b) and the chiral signal in Fig. 1(c) and found that the spatial extension of the near-field extinction decays faster than that of the chiral signal. To revel the physical origin of the difference, we performed electromagnetic field calculation of the chiral field by assuming the reciprocity of light propagation. Simulated distance dependencies of the near-field signal are well reproduced. We also examine spatial distributions of the electric and magnetic field. Near-field extinction is well correlated to the local electric field, while the chiral field is correlated to both the magnetic and electric field. We reveal from these simulations that the difference originates from the calm distribution of the magnetic field compared to those of the electric field. We have studied the near-field properties of the Si nanoparticle and found unique near-field characteristics. We will discuss the details at the conference.

Abstract: Multi-photon lithography (MPL) enables high-resolution 3D structuring using hybrid photoresists. The presence or absence of photoinitiators affects fabrication and application. Post-processing techniques, including selective coatings and heat treatments, enhance functionality without altering the material's chemistry. This work explores material characterization and post-processing strategies for advancing MPL.

The interaction between light and matter has driven significant advancements in manufacturing, particularly through femtosecond laser-based techniques [3]. Among these, MPL has emerged as a powerful tool for fabricating intricate 3D micro- and nanostructures with sub-micron resolution. MPL relies on multi-photon absorption (MPA), where two or more photons are simultaneously absorbed to induce polymerization or chemical transformations in a photoresist. The success of this process depends on the careful design of materials that exhibit high optical sensitivity, efficient cross-linking mechanisms, and precise control over photopolymerization [2].

Hybrid photoresists, consisting of both organic and inorganic components, are widely used in MPL due to their low shrinkage when processed with ultrafast laser radiation. However, their potential extends far beyond this advantage. The presence or absence of a photoinitiator (PI) in the photoresist—a molecule that generates reactive species upon photon absorption—significantly influences fabrication thresholds, resolution, processing speed, and the ultimate functionality of the 3D-printed structures [5]. While conventional PIs enhance polymerization efficiency, they often introduce challenges such as high fluorescence, and coloration, limiting their use in biomedicine and micro-optics. On the other hand, these properties can be beneficial for applications such as fluorescent microscopy and bio-imaging. Understanding the linear and nonlinear optical properties of hybrid materials and PIs is therefore essential for optimizing their performance [6]. These insights can guide the selection of appropriate MPL wavelengths beyond the conventional ~800 nm, potentially improving excitation efficiency through higher two-photon cross-sections.

Furthermore, the inclusion or exclusion of a PI alters the chemical composition of the hybrid photoresist, introducing constraints during both the MPL process and the final 3D printed object. To address such limitations, post-processing techniques have expanded the versatility of MPL, enabling functionalization of fabricated structures. For instance, selective coatings have unlocked new applications in optics, biosensing, and photonic

devices. Additionally, integrating MPL with metamaterials offers exciting opportunities for nanophotonics, sensing, and tunable optical components [4].

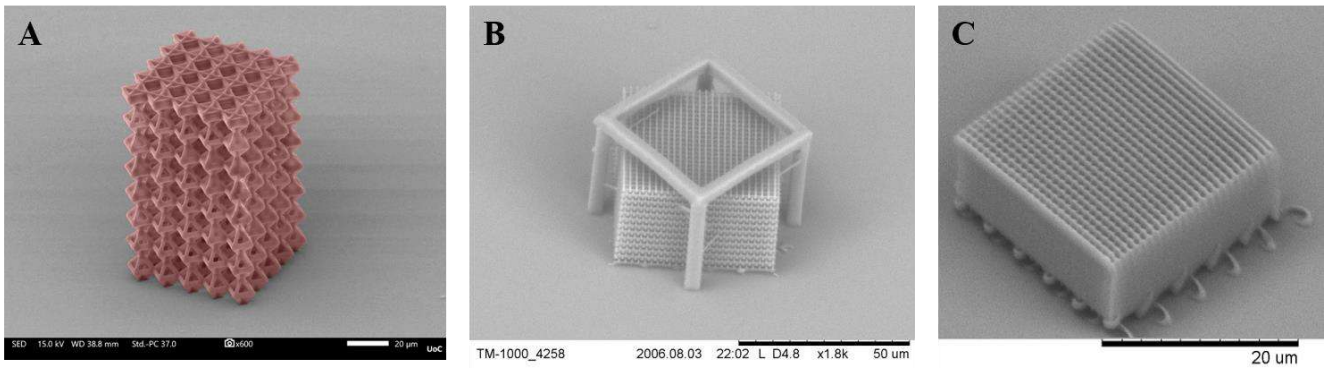

Figure 1 3D microstructures fabricated via MPL with **A.** a new-lab-made low-fluorescent PI, with red intrinsic coloration, onto the hybrid SZ2080^{TM}, **B.** hybrid SZ2080^{TM} dopped with Ytterbium and calcinated in 1200^{o} and **C.** hybrid SZ2080^{TM} without PI using 1035nm laser source

Emerging post-processing methods, such as heat treatments, further extend MPL's capabilities [1]. Calcination—a process that removes the organic fraction of a structure—and pyrolysis—the heating of organic material in the absence of oxygen—enable the fabrication of purely inorganic materials at micro- and nano-scales. These techniques provide a means to enhance the functionality of MPL-fabricated structures without chemically altering the hybrid photoresist itself.

This work highlights the versatility and suitability of hybrid photoresists in MPL, emphasizing the importance of material characterization in optimizing process parameters for diverse applications. Additionally, it explores post-processing pathways that enable functionalization of 3D-printed structures while preserving the fundamental properties of the hybrid photoresist.

Abstract: A molecular dynamics study revealed that functionalized gold nanoparticles are able to form stable complexes with Channelrhodopsin-2, without disturbing the protein structure and dynamics. The results pave the way for exploiting the polaritonic properties of nanoparticles to tune the photoactivity of light-gated ion channels in a controlled way.

Optogenetics, using light-sensitive proteins like Channelrhodopsin-2 (ChR2), is a powerful tool for manipulating neural activity [1]. ChR2's function relies on light-induced retinal isomerization, triggering ion channel opening [2]. Metal nanoparticles (MNPs), particularly gold nanoparticles, have been explored in optogenetics to enhance light penetration, to increase specificity, and to improve photothermal effects [3]. Interestingly, MNPs also have the potential to influence the photochemistry of photo-reactive systems like ChR2 through polaritonic effects, where strong coupling between molecular electronic excitations and localized surface plasmons on the MNPs creates polaritonic potential energy surfaces [4]. This work uses molecular dynamics (MD) simulations to investigate the interaction between ChR2 and a small hydrophobic-coated Au25 nanoparticle (NP) as a first step towards identifying configurations suitable for strong coupling and future quantum mechanical investigations of the NP-ChR2 system's response to electromagnetic excitation. The goal is to develop plasmon-mediated optogenetic tools with enhanced capabilities through the exploitation of computation-based polaritonic chemistry [5]. In this study, MD simulations are performed to investigate the dark state of a ChR2 dimer (with all-trans retinal), both alone and interacting with a hydrophobic thiol-protected gold NP.

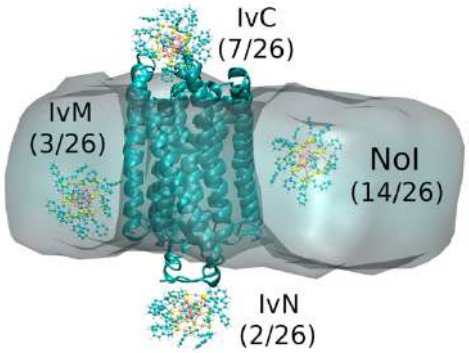

Figure 1. Representation of NP-ChR2 interaction sites: IvC, interacting via C-terminal; IvN, interacting via N-terminal; IvM, interacting via membrane; NoI, non-interacting. The numbers in parentheses indicate the fraction of MDs exhibiting the specific interaction.

By varying the initial relative positions of the protein and the NP, the spontaneous formation of a stable NP-ChR2 complex is observed at different protein sites in about 50% of the simulations (Fig. 1).
Importantly, the interaction with the NP does not significantly perturb the protein: the analyses performed indicate that the structural stability, the conformational dynamics, the content of water in the protein interior as well as crucial interactions inside the retinal binding cavity are not significantly affected by the presence of the nanoparticle. However, more subtle changes in the retinal binding cavity are observed, suggesting that NPs can be able to affect ChR2 photochemistry. These results open the way for the development of novel optogenetic tools that exploit direct effects such as a plasmon-mediated tuning of the photoactive protein activity.

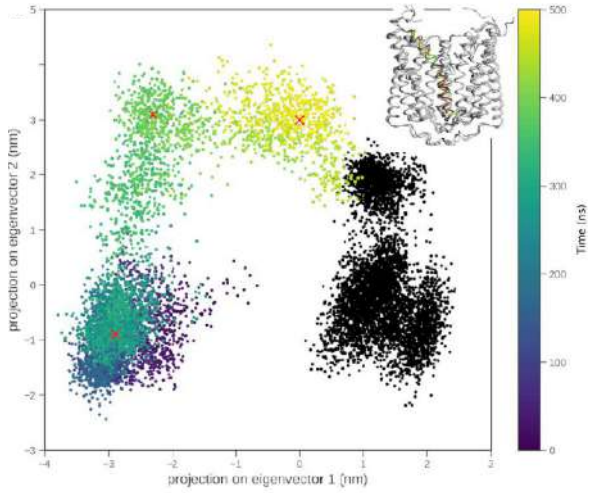

Figure 2. Projection of the trajectories without NP (black) and IvM2 (colored according to time) on the plane of the first two eigenvectors of the alfa-carbon covariance matrix. The red crosses mark densely populated regions from which representative structures are extracted.

Abstract: This paper introduces a novel design for passive, multifunctional metasurfaces that enable dynamic functionalities like beam steering and holographic imaging. Using neural network-driven optimization, these metasurfaces provide adaptable solutions for high-frequency wireless communication systems without the need for active components, offering a scalable, cost-effective approach for next-generation networks.

The rapid and unprecedented growth of wireless communication technologies has led to a significant increase in the number of connected devices. Projections suggest that next-generation wireless systems (6G and beyond) will achieve ultimate connectivity by integrating humans and machines, giving rise to a new “Internet of Everything” era, with an expected number of connected devices near 500 billion by 2030—far surpassing the projected world population of 8.5 billion by that time. Additionally, the increasing demand for data and higher speeds is driving the need for more bandwidth, pushing the limits of the microwave spectrum traditionally used for wireless communications. As a result, the microwave range's limited bandwidth struggles to meet both current and future demands effectively [1], [2].

To overcome these constraints, there is a shift toward higher frequencies such as millimeter-waves and terahertz, which naturally offer broader bandwidths for high-speed data transmission and are already integrated into next-generation communication systems [1], [2]. In this context, metasurfaces are emerging as a transformative solution for wireless communication devices, thanks to their ability to manipulate electromagnetic waves at subwavelength scales. This capability enables the development of compact, highly efficient, and adaptable devices that can address the challenges posed by future communication systems [3].

The integration of metasurfaces into wireless communication systems has led to the concept of Smart Walls, which are closely related to Reconfigurable Intelligent Surfaces (RIS) [4]. These Smart Walls turn passive surfaces into active components that manipulate electromagnetic waves to optimize signal propagation, enhance coverage, and improve overall system performance. By embedding intelligent metasurfaces into building walls or other structures, Smart Walls become integral to communication systems, enabling them to steer, focus, and modulate signals to meet the demands of modern wireless networks.

Current research is heavily focused on implementing RIS with dynamic responses, often relying on active components like PIN diodes, MEMs, liquid crystals, and varactors [4]. While these devices can be reconfigured in real time, they face significant challenges when operating at higher frequencies, particularly in millimeter-wave and terahertz ranges. These challenges include high insertion losses and limited availability, which hinder the practical implementation of RIS-based Smart Walls at these frequencies.

In response to these issues, we propose a novel approach that leverages non-reconfigurable metasurfaces with multifunctional capabilities. These passive metasurfaces exploit parameters such as polarization, angle of incidence, and frequency to achieve dynamic functionalities without the need for active components or complex control systems. By manipulating one or more parameters of a single illumination source, these passive metasurfaces can provide responses such as beam steering, focusing, and holographic imaging, simplifying the design and implementation of adaptable communication systems for high-frequency applications.

In this communication, we introduce a multifunctional metasurface design that can produce different outputs depending on illumination conditions. The required phase distribution for each response is calculated using a combination of established analytical methods and optimization techniques driven by neural networks. Neural networks optimize the metasurface design, enabling it to integrate multiple functionalities within a compact structure while maintaining high efficiency, low losses, and reliable performance across diverse conditions.

Ultimately, we show that by incorporating intelligence into the illumination system instead of the metasurface itself, we can create passive, adaptive smart walls with the potential to revolutionize wireless communication. This strategy provides a scalable, cost-effective solution while redefining the future of wireless infrastructure and reshaping our approach to next-generation networks.

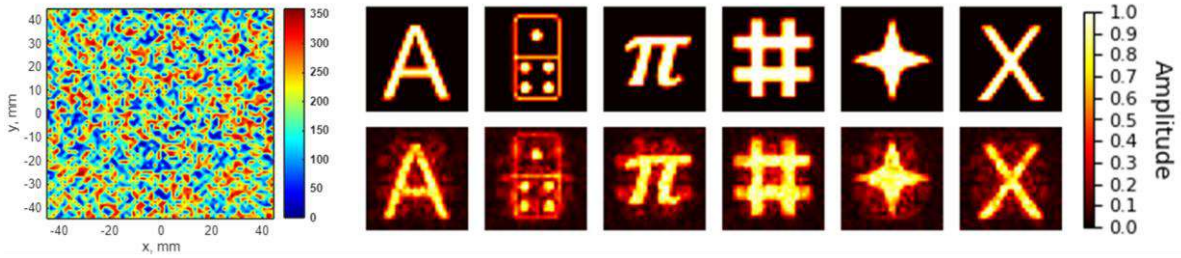

Fig. 1. (a) Phase distribution of the metasurface designed using the proposed neural network architecture. The design exhibits significant phase variability, enabling up to six distinct responses by modifying the illumination conditions. (b) Model convergence and performance after 10,000 epochs. The first row presents the original dataset, while the second row shows the predicted outcomes generated by the trained neural network, exhibiting minimal deviation and high precision.

Abstract: We present results that shed light on a quantum system's scalar Aharonov-Bohm (AB) phase and how the effect can be measured. We show that the electric-scalar effect is the temporal dual of the vector-magnetic effect and propose a setup using a Faraday cage, where the observable is the modification of a quantum system's energy levels. For the scalar gravitational potential, we propose a quantum system in an eccentric orbit, which manifests as a temporal generalization of the gravitational redshift.

The Aharonov-Bohm (AB) effect is a quantum mechanical phenomenon where potentials, rather than classical fields, produce observable effects on a quantum system. The original electromagnetic version included both electric-scalar and magnetic-vector potentials[1]. While the magnetic-vector AB effect has been extensively tested due to the relative simplicity of its experimental setup, the scalar-electric AB effect remains elusive. The electric AB effect involves a geometric phase created over time by a time-dependent scalar potential without spatial variation. Despite its theoretical importance, a clean experimental realization of the this effect has yet to be achieved.

Recently, we proposed a novel temporal experiment, which uses a Faraday cage as shown in Fig. 1[2], offering a promising path toward the first clean measurement of the scalar-electric AB effect on a quantum system, such as an atomic clock or a qubit. The observable to determine the effect is the generation of sidebands in a manner similar to the AC Stark effect[2].

More recently, we developed for the first time a resonant microwave Faraday cage[3], capable of use for this experiment. The Faraday cage consisted of a cylindrical microwave cavity resonator, operating in the capacitor-like $TM_{0,1,0}$ mode, and excited

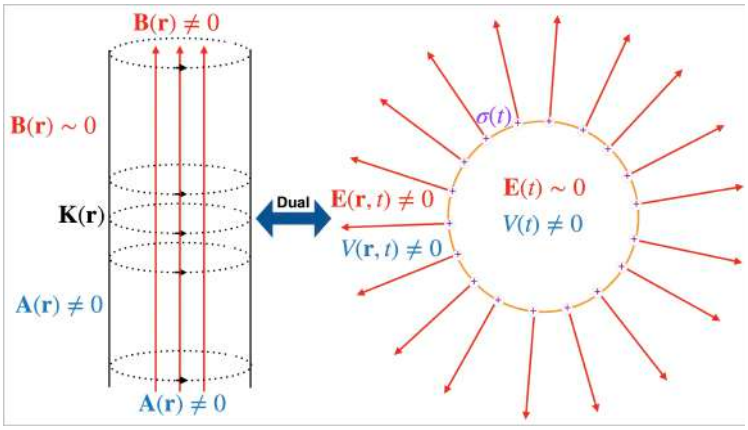

Fig 1. Comparison of magnetic AB setup (left) with the dual-electric AB setup (right). The former has been experimental proven to create a geometric phase shift on a quantum system due to the vector potential, **A**(**r**), while the magnetic field, **B**(**r**), is suppressed. In contrast, the latter has been predicted to create a temporal effect similar to the AC Stark effect due to the scalar potential, V(t), being non-zero inside a Faraday cage where the electric filed, **E**(t), is suppressed. The static magnetic AB effect has a azimuthal surface current density, K(r), at the solenoid boundary, compared to the electric AB effect which has a time-varying surface charge density, σ(t), at the Faraday cage boundary.

using an interferometric setup[3]. This novel design allowed precise manipulation of the electric field and potential within the resonator by adjusting the phase and amplitude in the two interferometer arms driving the system. Through fine tuning, a 25 dB suppression of the electric field at the resonance frequency was achieved, while simultaneously enhancing the time-varying electric-scalar potential. Under these conditions, the system exhibited a phenomenon analogous to electromagnetically induced absorption, caused by the cancellation of the electric field at resonance. This effect, may be regarded as a form of extreme dispersion, and has led to an order of magnitude increase in the cavity's phase response. This experimental setup is an example of a system that could be used to verify the electric-scalar AB effect.

More recently, the AB effect has been observed in the context of gravitational interactions using atom interferometry[4]. Additionally, recent predictions suggest that temporal variations in the phase of an electron wave function will induce modulation sidebands in the energy levels of a quantum-system, similar to the electric-scalar effect, solely driven by a time-varying scalar gravitational potential[5]. In this study, we considered an atomic clock as a quantum two-level system undergoing continuous Rabi oscillations between the electron's ground and excited state[6]. We assume that the photons driving the transition are precisely frequency-stabilized to match the transition, enabling accurate clock comparisons. Our analysis takes into account, that when an atom transitions from its ground state to an excited state, it absorbs energy, increasing its mass according to the mass-energy equivalence principle. Due to the mass difference between the two energy levels, we predict that an atomic clock in an eccentric orbit will exhibit a constant frequency shift relative to a ground clock corresponding to the orbit's average gravitational redshift, with additional modulation sidebands due to the time-varying gravitational potential. This type of experiment may be thought of as a temporal Pound-Rebka experiment[7].

Two-Dimensional Semiconductors for On-Chip Polarization-Sensitive Photodetectors

Marcos H. D. Guimarães[1]

[1]Zernike Institute for Advanced Materials, University of Groningen, The Netherlands
*corresponding author: m.h.guimaraes@rug.nl

Abstract: Optical communication of information through light polarization provides a viable route to overcome the interconnect problem in modern ICT architecture. In this talk I will show how atomically-thin semiconductors can be used for photodetectors with sensitivity to light polarization.

The continuous advancement of faster, smaller, and more energy-efficient electronic devices hinges on addressing two critical challenges: the energy inefficiency of interconnects, and the degradation of device properties at nanoscale dimensions. As the dimensions of front-end-of-line devices continue to decrease, the interconnects between them are also reducing in size, leading to smaller cross-sectional areas, leading to lower bandwidths and higher heat dissipation. While CPU and GPU performance is increasing by a factor of around 3 every two years, interconnect bandwidth is only increasing by a factor of 1.4. This is further aggravated by the constant need for information transfer between the data processing and storage units in a computer, a problem known as the von Neumann bottleneck. With this, energy demand is skyrocketing, with ICT projected to consume over 20% of the global energy by 2030. Additionally, the miniaturization of devices, now reaching feature sizes in the order of a few nanometers, leads to a steep decline in device properties due to small material imperfections, element interdiffusion, and relatively rough interfaces between two different materials.

In this talk I show how we can use 2D semiconductors as polarization-sensitive light detectors[1]. These atomically-thin devices can be used to read light information at fast time-scales and with high sensitivity. I will show how the Schottky barriers arising from the metal-semiconductor interfaces can play an important role in the response time and polarization sensitivity of 2D materials photodetectors. Additionally I will demonstrate how we can be fabricate lateral 2D heterostructures by laser writing, allowing for the design of all-2D circuitry for opto-electronics[2]. These $MoTe_2$-based photodetectors show significant improvement on the response time and responsivity, making this method a viable alternative for atomically-thin optoelectronic circuitry. Finally, I will discuss how strong crystalline anisotropy can be used to enhance the polarization contrast in the photocurrent response. In such crystals, we are able to achieve much stronger dichroic responses in photocurrent measurements than on optical reflectivity alone, indicating that the conductivity anisotropy plays an important role. Our works pave the way for the use of 2D materials in future photonic technologies.

Controlled Synthesis of Silver-Coated Gold Nanostars for Tunable Optical Properties

N. Pazos-Perez[1*]

[1]Department of Physical and Inorganic Chemistry, Universitat Rovira i Virgili, Tarragona, Spain
[*]corresponding author: nicolas.pazos@urv.cat

Abstract: This study explores the controlled epitaxial deposition of silver onto gold nanostars (NSts), enhancing their SERS properties while maintaining their branched morphology. The silver coating enables plasmon resonance tuning and boosts SERS brightness by an order of magnitude. These findings present silver-coated NSts as promising substrates for advanced plasmonic sensing applications.

Over the past decades, substantial research efforts have been dedicated to the development of plasmonic nanoparticles capable of delivering the highest possible surface-enhanced Raman scattering (SERS) intensities. Spherical gold and silver colloids have been extensively employed in SERS applications, but their inherent limitations often necessitate aggregation to generate localized electromagnetic field "hotspots," which are essential for achieving high SERS enhancement. While aggregation-based approaches can lead to exceptionally low detection limits, they suffer from inherent reproducibility issues, making them less reliable for practical applications. To address this challenge, strategies involving the controlled aggregation or assembly of nanoparticles into well-defined superstructures, such as core-satellite configurations,[1-4] have been widely explored. However, a key limitation of these constructs is that the hotspots formed between the plasmonic nanoparticles are often buried within the nanostructure, reducing accessibility to analytes and thus compromising their sensing efficiency.

An alternative approach to overcome this limitation is the use of individual nanoparticles that possess intrinsic hotspots, such as gold nanorods and nanostars (NSts).[5-7] Among these, Au NSts exhibit superior SERS properties due to their multiple sharp branches, each capable of sustaining highly localized and significantly enhanced electromagnetic fields at their tips. This unique structural feature provides multiple accessible hotspots directly at the nanostructure surface, ensuring both high SERS enhancement and efficient analyte interaction.

While gold nanostructures offer excellent chemical stability and tunability, silver nanoparticles are known to be optically more efficient due to their higher plasmonic activity. However, the controlled synthesis of anisotropic silver nanostructures remains challenging, limiting their widespread application in SERS-based detection. To overcome this issue, a well-established strategy involving the silver deposition onto preformed gold nanoparticles is commonly used.[8] This process not only preserves the high monodispersity and well-defined morphology of gold nanoparticles but also enhances their plasmonic response by exploiting the superior optical properties of silver. Although silver coating has been successfully applied to various gold nanoparticle morphologies, relatively few studies have focused on the deposition of silver onto gold NSts. Moreover, in most of the reported cases, silver growth occurs preferentially at the core of the NSts,[9] leading to morphological alterations that compromise the specific NSts features responsible for their exceptional SERS activity.

Beyond the enhancement of SERS intensities, silver nanoparticles exhibit plasmon resonances at shorter wavelengths, within the ultraviolet (UV) region. Consequently, the deposition of silver onto gold nanostructures has been widely employed as a means to systematically blue-shift their plasmon resonances, allowing for tunable optical properties across the visible to near-infrared (Vis-NIR) spectrum.[8]

In this study, we present a strategy for the controlled epitaxial deposition of silver onto gold NSts, achieving precise modulation of their optical properties while preserving their characteristic branched morphology. By fine-tuning the silver deposition process, we successfully obtained silver-coated gold NSts with varying degrees of silver coverage, enabling the systematic blue-shifting of their plasmon resonances within the Vis-NIR range. Importantly, this approach retains the distinctive multiple sharp branches of the NSts, ensuring the preservation of their intrinsic hotspots. In terms of SERS performance, our results demonstrate that the silver-coated NSts exhibit a one-order-of-magnitude increase in SERS brightness compared to their uncoated gold counterparts. These findings highlight the potential of silver-coated NSts as highly efficient SERS substrates with precisely tailored optical properties, offering new opportunities for advanced plasmonic sensing and molecular detection applications.

Abstract: Through experimental and theoretical methods, we demonstrate the controllable photodynamics of quantum emitters (NV colored centers in nanodiamonds) precisely positioned near silicon dimer nanoantennas. Then, by designing specific geometries with an evolutionary optimization algorithm, we explore enhancing the directional emission of these quantum sources numerically.

Introduction

Improving the brightness and efficiency of single photon sources by the mean of optically resonant nanostructures is a major stake for the development of efficient nanodevices for quantum communications.

For a couple of decades, these resonant nanostructures have mainly been made of noble metal that sustain strong localized resonances that can be used to manipulate, concentrate or redirect visible light. Such properties have led to numerous actual or potential applications in integrated optics, sensors, nonlinear optics, field-enhanced spectroscopies, or photovoltaics. Recently, an alternative emerged with high refractive index dielectric nanostructures, which offer the same range of applications as plasmonics by manipulating Mie optical resonances [1].

These resonances can be efficiently tuned by modifying the size, shape, and material of those nanostructures (e.g. silicon, n ~ 4) [2]. Furthermore, high index dielectric nanostructures offer several key advantages when compared to their metallic counterparts: absorption losses are far weaker for wavelengths longer than the direct band gap, access to semiconductor (CMOS) technology for nanostructure fabrication, and presence of intrinsic strong magnetic and electric resonances, providing an unique opportunity to spatially separate and redistribute the energy of the magnetic and electric parts of the electromagnetic field in the near field, otherwise inextricably connected in the far field [3].

Discussion

We discuss here the effect of simple high index dielectric nanoantennas on the spontaneous emission of model quantum emitters. First, we accurately positioned arrays of nanodiamonds hosting NV colored centers in the gap

of silicon dimer nanoantennas, using atomic force microscopy (AFM – [4]) nanoxerography [5]. The NV center is an ideal model system exhibiting single photon emission properties at room temperature, which is well adapted for proof of concept experiments in quantum nano-optics. Since the emission rate of the emitters, and therefore the local density of photonic states (LDOS), are modified by the nanostructure, we show by the mean of time-resolved photoluminescence acquisitions that the photodynamics of these emitters can be enhanced by the coupling to the nanoantenna down to the single photon emission regime [5]. Our experimental results are in good agreement with multipolar analysis and numerical simulations based on the Green Dyadic Method - GDM.

Next, to go a step further, we numerically investigate controlling the directional emission of quantum dipolar sources using complex Si antennas. These antennas, composed of specific numbers of building blocks, are optimized via an Evolutionary Algorithm (EA). The resulting geometries enable precise tailoring of emission direction, enhancing light intensity within defined solid angles. Our numerical experiments demonstrate the effectiveness of these EA-optimized antennas [6].

Optimising Cross-Polarisation Conversion of Ghost Hyperbolic Polaritons with a Twist

Mark C. Cunningham[1*] and Rair Macêdo[1]

Abstract: We demonstrate tuning and optimisation of cross-polarisation conversion in multilayered hyperbolic systems by introducing a twist angle between layers (i.e. their anisotropy orientations). Using a 4×4 transfer matrix method, we show significant enhancement of polarisation conversion efficiency due to Ghost Hyperbolic Polaritons. This could influence next-generation, direction-dependent infrared optical devices.

Manipulating polarisation of electromagnetic waves is a key aspect of a broad range of technologies including wireless communication [1] and sensing [2]. In the infrared, birefringence is the main mechanism behind optical components that convert polarisation [3], but their large form-factor limits their use in practical applications. To circumvent this, the development of thin metasurfaces - with respect to the device's operating wavelength - has received much attention [4]. However, manufacturing these metasurfaces can be a sophisticated and expensive process. An emerging alternative to this is using naturally occurring anisotropic crystals which display hyperbolic behaviour across the far-infrared range [5]. That is because, along with exotic effects such as surface polaritons [5], negative refraction [6] and subwavelength confinement [6], hyperbolic materials have been shown to support cross-polarisation conversion upon reflection at their interface, depending on the orientation of their anisotropy axis with respect to both incidence angle and incidence plane [7].

An example of such natural hyperbolic materials is low-symmetry crystals, such as calcite. This is due to anisotropic, infrared-active phonon resonances which, in turn, lead to the principal elements of its diagonal permittivity tensor possessing opposite signs [5] and consequently display a 'hyperbolic dispersion'. Hyperbolic dispersion is commonly referred to as type I when a single extraordinary component of the dielectric tensor is negative while the two ordinaries are positive, creating a two-sheet hyperboloid isofrequency contour. Conversely, when the extraordinary component is positive while the two ordinary components are negative, an open-sheet hyperbolic isofrequency contour forms, known as type II dispersion [6].

More recently, these materials have been shown to support ghost hyperbolic polaritons (GHP). For example, GHPs have previously been observed in bulk calcite at $1430\text{-}1500\ \mathrm{cm}^{-1}$ [8], corresponding to a free space wavelength of $6.6 - 7\mu m$. Supported in type II dispersion [8], GHPs possess slanted phase wavefronts into the bulk of the crystal, parallel Poynting vectors to the surface, and exponential decay away from the surface. In addition to long-range, directional, and diffraction-less polariton propagation [8] in s-NOM studies, the reflectance of the GHP has also been studied in-depth [9], showing direction-dependent cross-polarisation conversion.

In this study, we investigate how multiple layers of natural hyperbolic media - using calcite as the example material - can exhibit enhanced cross-polarisation conversion through introduction of a twist-angle γ to misalign their anisotropy axes with respect to each other. We consider the geometry shown in Fig. 1. (a) where a prism is placed close to the sample surface of our layered structure, separated by a thin air gap, i.e. using the Otto configuration [10]. P-polarised incident waves undergo total internal reflection at the prism-air interface, allowing for the excitation of the GHP on the sample surface. In this configuration, the top calcite layer (of thickness $4\mu m$) is rotated relative to the bottom semi-infinite calcite crystal by an angle γ. This has been analysed in depth in the

context of hyperbolic shear polaritons and their application in metasurfaces [11]. Here, we use this method to assess its effect on cross-polarisation conversion. For this, we model reflectance using a 4×4 transfer matrix method [12].

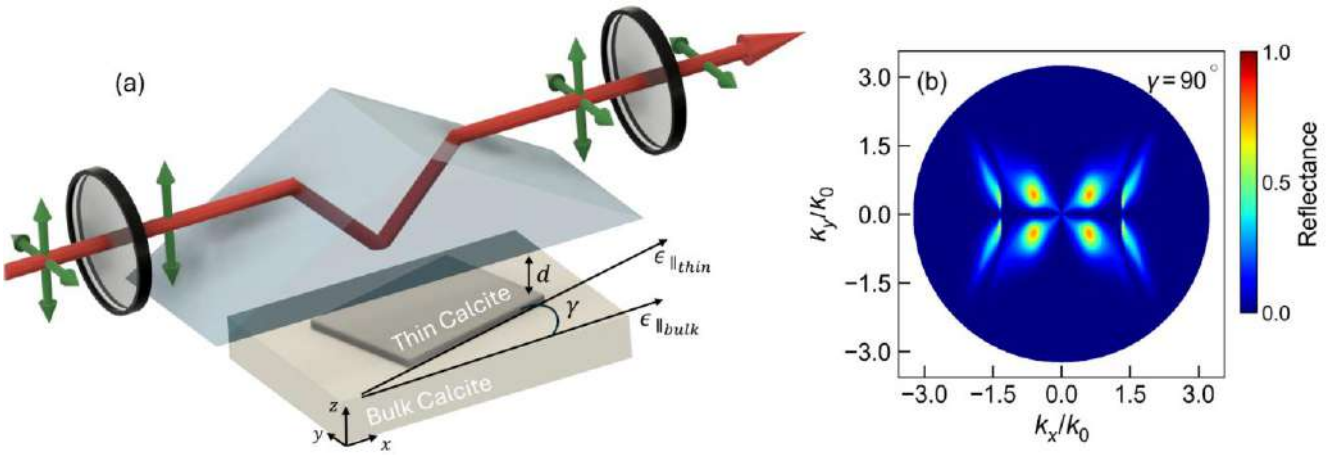

Fig. 1. (a) Setup Geometry, where a polariser is used to generate a TM-polarised beam which is incident at the surface of the calcite multilayer at an incident angle greater than that of the critical angle of the prism/air interface, creating evanescent decay to couple with the GHP on the thin calcite surface. After reflection, another polariser is used to capture the converted TE-polarised component of the beam. (b) The cross-polarisation conversion reflectance induced by the twisted GHP in the calcite multilayer at a twist angle of $\gamma = 90°$. This quantity is the amount of TE-polarised light reflected off the surface from the incident TM-polarised radiation.

With their anisotropy orientations aligned ($\gamma = 0°$), the maximum cross-polarisation conversion value $R_{ps} = 0.3$ at 1460 cm^{-1}. We find that polarisation conversion of the twisted GHP increases to $R_{ps} = 0.7$ when $\gamma = 90°$, as shown in Fig.1. (b). We can see four emission lobes corresponding to the GHP beyond k_x/k_0=1.4, with 4 enhanced sources of polarisation conversion at the boundary of the prism/air critical angle k_x/k_0=1.

Our results show that tailoring the twist angle can maximise polarisation conversion. These findings demonstrate the potential of twist-engineered interfaces in hyperbolic materials as a versatile tool in photonic design. By harnessing the sensitivity of cross-polarisation conversion to the twist angle, an optical device could dynamically manipulate light based on orientation and the polarisation state.

Broadband third harmonic generation through strong coupling between all-dielectric metasurfaces and epsilon-near-zero materials

Hui-Hsin Hsiao[1*]

Abstract: A hybrid metasurface, consisting of amorphous silicon nanocubes with a drilled hole on an ultrathin indium tin oxide film, is designed to explore the coupling among Mie resonance, quasi-bound states in the continuum, and the bulk-plasma mode, as well as their impact on third-harmonic generation.

Epsilon-near-zero (ENZ) materials such as Indium Tin Oxide (ITO), featured by a vanishing real part of the dielectric function at near infrared, possess a remarkable intrinsic nonlinear susceptibility and meanwhile sustain a significant field enhancement at bulk-plasma resonance [1]. However, the excitation of bulk-plasma mode requires transverse-magnetic polarized light under oblique incidence, and the effective nonlinearity is constrained to a narrow spectral range close to the zero-permittivity wavelength. To further enhance nonlinear conversion efficiency and broaden the spectral range of nonlinear response, the integration of ENZ materials with plasmonic or dielectric metasurfaces have been demonstrated as a promising platform for the enhancement of second harmonic generation (SHG) [2] and Kerr effect [3, 4].

In this work, we designed a hybrid metasurface to investigate the coupling between Mie resonances, quasi-BICs, and bulk-plasma modes. As displayed in Fig. 1(a) and 1(b), the hybrid metasurface consists of nanocube arrays drilled with a detuned square hole on an ITO film. Via the analysis of coupled mode theory (CMT) and near-field features of the hybridized modes, a more efficient strong coupling was found to take place between the Mie resonance and the bulk-plasma mode owing to their comparable resonant linewidths, resulting in a large measured Rabi-splitting energy of 190 meV. While the excited quasi-BIC resonances achieve stronger near-field enhancement than Mie resonance, they exhibit shallower resonant depths in the spectra and lower field intensity in the ITO layer within the hybrid metasurface (Fig. 1(c)). The hybrid metasurface exhibits at least 5 orders of magnitude THG enhancement in the wavelength (λ) range of 1100 to 1600 nm when compared to the planar Si/ITO film in simulations. The measured THG conversion efficiency shows a value beyond 10^{-7} from λ = 1340 nm to 1600 nm for nanocube arrays in the absent of ITO layer and further extends to the range of λ = 1230 nm to 1600 nm for the hybrid metasurface (Fig. 1(d)). Our findings provide promising advancements for broadband nonlinear optics and photonics applications.

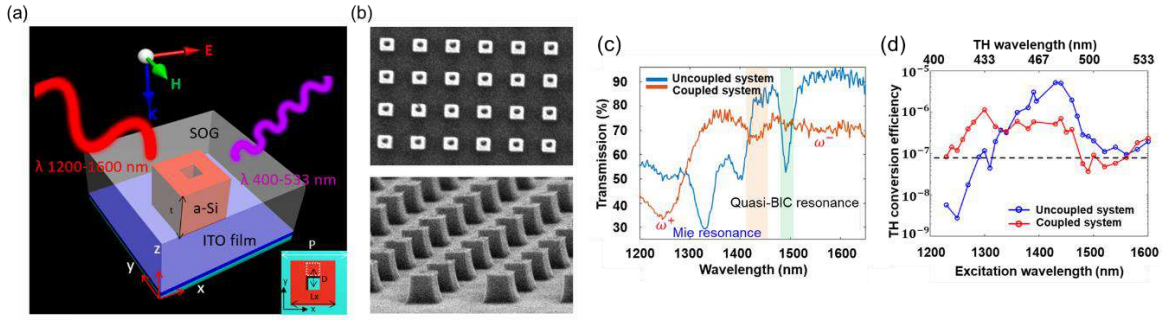

Fig. 1 (a) Schematic view of the nonlinear hybrid metasurfaces. (b) The SEM images of the fabricated sample at the top (upper) and lateral views (bottom). (c) Measured transmission spectra for the uncoupled (blue curve) and coupled (red curve) systems. The orange and green regions indicate the spectral position of the quasi-BIC mode in the coupled and uncoupled systems, respectively. (d) Measured TH conversion efficiency spectra for the uncoupled (blue dots) and coupled (red dots) systems.

Abstract: We present an optimization technique for sub-relativistic acceleration in guided-wave dielectric accelerators. Our approach exploits fast modal analysis of the guiding structure to explore geometric dependencies. Laser pulse propagation is then simulated using the Beam Propagation Method, while single-particle beam dynamics calculations are used to determine energy gain.

The miniaturization of particle sources has been attracting increasing interest worldwide. Indeed, laser-driven dielectric accelerators operating in the near infrared are potentially characterized by an increase in the accelerating gradient and a reduction of size and cost with respect to RF devices typically used in applications [1]. It is well known that dielectrics are characterized by a higher damage threshold compared to metals, and photonic crystals can suppress the propagation of higher-order modes, further enhancing the potential of dielectric accelerators. In this context, Dielectric Laser Accelerators (DLAs) have been studied by focusing mainly on side-pumped geometries [2]. However, this approach inherently puts an upper bound on the accelerator length and the energy gain. An alternative approach is based on a guided mode which is copropagating along the particle beam to achieve acceleration. In this scenario, particle and phase velocity need synchronization to guarantee net acceleration, therefore the guiding structure must be tapered by engineering its cross-section [3, 4]. Moreover, the temporal evolution of the pulses should be taken into account, since the interaction length in a waveguide can be large.

In this work we present an efficient numerical technique for the analysis of sub-relativistic acceleration in guided-wave dielectric accelerators. The proposed methodology is characterized by good accuracy and strongly improved computational efficiency with respect to cumbersome 3D FDTD simulations. The approach is based on a fast modal analysis of the waveguide cross-section as a function of the taper parameter, for instance the width a of the silicon strips in a tapered slot waveguide [3, 4]. The outcomes of this preliminary study are lookup tables with the modal properties of the waveguide, which can be summarized by propagation constant β_0, group velocity $v_g = 1/\beta_1$, second- and third-order dispersion β_2 and β_3 as a function of a. The optimal taper profile that

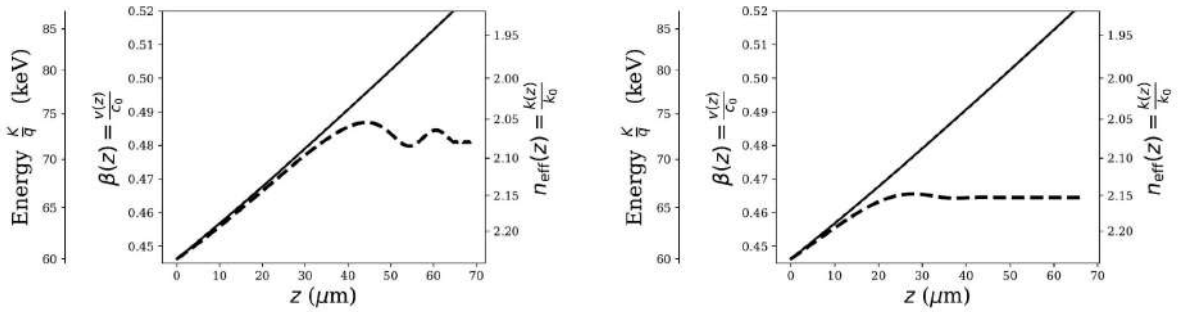

Figure 1. Acceleration profile in terms of energy and particle velocity (dashed lines) and waveguide effective index (solid lines) as a function of the propagation direction z. (Left) Pulse FWHM is 2 ps. (Right) Pulse FWHM is 0.25 ps.

guarantees synchronization between accelerating field and particles is obtained by solving single-particle beam dynamics (BD) and imposing that particle and phase velocity match along the propagation direction z. Next, the evolution $A(z,t)$ of the input pulse, which is governed by the linear Schrödinger equation (see Eq. 1), is determined by using the Beam Propagation Method (BPM) as commonly done in optical fibers. It should be noted that the BPM algorithm was implemented by exploiting the split-step technique, and at each step the correct values of the parameters β_0, β_1, β_2 and β_3 are taken from the lookup tables according to the taper geometry.

$$\frac{\partial A}{\partial z} = -\beta_1 \frac{\partial A}{\partial t} - j\frac{\beta_2}{2}\frac{\partial^2 A}{\partial t^2} - \frac{\beta_3}{6}\frac{\partial^3 A}{\partial t^3} \tag{1}$$

The proposed technique is quite general and can be applied to any kind of tapered waveguide geometry once a modal analysis is available. We studied both tapered slot waveguides and photonic crystal waveguides for sub-relativistic particle acceleration under pulse excitation, with the goal of identifying the main limitations imposed by the short-pulsed regime. As an example, in Fig. 1 we report the BPM-BD analysis of acceleration in a tapered slot waveguide [3, 4]. Design of the taper has been performed by assuming CW excitation, therefore a monotonic increase of particle and phase velocity is expected. Nevertheless, the behavior of the DLA is strongly affected by pulse duration when input energy and pulse amplitude are fixed. In fact, group velocity cannot be matched with particle velocity thus the effective interaction length is limited by pulse-particle walkoff. Furthermore, this detrimental effect is emphasized for short pulses, as it is possible to notice by analyzing the simulations reported in Fig. 1. Comparison between different scenarios wherein we vary pulse duration by modifying at the same time its amplitude to guarantee constant energy is underway, for the purpose of identifying an optimal pulse duration.

Nonlinear Photonics in Low-Index Time-Varying Systems

M. Ferrera[1,*], W. Jaffray[1], and S. Stengel[1]

[1] Institute of Photonics and Quantum Sciences, Heriot-Watt University, EH14 4AS, United Kingdom
[*]corresponding author: m.ferrera@hw.ac.uk

Abstract: Over the past decade, transparent conductive oxides (TCOs) have attracted interest due to their electro-optical properties. Operating near their cross-over wavelength, these materials have emerged as the most nonlinear solid-state platform for all-optical integrated devices. These systems closely approximate ideal time-varying systems, with potential applications extending into the quantum domain.

Summary: In recent years, there has been a resurgence of interest in transparent conducting oxides (TCOs) within the optics and photonics community. Historically, TCOs have been employed for over two decades as transparent electrodes in applications such as photovoltaics and touchscreens. This renewed attention was initially driven by their promise as low-loss metal substitutes in the design of highly compact plasmonic devices, and more recently by their extraordinary optical nonlinearities near the crossover wavelength [1].

TCOs are also notable for their epsilon-near-zero (ENZ) characteristics across a wide range of the near infrared spectrum, encompassing the entire telecommunications window. Within this spectral region, TCOs facilitate the realization of unique electromagnetic effects, such as super-coupling, wavefront freezing, and photon doping [2]. A distinctive feature of TCOs, in contrast to other ENZ materials, is their extremely low real refractive index ($n < 0.2$) near the ENZ wavelength, which is associated with relaxed phase matching conditions. The peculiar dispersion properties of TCOs have also been linked to a slow-light effect that further enhances the nonlinear optical responses [3-7]. Furthermore, it is important to note that these giant low-index nonlinearities come with an extremely broad bandwidth capable of accommodating optical pulses of just a few cycles in duration [8,9].

The fast-paced development of nonlinear optics with TCOs is fueled by experimental breakthroughs demonstrating extraordinary optical phenomena, including unitary refractive index changes, broad frequency shifts, and highly efficient on-chip nonlinear frequency conversion [10-12]. In this talk, I will discuss the evolving role of TCOs—from their origins in industrial applications as transparent electrodes to their emergence as a key solution for low-loss plasmonics and, most recently, as a pivotal enabler of advanced integrated nonlinear systems.

While providing a general overview of our latest findings, I will explore how evanescent coupling between a low-loss optical channel and an indium tin oxide layer enables the creation of novel nonlinear waveguides with unmatched nonlinear figures of merit over propagation distances spanning hundreds of microns (see Fig. 1-a). Furthermore, I will discuss how extreme modulation of the complex refractive index within a low-index thin film leads to a complete spatio-spectral fission of an incident pulse (see Fig. 1-b).

Finally, I will conclude by addressing the need for advanced material modeling and by offering some future perspectives for the use of these compounds in integrated quantum optics [13-14].

Abstract: Simulated and experimentally demonstrated photonic metamaterial antennas capable of emitting one or multiple ≈300μm diameter optical beams with customizable direction, intensity, phase, and polarization state (new result) at 460nm. Single transverse electric (TE) slab mode scatters from weak continuous perturbations superimposed on translationally-symmetric slab metamaterial.

Photonic integrated circuits (PICs) enable cost-efficient, large-scale fabrication of advanced photonic systems. PIC functionality can be further enhanced by direct coupling with photonic modes in free space, such as wide, collimated Gaussian beams [1]. We have previously demonstrated a fish-bone grating large beam emitter design based on breaking a continuous translational symmetry [2]. It allowed control over direction, intensity (shape), and phase of a TE, s-polarized output beam generated from an incident TE slab mode.

Heqing, et. al. [3] demonstrated precise and flexible control of the emitted intensity, wavefront and polarization at 1550 nm through discrete translation symmetry-breaking in 2D planar metamaterials. Such designs require accurate fabrication of dense 2D arrays of very small structural elements, which is particularly challenging for shorter wavelengths in the blue and even ultraviolet necessary for coupling PICs to miniature atomic systems.

In this work we demonstrate full polarization control with the continuous translation symmetry breaking which uses much larger minimum features and gaps, than its discrete counterpart [3]. The ability to create weak modulation without making very small features enables broad and smooth beam profiles while retaining ≈100 nm lines and spaces, compatible with 193 nm photolithography.

We introduce a mirror-anti-symmetric “wiggle” modulation along the walls (Fig.1(b)). Wiggle modulation emits transverse magnetic (TM) (p-polarized) light from the TE slab mode, while suppressing the TE (s-polarized) emission by symmetry. Fish-bone and wiggle modulations produce orthogonal linear polarizations. They can be superimposed with the appropriate relative amplitudes and phase to create any output polarization state. Different modulations and corresponding output polarizations are shown on Figure 1 (a-d). Light is outcoupled into wide collimated free-space beams emitted at near normal incidence. Polarization is measured by imaging through a rotating linear polarizer (Figure 1 (e,f)). Since modulation period controls the emitted beam angle, by superimposing modulations with different periods we simultaneously produce multiple beams with distinct polarizations and emission directions (Figure 2). Furthermore, by spatially varying the modulation across the device surface, it is possible to achieve complex, user-defined spatial distributions of phase, intensity, and polarization in the output.

To summarize, metamaterials with continuous translational symmetry breaking enable large-area, flat photonic beam emitters that can operate anywhere from the blue to infrared and generate a wide range of custom spatial profiles for polarization, intensity, and phase. Furthermore, the devices created from these metamaterials

are fully compatible with foundry-scale fabrication techniques, including photolithography, making them scalable and suitable for mass production.

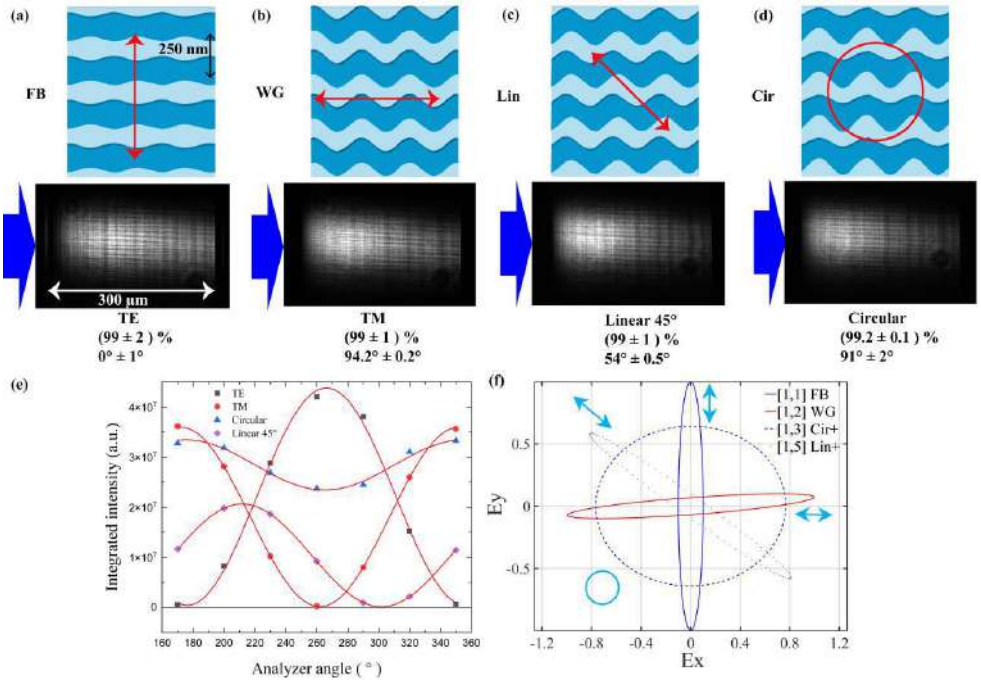

Fig. 1. (a) Fish-bone grating (FB) emitting TE polarization, (b) wiggle grating (WG) emitting TM polarization, (c-d) combination grating designs (45º linear and circular). The etched regions of 100 nm thick SiNx are depicted in dark blue, showing maximum modulations, located at the right-hand side of the spatially apodised gratings. Images show light emission from the corresponding gratings, with the slab mode light at 460nm incident from the left (indicated by the blue arrow). The numerical values below indicate the estimated fraction of the power emitted into the dominant linear/circular polarizations and polarization major axis orientation. (e) Integrated optical intensity through a linear polarization analyzer (symbols) with sinusoidal fits (f) Reconstructed field ellipses showing the electric field vector trajectory.

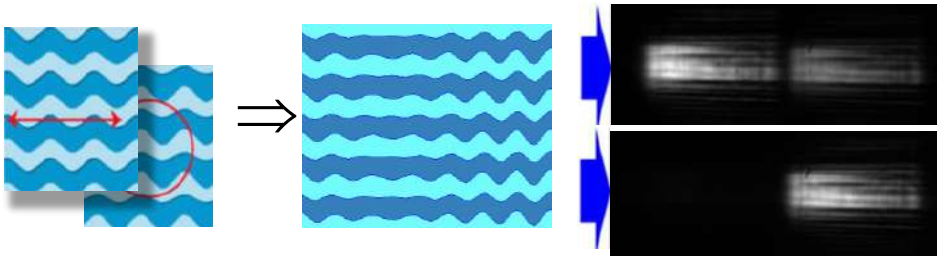

Fig. 2. A grating emitting two beams with the nominally circular and TM polarizations at different emission angles, which become spatially separated in the image plane ≈ 1.3 mm above the chip surface. The two images are taken at the same location with the orthogonal linear polarizer directions showing high extinction for the linear polarization.

Optical Fresnel zone plate lenses fabricated entirely of colored photoresist with i-line stepper

K. Konishi[1]
[1]Institute for Photon Science and Technology, Japan
*corresponding author: kkonishi@ipst.s.u-tokyo.ac.jp

Abstract: This study presents a method for fabricating optical Fresnel zone plate lenses using color photoresist, requiring only spin-coating, i-line stepper exposure, and development. The lenses achieved 1.1 μm resolution with 7.2% focusing efficiency. This approach, utilizing resist as a metasurface material, enables mass production and significantly reduces fabrication costs.

The demand for compact and high-performance optical lenses has led to increased interest in flat lens technologies, particularly metalenses. However, fabricating metalenses operating in the visible region requires high-resolution lithography and dry etching, making large-scale production challenging. As an alternative, Fresnel zone plates (FZPs) provide a diffractive optical solution that does not require high-aspect-ratio structures, making them more compatible with mass production techniques. However, conventional FZPs still require additional fabrication steps such as thin-film deposition and dry etching, increasing costs.

In this study, we demonstrate a simplified fabrication method for visible-light FZP lenses using color photoresist1. The process involves only spin-coating, exposure with an i-line stepper (widely used in semiconductor microfabrication), and development—without the need for etching or post-processing as show in Fig.1. The color photoresist exhibits high absorption at specific wavelengths, enabling the creation of amplitude-type diffractive optical elements. This method was successfully used to mass-fabricate FZP lenses on 8-inch silica glass wafers for different visible wavelengths.

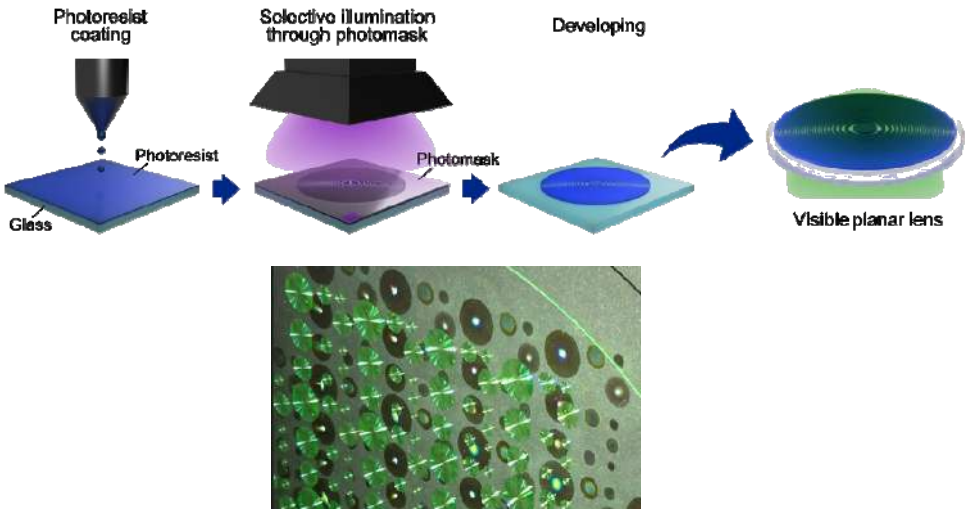

Fig. 1 Schematic diagram of the Fresnel zone plate lens fabrication method developed in this study and photograph of actual samples.

The FZP lenses were designed with a 0.8 μm minimum feature size, determining the outer radius and maximum numerical aperture. Fabrication involved spin-coating color resist, exposure via an i-line stepper, and development, using resists opaque at 450 nm, 550 nm, and 650 nm. Focusing tests showed a clean beam profile with FWHM of about 1.1 μm, with experimental results matching FDTD simulations. The focusing efficiency was 7.2%. Imaging tests using a USAF resolution chart demonstrated the ability to resolve 1.1 μm features, confirming the effectiveness of the FZP lenses for high-resolution imaging applications. The results of this research are innovative in that the resist itself is used as a metasurface material, which has the potential to reduce the cost of flat lenses significantly.

Integrating superconductors with silicon photonic circuits for high-performance quantum optic applications

Jeff F. Young[1,3*], M. Khalifa[2,3], P. S. Kirwin[2,3], and J. Salfi[2,3]

Abstract: Quantum information can be processed in the microwave or optical frequency domains, but can only be transported via optical or infrared photons. We propose and quantitatively model a novel microwave-optical quantum transducer that relies on intimate coupling of superconducting microwave and semiconducting optical cavities with an ensemble of color centers.

The past decade has seen major advances in chip-based quantum information processing solutions implemented on various platforms [1]. Superconducting circuits based on Josephson junction technologies, and spin qubit circuits process all of the information in the microwave domain, and operate at millikelvin temperatures [2], [3]. Photonic circuits operating at ambient temperatures can perform complex unitary operations on quantum information encoded at near-infrared frequencies, but the requirement for high-efficiency, discrete photon detection currently requires the use of superconductor-based detectors operating at cryogenic temperatures [4], [5]. Even spin qubit circuits often rely on passive and/or active components made of superconducting material. The anticipated scaling challenges associated with any of these technologies suggests that an efficient means of exchanging quantum information encoded at microwave and near-infrared frequencies will be required, thus driving research on hybrid circuits that co-locate superconducting and photonic components.

Experimental reports of chip-based parametric microwave-optical transduction via electro- and magneto-optic mechanisms have yet to demonstrate high efficiency conversion [6]–[8]. We recently proposed a transducer (see Fig. 1) based on co-integrated silicon photonic and Nb superconducting microwave resonators [9] wherein an ensemble of color centers embedded within the silicon provide a $\chi^{(2)}$ magneto-optic parametric coupling between signal microwave/near-infrared photons at $\quad_{\mu} \quad _{o}$. The color centers have a Λ energy level configuration wherein two spin-split states in the ground state manifold are resonantly coupled to the magnetic field of the surrounding microwave cavity, and each is dipole-coupled via the racetrack mode(s) to the high energy color center state. The strength of the nonlinear response is controlled by the vacuum Rabi strength of a classical pump field oscillating at frequency $\quad_{p} = \quad _{o} - \quad _{\mu}$.

Our work extends previous treatments in two important ways. First, it generalizes the transduction model to the regime where the cavity mode(s) are on resonance with, and can be strongly coupled/hybridized to the relevant ensemble transitions. Second, it quantitatively accounts for linear and nonlinear optical, microwave, and optically-induced microwave losses, in the presence of realistic inhomogeneous broadening of the ensemble transitions. A counter-intuitive operating regime is identified that is robust to these imperfections, allowing a predicted $\sim 95\%$

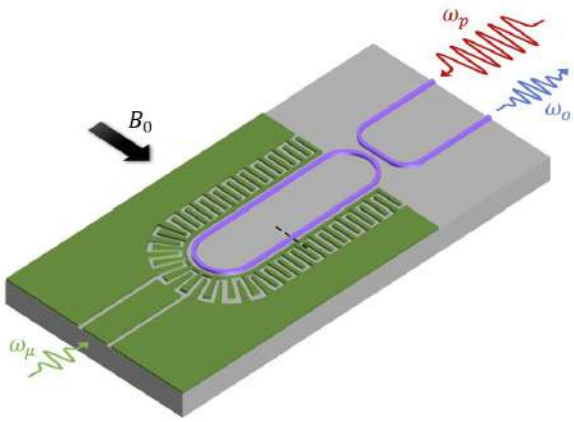

Figure 1: Device schematic comprising an optical racetrack cavity and a distributed superconducting microwave cavity loaded with an interdigitated capacitor, with applied magnetic field.

total conversion efficiency with added noise $\ll 1$ quanta possible at low (µW) pump powers for both Er- and T-centers in Si. This occurs when the signal photons are tuned *on resonance with the bare atomic transitions*, a situation that previous model assumptions precluded.

Recent progress in metasurface fluorescence biosensors: Expansion of the targets to next-generation nucleic acid biomarkers

Masanobu Iwanaga

National Institute for Materials Science (NIMS), Japan
*corresponding author: iwanaga.masanobu@nims.go.jp

Abstract: Metasurface fluorescence (FL) biosensors are a powerful biosensing tool that has been applicable for diverse biomolecules across DNA and antigen/antibody, exhibiting outstanding biosensing performance. We address a recent progress in the metasurface FL biosensors—extremely high sensitivity detection of next-generation biomarker of microRNA.

Metasurfaces are rapidly developing towards diverse optical and photonic applications. In addition to purely optical applications such as metalens, efficient interplay of metasurfaces with molecules enables us to conduct molecular sensing [1].

Resonant wavelength shift is used for small molecule sensing; the working principle is similar to surface plasmon resonance method. This type of sensors has been tested in various configurations [1].

Another type of metasurface biosensors is based on fluorescence (FL) detection [1]. In bioscience and biotechnology, FL detection is a major and established technique to identify and observe biomolecules and tissues. Recently, metasurface FL biosensors have been exploited to detect antigen/antibody [2–4] and DNA [5–7]. Especially, cell-free DNA (cfDNA) was detected in an ultimate high-sensitivity with discriminating one cfDNA from zero [6]. The detection signals representing target biomolecule concentrations are transduced to FL intensity, being quantified explicitly. This feature can contribute to huge numbers of bio-inspections and yield big data that would be the base for artificial intelligence use for healthcare services [8], as illustrated in Figure 1.

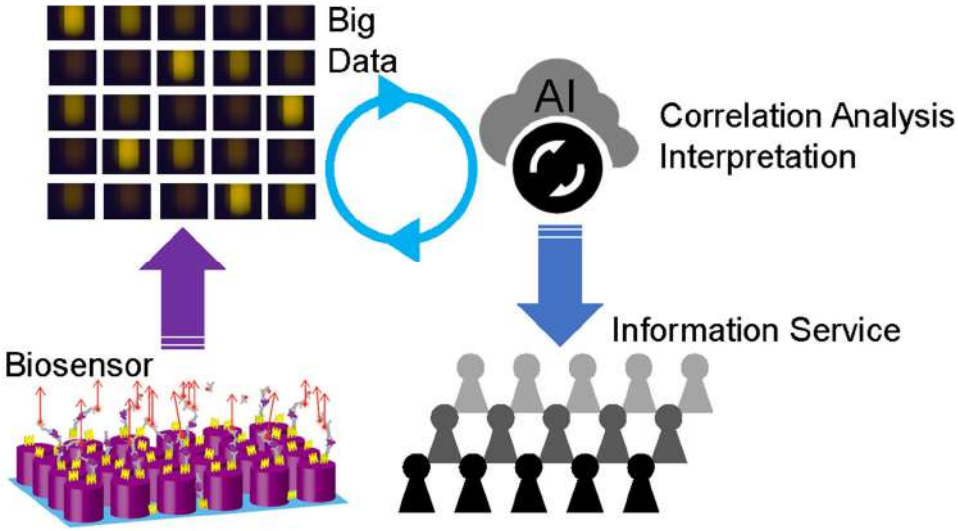

Figure 1. Illustration of all-dielectric metasurface FL biosensor to contribute to big data taking, which is the base for artificial intelligence (AI)-driven healthcare information service in the future. Cited from [8] under a CC BY license.

We address recent progress in the metasurface FL biosensors. In particular, extremely high-sensitivity detection of next-generation microRNA biomarkers has been attained employing the metasurface FL biosensors. A simplified protocol to detect the nucleic acid targets is described.

Anisotropic nonlinearities in crystalline gold and how to exploit them

S. Boroviks[1*], and O. J. F. Martin[1]

[1] Nanophotonics and Metrology Laboratory, École Polytechnique Fédérale de Lausanne (EPFL), Switzerland
[*]corresponding author: sergejs.boroviks@epfl.ch

Abstract: We demonstrate a monocrystalline plasmonic metasurface which takes advantage of the anisotropic second-harmonic generation from {111}-type gold surface. Furthermore, we provide a comprehensive description of this anisotropic nonlinearity that is rooted in the microscopic symmetries of the crystal, and validate experimental results with numerical simulations, which show excellent agreement.

Second-order nonlinear processes, such as second-harmonic generation (SHG) typically do not occur in bulk metals due to their centrosymmetric crystal structure. Nevertheless, SHG does occur at metal surfaces, since centrosymmetry is naturally broken at the interfaces. Albeit being small, these surface nonlinearities can be substantially enhanced by virtue of surface plasmon resonances, which is the central topic of research in the field of nonlinear plasmonics [1, 2].

Furthermore, in the case of monocrystalline metals, the second-order nonlinear response becomes more complex and manifold, as compared with conventional polycrystalline films. In particular, {111} gold surfaces possess C_{3v} symmetry (Fig. 1a), giving rise to a characteristic six-fold pattern of the SHG signal, that can be co- or cross-polarized, depending on the sample orientation angle (Fig. 1a). The SHG signal contains two contributions: isotropic (stemming from broken centrosymmetry in surface-normal direction) and anisotropic (due to centrosymmetry broken along $\langle 11\bar{2} \rangle$ crystal axis) [3].

In this work, we investigate the possibilities to control the anisotropic SHG by fabricating metasurfaces on the large {111}-type surfaces of chemically synthesized monocrystalline gold flakes [4,5]. The metasurface is comprised of V-shaped grooves with subwavelength periodicity, that are fabricated using focused ion beam (FIB) milling (Fig. 1 c and d). Intriguingly, FIB fabrication does not diminish the crystal structure and yields structures with outstanding quality. Tailoring the geometric dimensions of the grooves allows to tune the spectral position of the localized plasmonic resonance, which allows to considerably enhance the SHG signal [6]. Remarkably, isotropic and anisotropic SHG contributions are extremely sensitive to the near-field distribution at the resonance (Fig. 1 g and h), which allows to selectively amplify or reduce co- or cross-polarized SHG signals. We substantiate our results with numerical simulations, which show excellent agreement with the experiment (Fig. 1 e and f).

We anticipate that these results will serve as a guide for exploiting the tensorial nature of nonlinear susceptibility in gold and the development of compact nonlinear devices that operate in reflection mode.

Corresponding author: enns@rptu.de

Abstract: Using the technology of Direct Laser Writing, we fabricate sub-micron polymer structures on top of a cavity mirror, serving as potential landscapes to experimentally investigate the properties of photon gases, such as the 2D to 1D crossover of a photon Bose-Einstein condensate or topological edge states in a SSH-chain.

In this talk we will discuss the realization and basic principles of photon Bose-Einstein condensates (PBEC) in a harmonic microcavity. Showing recent measurements, the polarization properties of PBECs are demonstrated in good agreement to theoretical simulations. While simple potentials such as harmonic confinement can be achieved using curved mirrors, the technology of Direct Laser Writing (DLW) allows the microcavity to be modified by printing polymer structures onto one of the cavity mirrors, creating more complex potentials. Tailoring specific potentials enables the investigation of thermodynamic properties in different dimensions. Furthermore, the possibilty to create and study the characteristics of coupled photon gases is emphasised.

Bose-Einstein condensation is a quantum phase transition of a Bose gas in thermal equilibrium, leading to a macroscopic occupation of the system's ground state above a critical phase-space density. Especially for photon Bose-Einstein condensates, a crucial aspect of this process is thermalization. To achieve this, the photon gas is coupled to a dye solution, which serves as both a particle and heat reservoir [1]. A microcavity consisting of two Bragg mirrors with a reflectivity above 99,998% is used to increase the lifetime of the photons and obtain the required conservation of the average photon number. Within the cavity, photons can undergo several absorption and emission cycles, leading to a coupling of the photon energy distribution to the rovibrational energy levels of the dye. The free spectral range of the resonator is tuned by the distance of the cavity mirrors and is chosen such that the dye can only emit into one longitudinal resonator mode q. Hence, the photon gas is effectively two-dimensional and has a well-defined ground mode TEM_{q00}. The transversal modes are occupied according to the Bose-Einstein statistics. Increasing the pumping power leads to a saturation of the excited modes and results in the condensation into the ground mode [2].

To understand the nature of the PBEC, we experimentally investigate its polarization properties and show good agreement with previous theoretical predictions [3]. While the gas below the condensation threshold is unpolarized, a strong increase of the polarization strength can be measured for the condensate. Thereby it follows the polarization of the pump in case of

linear polarization. However, circular polarization cannot be imprinted onto the condensate due to the achiral nature of the dye. Additionally, the pump polarization influences the condensation threshold: linear polarization results in more efficient dye excitation and thus requires lower pump power to reach condensation compared to circular polarization.

The ability to create potential landscapes enhances the control over the experimental setup and more properties can be analyzed. Methods as heat induced delamination to structure the mirror and usage of the non-lineaer Kerr effect already exist to form such potentials. However, using the technology of Direct Laser Writing is offering advantages especially with regard to higher resolution and fabrication of structures with steep edges. DLW is a 3D laser lithography technology that enables the fabrication of nearly arbitrary three-dimensional polymer structures at the sub-micron scale. Therefore, a photosensitive material, also called photoresist, is deposited on a substrate and exposed to a focused femtosecond pulsed laser. Only in the focal area of the laser beam, the intensity is sufficient for two-(multiple-) photon absorption to occur, which then induces a polymerization process. The volume in which the polymerization takes place is called a voxel. By generating a relative movement between the voxel and the photoresist while controlling speed and laser power, crosslinked polymerized areas are created. A following development process to remove the unpolymerized resist delivers the final structure. By printing these structures onto one of the cavity mirrors, the refractive index contrast between the dye solution and the polymer creates a potential landscape for the photon gas.

Quantum mechanical phenomena such as quantized energy levels in a box potential can be visualized in this setup and confirm the general suitability of the method. But more important, it also enlarges the possibilities to investigate new phenomena. Due to the higher resolution of the DLW 1D and even 0D potentials are fabricated. Since the dimensionality of a system influences its properties, we investigate thermodynamic properties during the transition from two- to one-dimensional photon gases. This transition is realized by performing and comparing measurements on isotropic harmonic potential to anisotropic potentials of higher aspect ratios and stronger confinements. The results confirm theoretical expectations and show a second-order phase transition in 2D, while a crossover behavior is observed in 1D [4]. Recent measurements even show the possibility to investigate characteristics of coupled photon gases. This is demonstrated by observing the band structure of an SSH chain, including the topological trivial and the non-trivial case with its corresponding edge states.

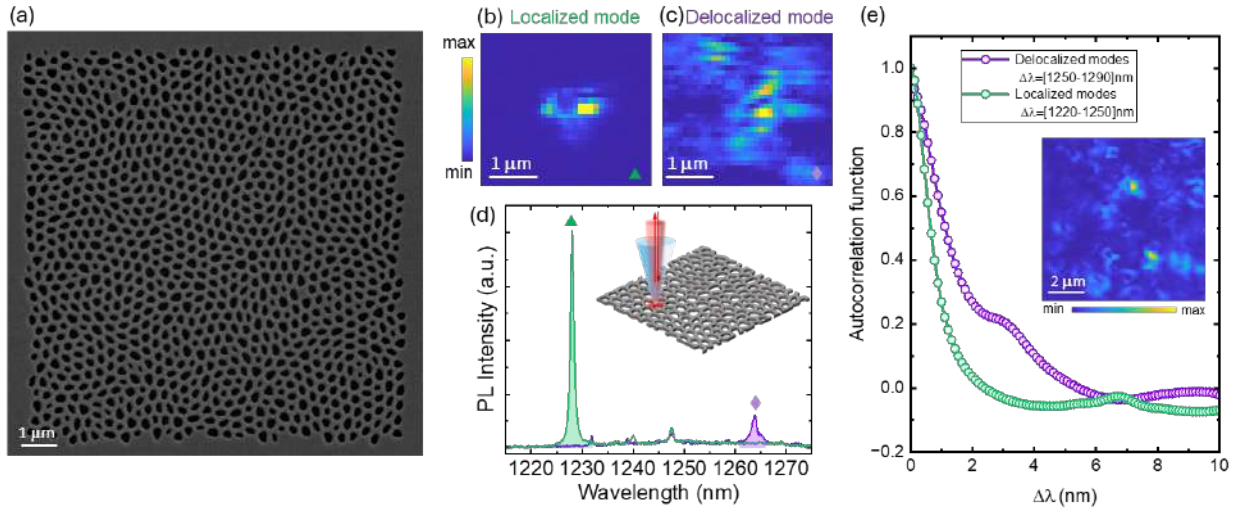
Abstract: A special class of disordered photonic heterostructures, hyperuniform disordered (HuD) photonic structures, allows to deterministically tailor Anderson localization and diffusive transport. Here, we detect for the first time the presence of level repulsion between delocalized states in a HuD photonic platform, by means of the Scanning Near-field Optical Microscopy technique.

Disordered photonic nanostructures have attracted tremendous interest in the past three decades, not only due to the fascinating and complex physics of light transport in random media, but also for peculiar functionalities in a wealth of interesting applications. Recently, the interest in dielectric disordered systems has received new inputs by exploiting the role of short and long-range spatial correlations within scatterer configurations. Hyperuniform disordered (HuD) photonic materials [1], that share features of photonic crystals and random systems, are an example of engineered disorder to control, through short range-order, both spectral and momentum responses of light.



Recently, an experimental study has revealed the transition from light localization to diffusive transport in an optically active platform with a HuD design [2], showing that this type of correlated disorder system hosts Anderson-like modes very promising for fundamental studies but also for technological applications in the field of light-matter interactions. The presence of deterministically tailored localized and diffusive transport within the same photonic platform has raised novel and exciting questions.

Quantum mechanical level repulsion in complex and disordered quantum systems has first been modeled by Wigner and Dyson's random matrix theory [3], and thanks to the many experimental verifications in various branches of physics, became a most valuable criterion for the study of the Anderson transition [4,5].

Here, taking advantage of the Scanning Near-field Optical Microscopy (SNOM) technique, we present the first experimental evidence of level repulsion in HuD systems in a tailored diffusive regime.

The studied samples consist in 200nm thick GaAs slabs patterned with a HuD design (Fig.1a); embedded in the middle of the slab are InAs quantum dots that act as optically active medium. The room temperature SNOM, capable of subwavelength spatial resolution in the near-IR range, is employed in illumination/collection configuration, meaning that the sample is excited with light from a diode laser (785 nm) coupled into a chemically etched optical fiber. Photoluminescence (PL) spectra from the sample are collected at each tip position through the same probe. Fig.1b-d report the results of a SNOM measurement performed on the sample; the PL SNOM maps of a typical Anderson localized mode (b) and of a delocalized one (c), along with their relative spectra acquired in the positions of maximum intensity (d).

The method employed to detect the level repulsion phenomenon is based on the evaluation of the autocorrelation function [4,6], which allows for a statistical description of the systems in terms of energy level distribution of the optical modes sustained by the system. Within a single SNOM scan performed on the entire sample (as shown in the inset of Fig.1e) we have access to all the modes within a large spectral range. We selectively evaluate the autocorrelation function in the two spectral ranges corresponding to localized and delocalized modes, and the results are plotted in Fig.1e. The presence of a pronounced shoulder at short spectral distances in the purple curve is a clear indication of level repulsion between delocalized modes, differently, from what is observed in the autocorrelation function of localized modes. Moreover, through the evaluation of the spectral width of the autocorrelation peak, our spatially resolved spectroscopy technique gives direct insights on the typical hallmark of light localization regimes, like for example the smaller (larger) spectral width of localized (delocalized) modes.

Spectroscopic proof of the non-thermal reactant activation in plasmon-photocatalysis

Z. H. Kim*

Department of Chemistry, Seoul National University, Seoul 08826, Korea

Abstract: Recent studies on plasmon photocatalysis suggest that the hot-electrons generated by plasmon-excited nanostructures may induce non-thermal vibrational activation of metal-bound reactants. However, this postulate has not been fully validated. Here, we provide direct and quantitative evidence that such activation occurs on plasmon-excited nanostructures.

Using anti-Stokes surface-enhanced Raman scattering (SERS) spectroscopy, we mapped the vibrational state population distributions of reactants on plasmon-excited nanostructures (Fig. 1a). The vibrational quantum state distributions reveal that a specific vibrational mode of the reactant is selectively excited (Fig. 1b), with the reactants exhibiting >10 times more energy in this mode than expected for fully thermalized molecules at the given local temperature [1]. Furthermore, a significant portion (>20%) of the excited reactant is in multi-quantum excited vibrational states ($v \geq 2$, Fig 1c). This mode-specific and multi-quantum vibrational excitation cannot be explained by photothermal heating of the reactant or direct optical transitions of the metal-molecule complex [2]. Instead, the observation can be modeled by hot electron-molecule energy transfer mediated by the transient negative ions. This establishes links between non-thermal reactant activation, plasmon-induced hot electrons, and negative ion resonances. Our findings validate the mechanism of plasmon photocatalysis and introduce a new method to explore the vibrational reaction control on metal surfaces.

Abstract: We investigated the room temperature, low-voltage-enabled modulation of the optical response of a Al:ZnO film with controlled structural quality (from crystalline to amorphous) coupled with $BaTiO_3$ film by means of in-operando spectroscopic ellipsometry, ascribed to a combination of charge accumulation/depletion at the interface and Pockels effect in the $BaTiO_3$ layer.

Transparent conductive oxides (TCOs) show the ability to adjust the free carrier concentration through the doping level and allow epsilon-near-zero conditions to be tuned in visible light communications and infrared telecommunication windows. While the tuning of the optoelectronic properties of TCO by modulating their intrinsic properties is extensively exploited, a great challenge is their control by external stimuli, which would pave the way for intriguing applications in photonic devices. The most flexible and appealing method to perform optical modulation is to exploit the field effect (FE) by applying an external bias to TCO thin films within a suitable metal–oxide–semiconductor (MOS) device and inducing an ultrathin accumulation/depletion layer at the dielectric/conducting oxide interface.

In this work we have investigated the room temperature, low-voltage-enabled modulation of the optical response of hybrid transparent-conductive-oxide/ferroelectric multilayers. We have shown that Al-doped ZnO (AZO) films in a plane capacitor configuration have been optically modulated through FE gating and a 100 V bias at 4.2 K determines a sizable charge displacement and a variation of the refractive index in the infrared range up to value of more than 0.1.[1] Reducing the insulator thickness by exploiting a high-k-dielectric $BaTiO_3$ (BTO) film allows boosting the charge-density modulation by increasing the capacitance of the system, allowing lower bias and room temperature operation, with relevant applicative consequences. For this purpose, we have fabricated an optical multilayer consisting of AZO and BTO films deposited on a Nb-doped $SrTiO_3$(110) (NSTO) substrate. We have exploited AZO films prepared with different structural order by magnetron sputtering.[2] Epitaxially grown films on STO(110) substrates have been compared with polycrystalline films grown in the same conditions on SiO_2/Si. Epitaxial films with larger crystalline grains retain their optimal properties down to low thickness, limited mostly by ionized impurity scattering, while polycrystalline films, where grain boundary scattering is dominant, are considerably more resistive. Optical properties do not show significant differences, confirming that the intrinsic properties of the material are not affected by crystal quality. Amorphization, on the contrary, induces an increase in carrier density but a strong reduction in mobility.

We have then fabricated AZO/BTO/NSTO capacitors of about 100 μm lateral size by EBL. We have detected a sizable variation of the optical response at an applied bias of 0.2 V at room temperature that we have

ascribed to the combined effect of exponentially graded charge accumulation/depletion at the AZO/BTO and BTO/NSTO interfaces, accompanied by the voltage-induced Pockels effect in the BTO layer through the development of a complex optical model.[3] Despite the complexity of the system and the variety of the physical effects concurring to its FE-induced variation of the optical response, we have succeeded in modeling the optical response of each layer involved and in introducing the main bias-induced mechanisms that lie underneath the FE-induced variation of the refractive index in the infrared range up to value of more than 0.1. This work therefore provides important clues to model and understand in detail the behavior and the working mechanisms of optically active systems, with relevant applications in the field of active photonics.

Abstract: Photonic force microscopy has been used to highlight a pN range levitation force on a 1 μm polarizable particle trapped in proximity of an Epsilon-near-zero (ENZ) surface.

Photonic force microscopy uses optically trapped micro and nanoparticles to probe the interactions with a surface [1-3]. Short-range repulsive or attractive forces between the probe and the surface, due to electrostatic and Van der Waals interactions or Casimir effect, or even the limitation of the particle hydrodynamic due to the presence of the wall may be considered for the correct evaluation of the total force on the trapped particle. A careful calibration of the trap is necessary to precisely measure dynamic axial forces and surface force gradients [4, 5]. Moreover, some peculiarities of the surface itself may introduce additional forces that must be taken into account. As an example, a repulsive near field force is expected [6] when a point dipole is in front of an Epsilon-near-zero (ENZ) surface which is illuminated at its ENZ wavelength. In this talk, we will discuss, both theoretically and experimentally, the possibility of using photonic force microscopy to investigate if such an ENZ-related force could be observed on a trapped particle with size larger than a point dipole. By using different theoretical methods (dipole approximation, finite elements calculation, transition (T-)matrix) we will show [7] that particle optomechanics depends on surface and particle characteristics, such as particle size, particle-surface edge-to-edge distance, surface nature (dielectric, metallic, ENZ). Moreover, we devise an experimental procedure in which a 1 μm radius dielectric bead is optically trapped in front of a surface with ENZ properties at 547 nm. The trap equilibrium point of the particle is perturbed by a square-wave pulsed beam, exciting the surface at wavelengths ranging between 480 nm and 620 nm. A repulsive force in the pN range, having a maximum close to the ENZ wavelength of the surface, has been measured on the trapped particle; on the contrary, an attractive force is observed when trapping in front of dielectric or metallic surfaces. We attribute this repulsive-attractive optomechanics to ENZ-related repulsion and thermal effects.

Extracting resonances in nanophotonic systems from light scattering simulations

Abstract: In this contribution, we present a rigorous method for calculating resonance modes from scattering solutions of nanophotonic systems. We demonstrate its application in computing resonant states in periodic nanostructures such as metasurfaces, nanostructured waveguides, and other photonic systems.

In this contribution, we review a recently introduced approach for the calculation of resonance modes based on the rational approximation of optical response functions [1]. The rational approximation of the optical response is calculated by the AAA algorithm [3], where scattering solutions are computed at selected sampling points and superposed based on the poles and weights of the rational approximation. These are used to determine the resonance modes, the solutions of the nonlinear, non-hermitian eigenmode problems that would be otherwise difficult to calculate for most nanophotonic systems with state-of-the-art solvers like the Arnoldi method.

We demonstrate the method, explain the solution approach, and show accuracy and convergence in selected examples. For a chiral metasurface, we show that the chiroptical response on parameter variations can be accurately modeled in the vicinity of the relevant resonance frequencies [1]. We demonstrate that we can obtain parameter sensitivities in addition to the fields of the resonance modes.

Furthermore, we report on an application of the approach to microstructured photonic waveguides recently presented in [2]. Special light sources for solving the scattering problems are used to calculate only the fundamental resonance modes of the waveguides. Other types of modes, such as modes localized in the cladding of the waveguides or higher-order modes, are filtered out directly. We compare the AAA-based approach with a standard approach from the field of computational photonics and discuss corresponding numerical convergence studies.

Towards photonic orbitronics: exploiting the orbital angular momentum of light

Abstract

Combining higher order modes in coupled waveguide systems with light possessing orbital angular momentum allows for preparing and studying interesting solid-state-phenomena like the orbital-Hall-effect in a photonic model system. We report on several recent experimental realizations.

Coupled waveguide arrays have long been established as photonic model systems to explore solid state physics described by the 2D time-dependent Schrödinger equation. The mathematical analogy between the Schrödinger equation and the paraxial Helmholtz equation allows to visualize quantum mechanical effects like topological protection in quantum-Hall systems, thus providing visual insights into complex condensed matter physics effects not easily imaged in electronic solid state systems. The most prominent example being photonic graphene, demonstrating the existence of topologically protected edge states under the influence of an artificial magnetic field. [1]

However, most of the work along this line of photonic quantum simulation has been limited to waveguides supporting only the fundamental mode of the waveguides, thus simulating the s-orbital of the corresponding atoms.

Higher orbitals can be addressed using higher order modes of the waveguides, either by changing the size and/or shape of the waveguide or by adjusting the wavelength. Along these lines we could recently demonstrate a quadrupole topological insulator, [2] realizing the required artificial magnetic π-flux in one plaquette of the structure via a combination of s- and p-orbitals.

Besides hard-wiring the orbitals in the sample, another degree of freedom is achieved externally with the help of a spatial light modulator, which allows shaping the exciting light between Gaussian modes and modes with orbital angular momentum. Switching between modes without and with orbital angular momentum leads to switchable gauge fields and thus to either localization or propagation of light inside the structure. [3]

Combining both approaches, i.e. using higher orbitals of the waveguide system and light with orbital angular momentum, allows for the realization of photonic orbitronics, following the recent development in solid-state physics, [4] where realizing the orbital-Hall-effect is especially difficult due to the omnipresent spin-orbit-coupling and orbital quenching.

Coupled waveguide arrays are fabricated using direct laser writing via two-photon polymerization using a commercial device (Nanoscribe Photonic Professional GT). In a first step, hollow waveguide arrays are written in the commercial resin IP-Dip (Nanoscribe), which are subsequently infiltrated with SU8-10 (Microresist technology) and baked to remove remaining solvents. Dimensions and separation of the individual waveguides are optimized using beam propagation simulations. The waveguides are arranged to emulate a polarized SnTe lattice, found in solid-state physics under application of an external electric field. The distortion breaks the mirror symmetry and thus lifts the orbital quenching.

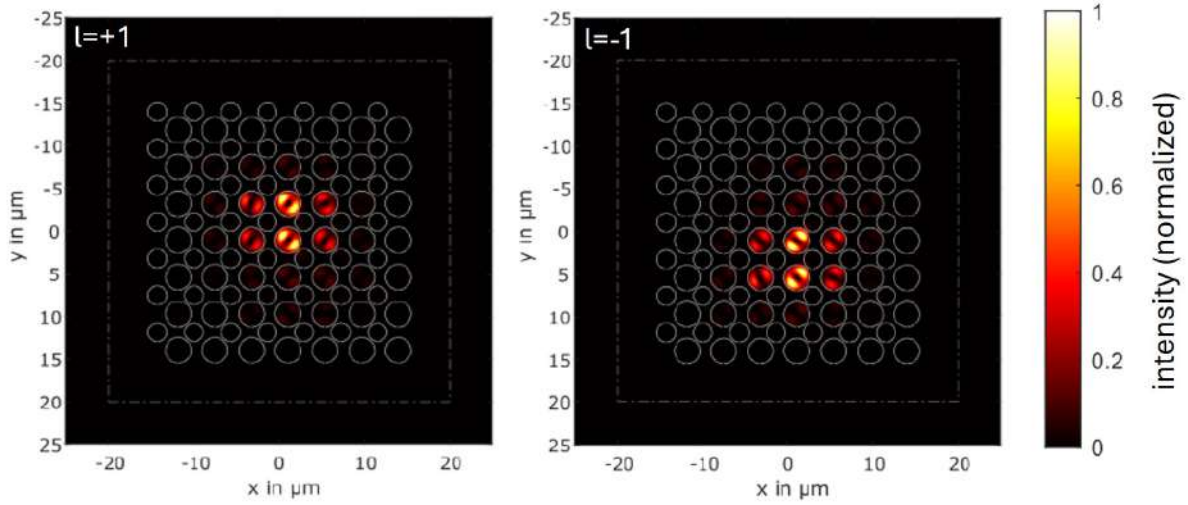

Figure 1: Numerical simulation: Light with orbital angular momentum with different handedness is coupled into the waveguide structure highlighted by the gray circles. Depending on the orbital angular momentum the wave package either moves up (left hand side) or down (right hand side), demonstrating the realization of the orbital Hall effect.

Light from a HeNe-laser is sent to a spatial light modulator (Hamamatsu) to prepare a wavepacket of modes with orbital angular momentum either with $l = +1$ or $l = \in 1$ and with a separation in phase to address certain k-vectors of the Brillouin-zone. These modes are coupled into the waveguide array at the entrance facet.

Observation at the output facet after a propagation length of 700 µm shows transport either up or down in good correspondence with the respective orbital angular momentum of light and in accordance with numerical simulations shown in Figure 1.

In conclusion we could demonstrate a first realization of the orbital Hall effect in a polarized photonic SnTe lattice by combining proper waveguide design with orbital angular momentum of the light propagating inside the structure.

Abstract: Tin-doped indium oxide nanocrystals are promising candidates for optoelectronics and active plasmonics in the NIR. Here, an integrated approach was developed involving magneto-optics and single particle spectroscopy to directly determine experimentally the carrier parameters as a function of tin doping, which is challenging in such small nanosystems.

Indium Tin Oxide (ITO) is the prototype conductive oxide, which has recently gathered interest in nano-optics,[1] owing to the excellent plasmonic properties displayed by ITO nanocrystals (NCs) in the infrared spectral region. Unlike noble metals, the plasmonic resonance frequency in spherical ITO NCs can be tuned synthetically by controlling the tin content.[2] Nanostructuration typically introduces several challenges in the characterization of electronic parameters in NCs, hampering advanced material design. Indeed, while films of doped oxides are routinely studied through electrical experiments, these cannot be reliably applied to NCs, since the insulating ligand layer forces charge hopping and results in a complex (albeit interesting) behaviour. Moreover, the surface potential creates a depletion region near the surface, which typically requires core@shell models with a purely dielectric shell to fit the extinction spectrum.[3]

In this work,[4] we present an integrated approach (Figure 1) based on magneto-optics, single-particle Electron Energy Loss (EELS) spectroscopy and ^{119}Sn Solid State Nuclear Magnetic Resonance (SSNMR) spectroscopy to extract the fundamental electronic parameters of a series of ITO NCs with variable tin doping. Our methodology overcomes the limitations of standard fitting approaches based on extinction spectroscopy, which can only determine the ratio between carrier density and mass. Conversely, exploiting concepts from magnetoplasmonics[5,6] we determined the carrier effective mass directly on the NCs, discarding the use of literature values. We found that mass values depart appreciably from those measured on thin films; consequently, we found carrier density values that are different from reported literature values for similar systems. The effective mass was found to deviate from the parabolic approximation at high carrier density. This approach can be generalized to other plasmonic heavily-doped semiconductor nanostructures and represents, to the best of our knowledge, the only method to date to characterize the full Drude parameter space of 0-D nanosystems.

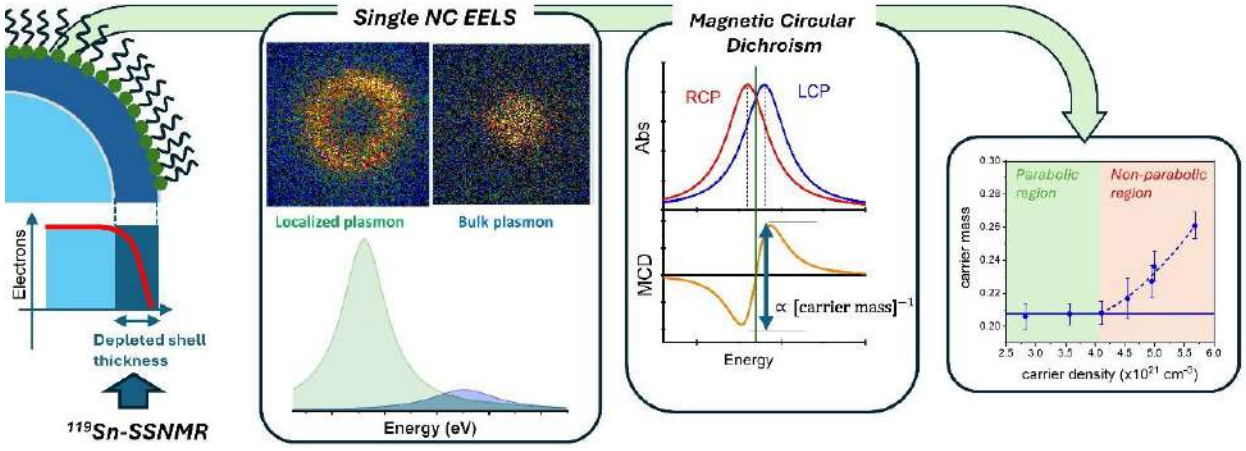

Figure 1: Scheme of the multitechnique approach employed in this work to extract the relation between carrier mass and carrier density in a series of chemically prepared ITO NCs with variable Sn content.

Abstract: We report metasurface photodetectors that can selectively measure the local phase gradient of only one circular polarization component of any incident wave, in a single shot and with standard imaging optics. Pixel arrays of these devices may enable new functionalities for applications in chemical sensing, biomedical microscopy, and machine vision.

Light waves possess multiple degrees of freedom besides intensity, including phase and polarization, that can contain important information of interest but require complex and bulky systems for their measurement. As a result, recently there has been growing interest in the development of miniaturized multifunctional photodetectors that can provide direct access to the same information [1]. Within this general context, the present work introduces an entirely new functionality for an integrated device – the ability to selectively measure the local phase gradient of only one circular polarization component of the incident light [2].

These devices consist of planar photodetectors stacked with a plasmonic gradient metasurface that introduces a strong dependence of responsivity on illumination angle and polarization. Specifically, the metasurface is designed to couple light incident at the desired detection angles and polarization into surface plasmon polaritons (SPPs) supported by an underlying metal film, which are then scattered into the photodetector active layer by a set of subwavelength slits perforated through the metal film [Fig. 1(a)]. A similar architecture (with a periodic diffraction grating instead of a gradient metasurface) has been used in our prior work focused on lensless compound-eye vision [3] and linearly polarized phase contrast imaging [4]. For phase imaging, the target detection angle θ_p should be small enough so that the resulting peak in the angular response overlaps asymmetrically with normal incidence, leading to large variations in responsivity with illumination angle around $\theta = 0$. The resulting devices can therefore be used to measure any deflection in the local direction of light propagation away from normal incidence, which in turn is proportional to the local transverse phase gradient of the incident light.

For the angle- and circular-polarization-selective excitation of SPPs, here we rely on the combined use of the plasmonic resonance and Pancharatnam-Berry (PB) phase of the individual meta-units, which consist of rectangular Au nanoparticles (NPs) of different size and orientation [Fig. 1(b)]. The NP array is designed so that, for one circular polarization component, the resonance and PB scattering phase profiles cancel each other, leading to specular reflection. At the same time, for the other circular polarization, these two phase profiles add up to each other to match the incident-light wavevector at the target detection angle to that of an SPP on the Au film. Using this design strategy, we have developed two devices (labeled R and L) providing angle-sensitive photodetection peaked at $\theta_p \approx -2°$ for right and left circularly polarized (RCP and LCP) light, respectively.

Figures 1(c)-(e) show the measured responsivity data of device R, illustrating the expected angle and polarization dependence. For circular-polarization-selective phase imaging, the key feature of these data is the large versus near-zero responsivity slope $d\mathscr{R}/d\theta$ at normal incidence ($\theta = 0$) for RCP and LCP light, respectively

[see Fig. 1(e), where the shaded region indicates the range of angles incident on the sensor array in a typical microscope]. In particular, our measurements show that the ratio $|d\mathscr{R}_{RCP}/d\theta|/|d\mathscr{R}_{LCP}/d\theta|$ is 37× on average over a bandwidth of ~70 nm around the 1.55-μm design wavelength, which provides a measure of the polarization selectivity of this device with respect to phase gradient. Similar results with the two states of circular polarization interchanged were obtained with device L. A detailed analysis of these data also provides a direct illustration of spin-momentum locking in SPPs and the role of spin conservation in photon/plasmon interactions.

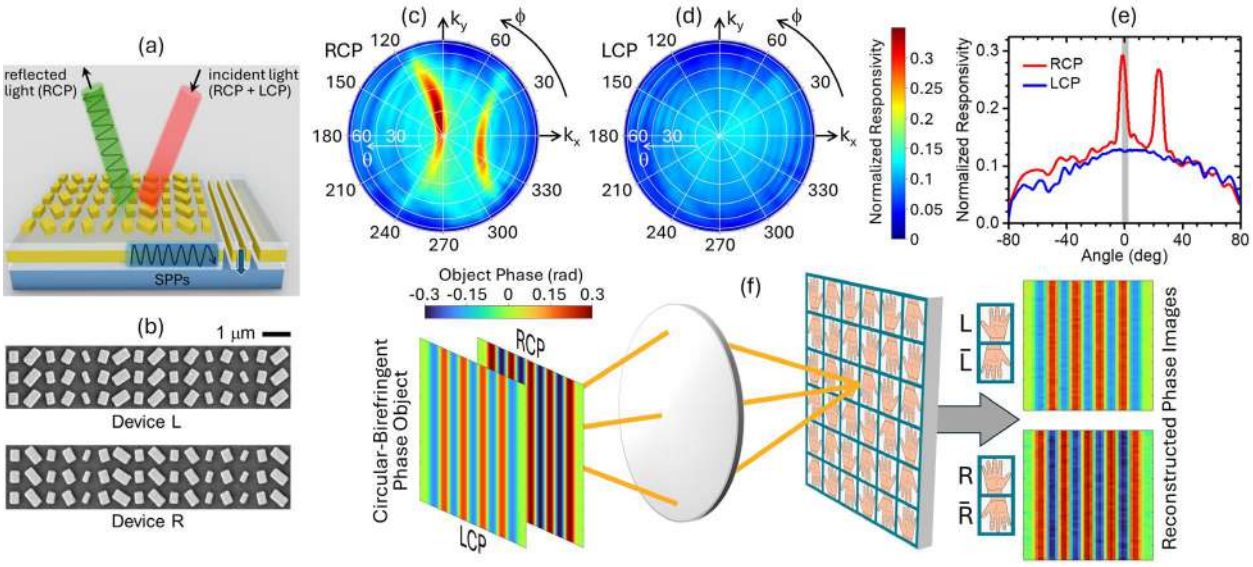

Fig. 1. (a) Schematic device structure. (b) SEM images of the metasurfaces of devices L and R. (c), (d) Measured responsivity of device R versus illumination angles under RCP (c) and LCP (d) illumination. (e) Horizontal line cuts of the color maps of (c) and (d). (f) Computational imaging results for a pixel array combining both types of devices.

Finally, we have conducted computational imaging simulations based on the measured angular response maps to show how these devices can be combined in a pixel array that allows for the simultaneous separate mapping of the RCP and LCP incident wavefronts [Fig. 1(f)]. This capability could benefit multiple imaging applications involving chiral matter, e.g., for drug development, studies of live cells, and biomedical diagnostics. Furthermore, these devices provide a key enabling ingredient for the development of a sensor array that could directly measure, in a single shot and with standard imaging optics, the spatial distribution of the incident optical intensity, phase, and polarization. In turn, such a system could dramatically improve our ability to sense visual information in low-contrast environments, with broad applicability in machine vision and image processing.

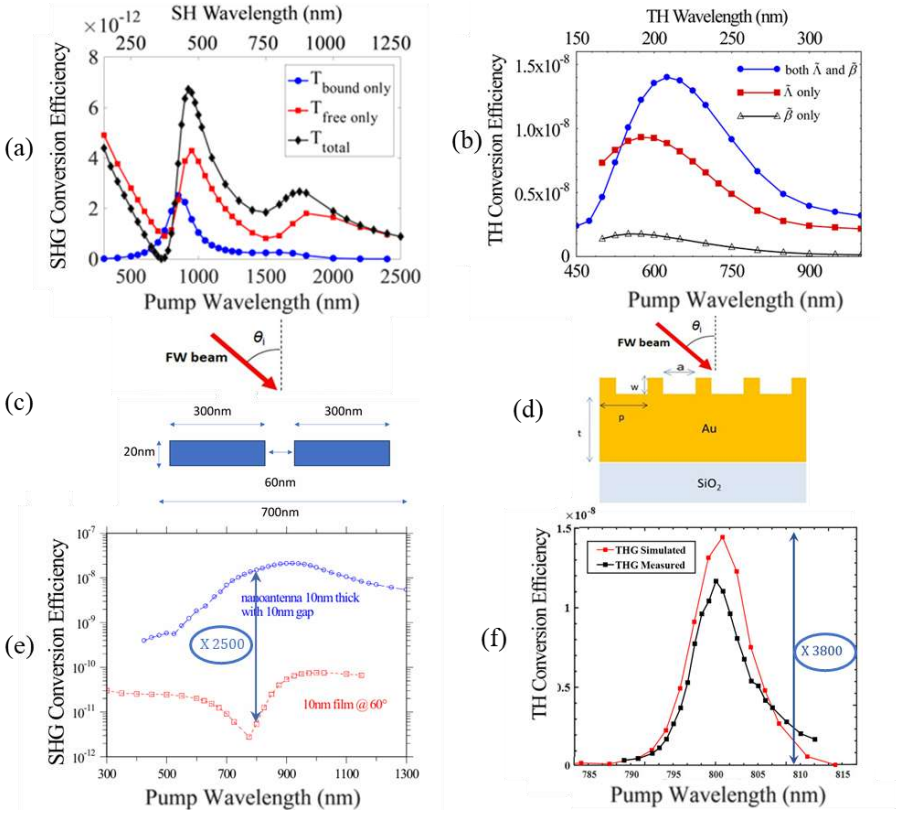
Abstract: We report a combined experimental-theoretical investigation on the second and third harmonic generation from aluminium and gold nanolayers and nanostructures, with specific focus on bound and hot electron contributions. Our experimental results are validated by our unique microscopic, hydrodynamic model for linear and nonlinear interactions in metal surfaces.

In the last few decades, both experimental and theoretical nonlinear (NL) optical studies have not considered the use of metals as potential materials for harmonic generation due to its large absorption. However, despite their high absorption in the visible and near infrared spectral ranges, metals are highly NL materials and the study of NL optics from metal surfaces combined with plasmonics is a very active field of research with important applications in the fabrication of functional nano-photonic devices.



Most of the experimental results presented in literature often show only qualitative aspects of NL generation from metal surfaces and metallic nanostructure. Also, the theoretical models rely on assigning effective surface and volume $\chi^{(2)}$ and $\chi^{(3)}$ to describe second harmonic generation (SHG) and third harmonic generation (THG) respectively, that generally lack a detailed, microscopic, dynamical description of light propagation and light-matter interactions. Our approach consists in formulating a microscopic, hydrodynamic model in order to understand linear and NL optical properties of metals by accounting for competing surface, magnetic, and bulk nonlinearities arising from both free (conduction) and bound (valence) electrons. Just as importantly, our model preserves linear and NL material dispersions, nonlocal effects, and the influence of hot electrons, i.e. electrons that may be temporarily excited from the valence into the conduction band, thus causing a transient increase of the free electron density [1].

Here, we present experimental measurements of the spectral dependence of SHG from Aluminium (Al) nanolayers that display Lorentz-like behavior and interband transitions centered near 810 nm. Detailed analysis of the results reveal that bound charges play a previously unknown role in SHG, pointing to the fact that predictions based solely on the free electron model do not adequately describe light-matter interactions in these materials, and that the absorption resonance plays a pivotal role well beyond pre-supposed limits [2].

On the other hand, third harmonic generation from 20 nm- and 70 nm-thick gold (Au) layers, described by combined Drude and Lorentz electrons illuminated by a pulsed pump laser source has at least two main THG sources: interband transitions (Lorentz resonances, with NL interactions governed by the bulk nonlinearity) and hot electrons, whose relative strength is determined by temperature-dependent effective mass (Fig. 1(b)) [3].

Heading towards structured nanomaterials, hence the grating, we take advantage of strong plasmonic resonances that significantly enhance light-matter interaction in the metal-dielectric interface, and generate very large surface nonlinearities promising more practical applications such as sensors, photonic circuits etc. Our sophisticated detection system and precision calibration enables us to detect and quantify SH/TH efficiencies,

and corroborate our theoretical and experimental observations of shape, spectral width, and amplitude of the spectral response. Fig. 1(c) and (d) shows the Al and Au grating simulated and experimentally measured. Fig. 1(e) and (f) shows the SHG from the Al grating and the THG from the Au grating being enhanced by three

orders of magnitudes, compared to the SH/TH signal from the unpatterned metal [4].

Fig. 1(a) Reflected SH conversion efficiencies from a free-standing 20nm-thick Al membrane. 100fs pulses are incident at 60°, Conversion efficiency has been calculated assuming NL sources reside only in: (i) bound electrons (blue curve), (ii) free electrons (red curve) [2] (b) Prediction of reflected THG conversion efficiency vs. wavelength for pump pulses incident at 55° [3]. (c) Al grating and (d) Au grating investigated. (e) SHG from Al grating and (f) THG from Au grating, showing the corresponding enhancement factors when the pump is tuned around the resonant frequency of the structure [4].

Abstract: We demonstrate low-loss, in-plane hyperbolic plasmon polaritons in $MoOCl_2$ thin films at visible and near-infrared frequencies. Predicted using biaxial media theory and confirmed via nano-imaging, $MoOCl_2$ hyperbolic plasmons enable extreme light confinement in the visible for applications like hyperlensing and super-resolution imaging, overcoming the losses and limitations of traditional metamaterials.

Polaritons—hybrid light-matter states formed by coupling photons with material excitations—enable subwavelength light control for a range of applications, including in optical sensing, nanoscale heat management, photocatalysis, and nonlinear optics. The associated light confinement is determined by the material dielectric permittivity setting specific isofrequency contours (IFCs), which can have different shapes in k-space. Media where the permittivity elements all have the same sign yield closed IFCs and elliptical wavefronts, whereas strongly anisotropic materials with mixed sign permittivity support hyperbolic polaritons with unbounded wavevectors. The unboundedness of the IFCs results in extreme subwavelength light confinement over a broadband range. Van der Waals (vdW) materials like hBN[1] and α-MoO_3[2] have demonstrated hyperbolic phonon polaritons in the mid-infrared. However, many applications—such as hyperlensing, super-resolution imaging, and high-resolution photolithography—require visible-frequency operation. While nanostructured metamaterials can be tailored to host visible hyperbolic plasmon polaritons, they face challenges including complex nanofabrication and high ohmic losses. We report the discovery of low-loss in-plane hyperbolic plasmon polaritons in thin films of the vdW molybdenum oxide dichloride ($MoOCl_2$) at visible and near-infrared frequencies[3]. Using the theoretical framework of biaxial media, we identify hyperbolic plasmon polaritons alongside directional ghost modes with damped propagation even in lossless conditions. $MoOCl_2$ exhibits a broad hyperbolic region spanning visible and near-infrared frequencies. We confirm $MoOCl_2$'s optical anisotropy via reflectivity measurements on exfoliated flakes. The axis orientation with respect to the flakes geometry is probed by atomic force microscopy with atomic resolution, enabling reconstruction of the unit cell shape. Finally, real-space polariton nanoimaging $MoOCl_2$ demonstrates the presence of hyperbolic plasmon polaritons as launched by a gold scattered fabricated on top of a flake. Our findings introduce MoOCl2 as a the first material supporting low-loss visible-frequency hyperbolic polaritons, enabling applications envisioned for hyperbolic metamaterials but without the need for nanofabrication and reduced ohmic losses.

Abstract: Nano-to-micrometer size single-shot *femtosecond laser delamination* (FLD) membranes or cavities of ferromagnetic thin films and multilayers are quantified using the Abbe-limited interferometric, ultrafast scanning photo-acoustic and magneto-plasmonic microscopies. Cavity formation mechanisms as well as their applications for ultrafast GHz-to-THz frequency acoustics and magneto-plasmonics in the Otto configuration are discussed.

Femtosecond laser pulses are commonly used both to produce and investigate new structures for a wide range of applications in nanotechnology, chemistry, solid-state physics, life sciences, and today in industrial processes (e.g. micromachining). At low energies, these ultrashort pulses can excite ultrafast dynamics in the samples under study, or, at higher intensities, induce permanent modifications creating new nanostructures with unique physical properties. For example, closed FLD cavities can be produced from thin-film or multilayer samples by delamination, i.e. local film separation from the substrate.

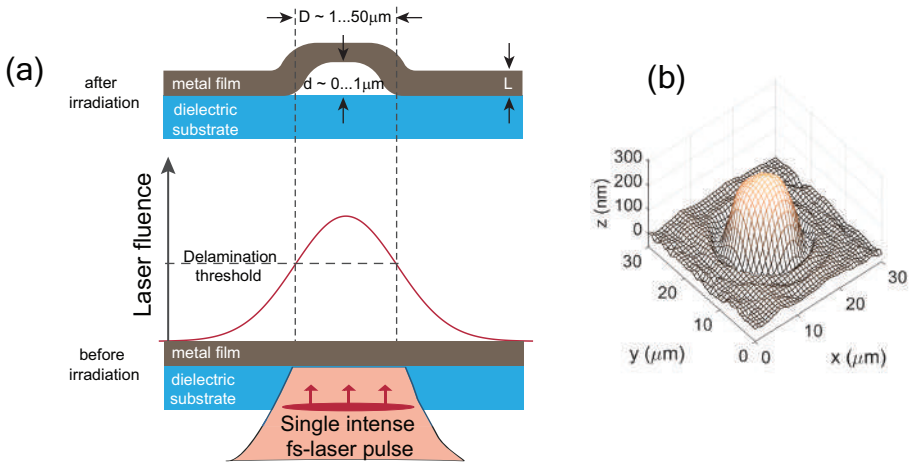

Figure 1: (a) A single high-energy femtosecond laser pulse with peak fluence >0.1 J/cm^2 focused on a thin metal film (or multi-layer structure) produces a closed FLD-cavity. (b) The resulting cavity shapes can be observed by in-situ optical interferometric microscopy.

The principle of femtosecond laser delamination (FLD) is quite simple: single laser pulses are focused onto the thin film or multilayer through an optically transparent substrate [1]. The film thickness and laser focusing conditions are chosen so that only the central part of the excited film separates from the substrate, forming closed cavities. Depending on laser focusing and fluence (incident laser energy per unit surface area, measured in J/cm^2), their lateral size D ranges from a few hundred nanometers to several tens of microns (Fig. 1). The film-substrate separation d can be further quantified with nm-precision by optical interference microscopy during the laser nanofabrication process.

Physical properties of the cavities obtained by FLD are noteworthy: the delaminated part of the membrane forms a high-quality "acoustic" cavity. Time-resolved photoacoustic microscopy using low-energy laser pulses (<1/100th of the high-energy pulses creating the structure) allows to record pulses of coherent acoustic phonons propagating in the membrane (Fig. 2). The analysis of acoustic pump-probe dynamics provides access to the properties of these ultra-high-frequency (>100 GHz) phonon modes and evidence some modes with a high quality factor Q>40 [2].

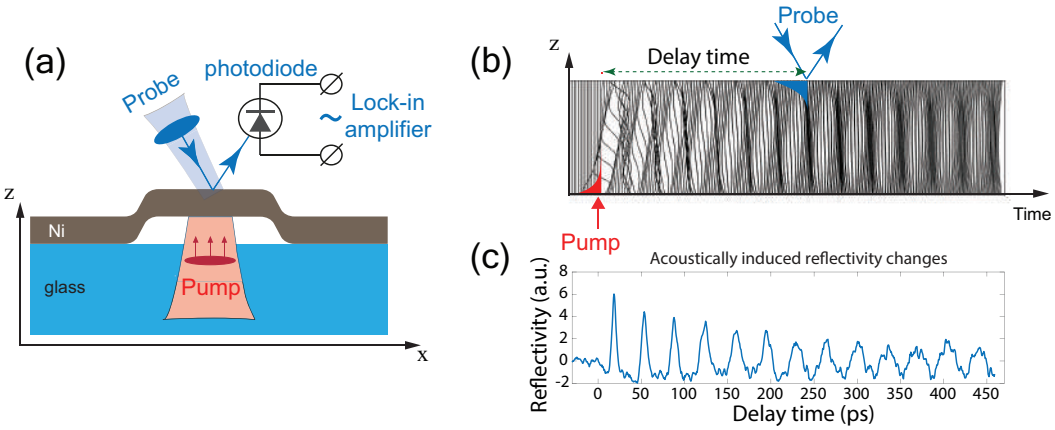

Figure 2: Using low-energy pulses, time-resolved pump-probe microscopy can be used to measure the ultrafast dynamics in FLD cavities, obtained by laser delamination of a thin layer of nickel on a glass substrate. (b) Elastic vibrations evidence long-lived oscillations of FLD cavity/membrane, as shown in (c) by multiple peaks in the time-resolved reflectivity signal.

Another system based on cobalt-gold bilayers on sapphire [2] shows that FLD cavities with a large separation $d \sim \lambda$ can be used for plasmonic measurements in the Otto-configuration, which is otherwise different to achieve experimentally. FLD structures with smaller gap $d \ll \lambda$ could be used to measure the theoretically predicted nanogap resonances [3]. The results of all-optical fabrication and characterization of magnetic FLD cavities uncover the potential of single femtosecond laser pulses for the controlled nanofabrication of new architectures for acousto-magneto-plasmonic and nanophotonic applications.

Abstract: Upconverting the solar spectrum to ultra-violet using lanthanides is of major interest for photocatalysis applications, but limited by their low absorption cross-sections. We have designed, fabricated and characterized two dimensional photonic crystals enhancing multisolar upconversion process from near infra-red and visible to ultra-violet in Yb^{3+}, Tm^{3+}.

UV upconversion is a lever for improving the efficiency of photocatalysis processes [1]. Harvesting the long-wavelength part of the solar spectrum requires substantial anti-Stokes conversion, which can be achieved with lanthanides [2,3]. The co-doped system Yb^{3+}, Tm^{3+} is used to ensure UV emission from part of the visible and IR solar spectrum absorption. However, the energy conversion efficiency is limited by lanthanides low absorption cross-section [4, 5]. So far, two-dimensional photonic crystals (2D PC) have been designed to assist the NIR to visible upconversion [6, 7], but not to UV upconversion. Here we present a design composed of a non-stochiometric silicon nitride (SiN_x) 2D PC and a Y_2O_3:Yb^{3+}(7,5%),Tm^{3+}(0,5%) thin film on a fused silica wafer, enhancing the UV emission from NIR and visible upconversion with guided mode resonances on excited state absorption (ESA) and emission transitions. SiN_x, deposited by plasma-enhanced chemical vapor deposition, has been optimized to be transparent from the UV to the NIR range, and exhibits a refractive index close to the Y_2O_3:Yb^{3+},Tm^{3+} thin film one. Doping rates of the Y_2O_3:Yb^{3+},Tm^{3+} thin film, deposited by pulsed laser deposition, have been studied to find the best compromise to foster the energy transfer upconversion while avoiding concentration quenching. 2D PC structure has been investigated with rigorous coupled-wave analysis simulations, then fabricated using electron-beam lithography and inductively coupled plasma - reactive ion etching.

The 2D PC illustrated Figure 1a is designed in order to promote ESA in Tm^{3+} from the metastable excited-state $^3F_4$ to $^1D_2$ ($\sim$ 450 nm), which emits UV while relaxing to the ground-state $^3H_6$ ($\sim$ 365 nm). $^3F_4$ being sensitized by Yb^{3+} in the NIR ($\sim$ 980 nm), it is a multisolar absorption process [3]. The nanophotonic structure consists of a Y_2O_3:Yb^{3+},Tm^{3+} thin film and a SiN_x layer with hole patterns in a square lattice, whose lattice parameter is standing in the 240-280 nm range. In this way, the visible guided mode resonance is confined in the lanthanide doped thin film according to our simulations. The experimental measurement of ΓX dispersion-band diagram of the 2D PC (Figure 1b) confirms a guided mode resonance increasing the photonic density of states on the ESA transition for a normal incidence ($\theta = 0°$). It also shows modes on the emission range, whose impact on the emission directionality is still under study. UV emission spectra measurement under visible and NIR excitation (Figure 1c)

finally demonstrates that these modes assist the multisolar absorption process: the fabricated 2D PC shows a ×6 4 enhancement of the UV emission compared to an unpatterned reference.

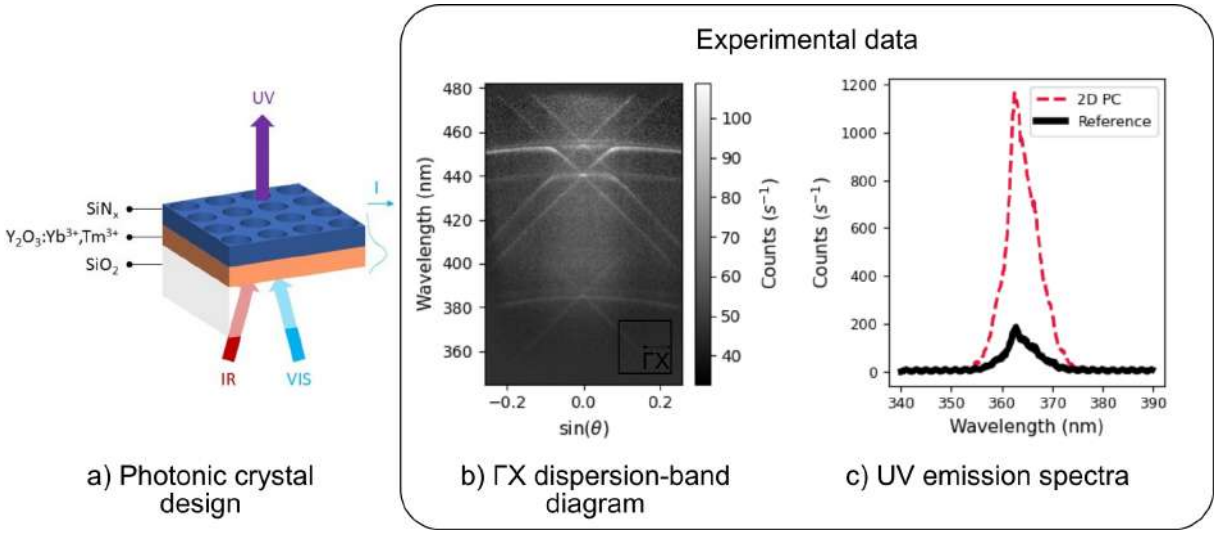

Figure 1: a - Schematic of the 2D PC combined with lanthanide-doped thin film. b - ΓX dispersion-band diagram of the 2D PC measured by angle-resolved reflectance, θ referring to the incidence angle. c - The 2D Photonic Crystal UV emission (red dashed line) is compared to the unpatterned reference one (black continuous line), under the following excitation conditions: 447 nm (58.5 kW/cm^2) + 995 nm (228.4 kW/cm^2).

We acknowledge the funding from Agence Nationale de la Recherche through the grant number ANR-22-CE09-0036. We acknowledge support from the CNRS/IN2P3 Computing Center (Lyon - France) for providing computing and data-processing resources needed for this work. Photonic crystals have been realized on the Nanolyon plaform, member of the CNRS-RENATECH+ national network.

Abstract: Acute myocardial infarction is one of the most severe cardiovascular diseases. As a result, considerable efforts are being made to develop biosensing technologies that can efficiently detect cardiac troponin biomarkers. Therefore, we developed a microfluidic plasmonic chip for the fast and real-time detection of the cardiac troponin I biomarker.

The fabrication of a plasmonic nanoplatform is based on immobilized gold nanobipyramids, which exhibits optical and thermoplasmonic properties that favour a multimodal localized surface plasmon resonance (LSPR) & surface enhanced Raman spectroscopy (SERS) & thermal detection of the cTnI biomarker. The plasmonic nanoplatform is characterized in terms of LSPR and SERS sensitivity and the thermoplasmonic performance is evaluated. Based on a sandwich-like immunoassay, the “proof-of-concept” LSPR-SERS-thermal detection of the cTnI in simulated conditions is evidenced. Furthermore, after the integration of the plasmonic nanoplatform in a microfluidic channel, the determination of the cTnI in real plasma samples is successfully realized and compared with a conventional high-sensitivity clinical assay proving good correlation. Thus, the proposed portable and miniaturized microfluidic plasmonic chip is validated for clinical applications supporting the further transfer to clinical settings for the early diagnosis of cardiac diseases and progress of personalized medicine.

Natural hyperbolic Van der Waals materials towards low-loss near unity linear dichroism

Abstract: In-plane hyperbolic crystals, enable nearly perfect linear dichroism by exhibiting metallic behavior in one direction and dielectric in the orthogonal. $MoOCl_2$ achieves strong polarization control with low loss, making it promising for miniaturized photonic devices, including direct integration into optical fibers.

Control over light polarization is essential for various optical technologies, including optical fiber communication[1], quantum cryptography[2], and display technologies[3]. Achieving polarization control requires materials with strong optical anisotropy that produces distinct transmission or reflection coefficients along orthogonal axes. Traditional approaches, such as wire-grid polarizers and metasurfaces, offer broadband polarization control but often suffer from high losses and complex fabrication processes[4]. As a result, there is a growing interest in natural anisotropic materials for low-loss, integrated photonic applications[5].

An ideal polarization control material should achieve "perfect linear dichroism," where one polarization is completely transmitted while the orthogonal one is fully reflected. This scenario is characterized by a high contrast between reflection and transmission coefficients without introducing optical losses, and can be quantified by the parameter

$$\Delta_{LD} = \frac{(R_x - R_y) - (T_x - T_y)}{2}$$

Perfect linear dichroism can be realized in bulky polarizing beam splitters or wire-grid polarizers in the IR low-loss region but a natural, versatile and miniaturizable platform is yet to be found.

The best configuration to achieve this effect in a natural material requires a combination of metallic and dielectric behavior along different crystallographic axes, which is the defining characteristic of hyperbolic materials. Hyperbolic materials possess a permittivity tensor where one principal component is negative while the other is positive, leading to strongly anisotropic light-matter interactions. While hyperbolic behavior has been observed in materials like MoO_3[6] and $CaCO_3$[7] in the mid-infrared, few materials exhibit hyperbolicity in the visible and near-infrared ranges, with only few reported materials mostly working in the UV region[8,9].

In this contribution, we demonstrate that van der Waals crystal $MoOCl_2$ exhibits a broad hyperbolic region spanning the visible and near-infrared spectrum by extracting the dielectric permittivity tensor experimentally. The in-plane hyperbolicity in the visible spectrum makes $MoOCl_2$ an excellent candidate for achieving perfect linear dichroism. Indeed, experimental results reveal that $MoOCl_2$ exhibits strong optical anisotropy in reflection and transmission simultaneously across the visible spectrum above 550 nm. This remarkable anisotropy enables nanometer-scale $MoOCl_2$ flakes to achieve record-high value of $\Delta LD \sim 0.8$, surpassing even the previous record-holder $NbOCl_2$[10]. To demonstrate the ready integrability of MoOCl2 nanocrystals in working optical elements, we fabricated a broadband polarizing fiber by transferring a flake of MoOCl2 onto the core of a commercially

available optical fiber.

Our findings highlight the potential of hyperbolic vdW crystals as excellent candidates for developing low-loss, compact optical components for advanced polarization control in integrated photonic systems

Abstract: In this report, we will discuss exquisite optical properties of single-crystal two-dimensional gold flakes (2DGFs). The ultrathin thickness of the 2DGFs leads to the onset of quantum confinement effects, which create new pathways for gold photoluminescence and nonlinear harmonic generation, leading to their enhancement by orders of magnitude.

In this report, we will discuss exquisite optical properties of single-crystal two-dimensional gold flakes (2DGFs) having a large area together with a thickness down to few nanometres, which are synthesised via a chemical etching approach providing atomic-level precision [1,2]. The ultrathin thickness of the 2DGFs leads to the onset of quantum confinement effects, which create a new pathway for gold photoluminescence, increasing its magnitude manyfold [3]. Furthermore, the quantisation boosts optical nonlinearity of the 2DGFs and provides over two orders of magnitude enhancement in harmonic generation compared to thicker polycrystalline counterparts. The single-crystal quality and atomically smooth surfaces also makes 2DGFs highly attractive for low-loss nanoscale plasmonics. For example, nanoribbon arrays produced from them exhibit strongly confined near-infrared plasmonic resonances with high quality factors. These findings establish two-dimensional gold as a versatile platform for nanophotonic research, with promising applications in ultrathin plasmonics, optoelectronics, and quantum devices.

Infrared electroluminescence and energy transfer in hBN-encapsulated graphene devices under high bias voltage

Y. De Wilde[1*]

[1] Institut Langevin, ESPCI Paris, Université PSL, 1 rue Jussieu, 75005 Paris, France

[*]corresponding author: yannick.dewilde@espci.fr

Abstract: We detect mid-infrared radiation from high-mobility graphene devices encapsulated in hexagonal boron nitride (hBN) under large bias voltage, and demonstrate that it results from the electroluminescence of hyperbolic phonon-polaritons. We show that the effect is concomitant with the onset of a highly efficient out-of-plane energy transfer process.

Electroluminescence corresponds to the emission of electromagnetic radiation beyond incandescence. It is usually known to occur at visible wavelengths in light emitting devices made of doped semiconductors. However, electroluminescence of hyperbolic phonon-polaritons (HPhPs) has been proposed by Baudin's group at LPENS as an explanation for the peculiar radiative energy transfer within hexagonal boron nitride (hBN)-encapsulated graphene transistors [1][2]. The first indication of electroluminescence was based on electrical transport measurements using noise thermometry, which gave only indirect evidence of the existence of the effect.

We recently collaborated with the LPENS group to help them search for direct evidence of electroluminescence in hBN-encapsulated graphene transistors [3]. The structure of the investigated devices is shown in figure 1a. Infrared microscopy combined with high sensitivity modulation spectroscopy [4][5] has been used to investigate the radiation produced by high quality hBN-encapsulated graphene transistors with a mobility of tens of thousands of $cm^2 . V^{-1} . s^{-1}$. When a sufficiently large bias voltage is applied between the source and the drain, electron-hole pair injection occurs as a result of interband Zener-Klein tunneling [1][2]. We observe then a substantial mid-infrared emission from the device channel, as shown in Figure 1b. It appears above the threshold voltage of the Zener-Klein tunneling effect.

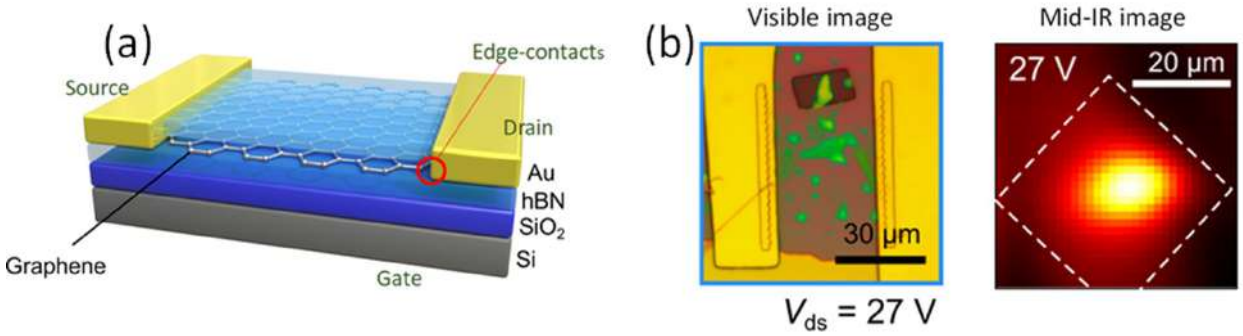

Figure 1: (a) Sketch of the hBN-encapsulated graphene transistors; (b) Visible microscopy image and spatial scan of the spectrally integrated mid-IR emission of the device biased above the Zener Klein threshold voltage.

Indeed, as hBN is a hyperbolic material, interband electron-hole recombination in graphene gives rise to the emission of HPhPs in hBN. Based on far-field mid-IR spectroscopy and electromagnetic simulations, we show

that electroluminescence is due to propagating small-wavevector HPhPs scattered elastically at discontinuities in the Van der Waals heterostructure. This produces a spectral peak at ~ 190 meV beyond incandescence. Large wavevector HPhPs are also produced by electron-hole recombination above the Zener-Klein threshold voltage. Their dissipation occurs over nanometric length scales near the graphene layer, producing a heating of hBN and out-of-plane energy transfer through the silica layer at the gate of the device. Incandescent emission results from the hot silica, whose intensity makes it possible to quantify the energy transfer.

This work is the result of a project whose principal investigator is Prof. Emmanuel Baudin (LPENS). It involves collaboration [3] between groups from LPENS, Institut Langevin, ONERA, MATEIS, Laboratoire des Multimatériaux et Interfaces, Laboratoire Charles Fabry-IOGS, Advanced Materials Laboratory, IEMN, Tim Taylor Department of Chemical Engineering. The research leading to these results has received partial funding from the European Union Horizon 2020 research and innovation program under grant agreement No.881603 "Graphene Core 3", and from the French ANR-21-CE24-0025-01 "ELuSeM". This work has received support under the program “Investissements d’Avenir” launched by the French Government.

Unified Framework for Enhancing Chiral Light-Matter Interactions

C. F. Doiron[1]
[1]Center for Integrated Nanotechnologies, Sandia National Laboratories, USA
Corresponding author: cfdoiro@sandia.gov

Abstract: While nanophotonics can enhance, typically weak, chiral light-matter interactions, the absence of a unified theory for understanding the flow of energy and chirality prevents a complete understanding of ultimate performance limits and requirements. Here, we present a unified framework for simultaneously understanding energy and chirality flows in resonant nanophotonic systems.

Over the past 20 years, significant advances have been made in harnessing chirality with experimental demonstrations of circularly polarized lasers, chirality-sensitive emission, and chiral molecular sorting. Understanding the role of chirality in nanophotonics traces back to Lipkin's discovery of the conserved "00-zilch" quantity, which is carried solely by circularly polarized waves [1]. Subsequent works [2, 3] established 1) this conserved quantity directly relates to chirality and 2) the conservation of such a quantity allows the formulation of a chiral continuity equation analogous to the energy conservation continuity equation (Eqs. 1-8), where the optical chirality ($\bar{\chi}$) parallels the electromagnetic energy ($\bar{u}$) comprised of electric ($\bar{\chi}_e$ and $\bar{u}_e$) and magnetic ($\bar{\chi}_m$ and $\bar{u}_m$) contributions. The generation and dissipation of chirality ($\mathrm{Im}(\bar{\chi}_e \in \bar{\chi}_m)$) is linked to a chiral flux ($\mathbf{F}$) through a continuity equation similar to how the generation and dissipation of energy ($\mathrm{Im}(\bar{u}_e \in \bar{u}_m)$) is related to the Poynting vector ($\mathbf{S}$).

Energy		**Chirality**	
$\bar{u} = \bar{u_e} + \bar{u_m}$	(1)	$\bar{\chi} = \bar{\chi_e} + \bar{\chi_m}$	(5)
$\bar{u}_e = \frac{1}{4}\mathbf{E}\cdot\mathbf{D}^*$	(2)	$\bar{\chi}_e = \frac{1}{8}\left[\mathbf{D}^*\cdot(\nabla\times\mathbf{E}) + \mathbf{E}\cdot(\nabla\times\mathbf{D}^*)\right]$	(6)
$\bar{u}_m = \frac{1}{4}\mathbf{H}\cdot\mathbf{B}^*$	(3)	$\bar{\chi}_m = \frac{1}{8}\left[\mathbf{H}^*\cdot(\nabla\times\mathbf{B}) + \mathbf{B}\cdot(\nabla\times\mathbf{H}^*)\right]$	(7)
$0 = -2\omega\int_V \mathrm{Im}(\bar{u}_e - \bar{u}_m)\,dV + \int_V \mathrm{Re}(\nabla\cdot\mathbf{S})\,dV$	(4)	$0 = -2\omega\int_V \mathrm{Im}(\bar{\chi}_e - \bar{\chi}_m)\,dV + \int_V \mathrm{Re}(\nabla\cdot\mathbf{F})\,dV$	(8)

Such a continuity equation not only allows the flow of chirality to be accounted for, but also provides near-field definitions for the spatial distribution of chirality storage and generation. As these definitions have been applied to resonant photonic systems, the physical mechanisms behind chirality have attracted a long list of adjectives including "extrinsic," "intrinsic," "false," "true," and "super." To date, there is no unified framework for combining the near-field distribution and conservation of chirality with the conservation of energy in resonant systems. Moreover, the absence of such a framework obscures the roles that geometric and material asymmetries play in generating chirality in resonant systems. Consequently, there are numerous claims regarding the features of chirality needed or preferred for chiral emission (both direct and through

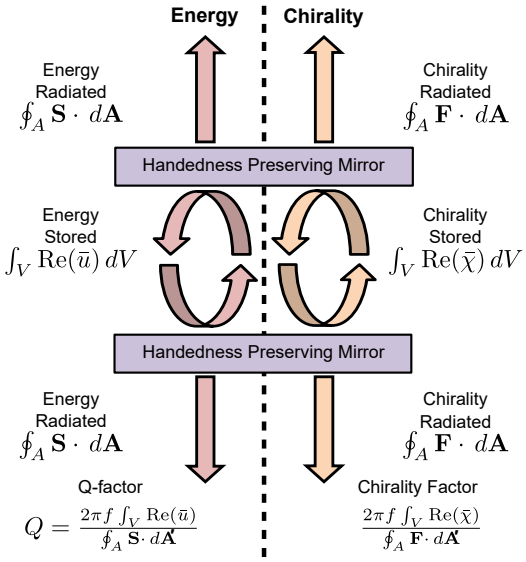

Figure 1: Schematic diagram of energy and chirality flow in a lossless, single-handed cavity where there is no chirality creation or destruction.

non-linear optical effects), molecular sensing, and trapping. The lack of a unified framework for combining chirality and energy prevents a thorough understanding of how chirality needs to be controlled for a specific situation, hindering the design of metasurfaces for enhancing chiral light-matter interactions.

Here, we present a unified framework centered around a chirality analogue of temporal coupled mode theory for simultaneously understanding chirality and energy flows in resonant systems to enhance light-matter interactions. By applying this framework to non-resonant interference systems with bi-isotropic materials, resonant cavities, chiral quasi-bound states in the continuum, and systems with geometric and material asymmetry, we demonstrate the necessity of considering chirality and energy to maximize chiral light-matter interactions. Moreover, we use this unified framework to reveal the definitions and roles of "extrinsic," "intrinsic," "false," "true," and "super" chirality when designing metasurfaces for lasing, single-photon source emission, non-linear mixing, and chiral sensing and separation.

Abstract: Transition metal nitrides (TMNs), have emerged as promising alternative plasmonic materials, displaying spectral tunability, thermal stability and mechanical stability. This work reports the CMOS compatible deposition of plasmonic TMN films at low temperature. We also describe dry etching methods for the scalable production of TMN metamaterial nano-arrays.

TMNs such as titanium nitride (TiN) have emerged as promising alternatives to gold and silver for tailored plasmonic applications. TiN has potential applications for plasmonics and optoelectronics in the visible and near-IR spectral ranges including sensing, catalysis, and thermophotovoltaics.[1-3] However, the realization of these applications has been limited by the high deposition temperatures (> 800 °C). required for the production of TMN thin films with suitable optical properties. For example, such deposition temperatures are a barrier to the integration of plasmonic TMN components in CMOS fabrication processes.

In this paper, we report the deposition of binary, ternary, and layered TMN thin films at low (< 300 °C) temperatures using High-Power Impulse Magnetron Sputtering (HIPIMS). The optical, structural, and morphological properties of the thin films are characterized via spectroscopic ellipsometry, XRD, AFM, and XPS. We demonstrate that the thin film properties obtained using this low temperature deposition method are comparable to those reported in the literature.[4]

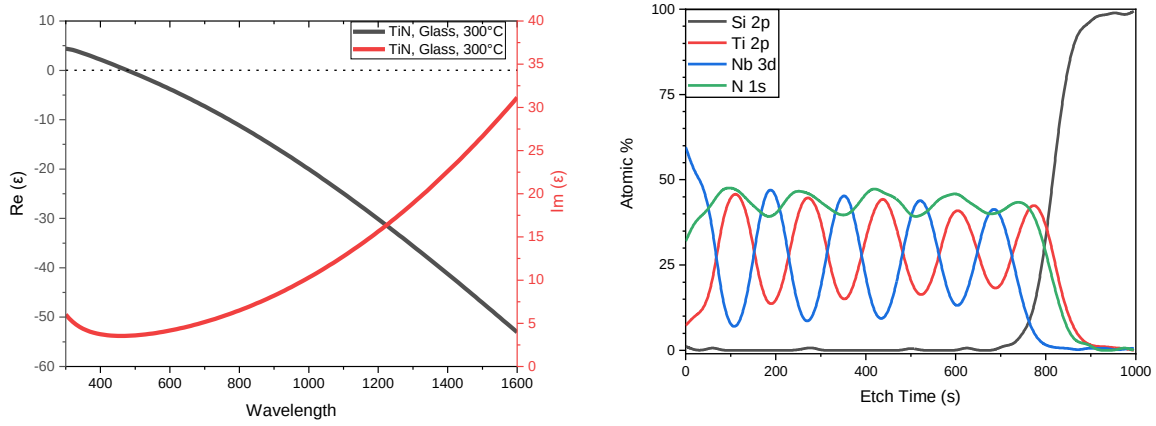

Figure 1: (Left) Spectroscopic ellipsometry data for TiN thin films deposited at 300 °C. (Right) XPS depth profiling data of multilayered TiN/NbN thin films.

In addition to low temperature deposition methods for plasmonic TMNs, we report the fabrication and characterization of plasmonic nano-arrays and meta-surfaces. Dry-etching methods including Reactive Ion Etching (RIE) and Chemically Assisted Ion Beam Etching (CAIBE) are used to fabricate plasmonic nanofeatures. We also discuss scalable fabrication methods for the large area (cm-scale) production of TMN metamaterial arrays.

Abstract: We introduce multilayer structures with the phase-change material germanium-antimony-tellurium (GST) for use as broadband switchable absorbers in the infrared wavelength range. We also introduce multilayer structures with GST for switchable radiative cooling.

We introduce multilayer structures with the phase-change material germanium-antimony-tellurium (GST) for use as broadband switchable absorbers in the infrared wavelength range. In many cases, multilayer structures can provide absorption spectra similar to that of more complex and harder-to-fabricate three-dimensional structures. We use a memetic optimization algorithm coupled with the impedance method to optimize both the material composition and the layer thicknesses of the multilayer structures. We maximize the difference between the absorption for GST in its crystalline phase and the absorption for GST in its amorphous phase in the wavelength range of interest. We show that in the optimized structures near perfect absorption can be switched to very low absorption in a broad wavelength range by switching GST from its crystalline to its amorphous phase. We find that our approach of simultaneously optimizing the material composition as well as the layer thicknesses leads to structures which achieve better performance with smaller number of layers. Our results could pave the way to a new class of broadband switchable absorbers and thermal sources in the infrared wavelength range.

In addition, we introduce multilayer structures with GST for switchable radiative cooling. Our system is based on two components: a wavelength-selective filter on the top and a radiative cooler at the bottom, separated by a large air gap. We calculate the net cooling power of our system, which depends on the emissivity of the radiative cooler in the presence of the top filter, by solving the heat balance equation. We use the memetic optimization algorithm to optimize the multilayer filter and cooler structures. We show that our optimized system can achieve a very high net cooling power when the GST layers in the cooler are in their crystalline phase. By switching the GST layers in the cooler to their amorphous phase, our system can achieve a near zero net cooling power. Our proposed switchable radiative cooling system could advance the thermal management of buildings, smart windows, vehicles, and textiles.

Detection of Ammonia in Water Using Self-Assembled Plasmonic Colorimetric Sensor

Abstract: Monitoring chemicals, such as elevated ammonia levels, is crucial for safeguarding public health and the environment. Elevated ammonia indicates contamination from agriculture, industry, or sewage. We have developed a plasmonic sensor to detect ammonia by correlating changes in optical response to analyte concentration, developing a portable, high-resolution, and affordable solution.

Summary:

Conventional methods for detecting ammonia in water are classified as electrochemical, biological, and optical[1]. Electrochemical sensors for ammonia detection use ion-selective electrodes sensitive to the presence of ammonia. These sensors translate changes in electrical properties such as voltage, conductivity, or current flow into ammonia concentrations. In contrast, biological methods excel in ammonia detection when high specificity is required. However, despite delivering precision, these methods necessitate intricate sample preparation and entail higher costs[2]. Alternatively, optical detection methods harness the optical attributes of substances to conduct chemical analyses, demonstrating portability, cost-effectiveness, and high resolution. Recently, Surface-enhanced Raman scattering has drawn attention among all optical detection methods due to its low detection limit (1 ppm), high response time (within a few seconds), and high sensitivity. In addition, colorimetric or fluorescent reagents are introduced into the target solutions to interact with ammonia, inducing alterations in color or fluorescence that are directly correlated to the ammonia concentration. Among these, the prevailing methods are the Indophenol Blue (IPB) method, a colorant-based approach, and the o-phthalaldehyde (a fluorant-based approach). Past decades have observed the widespread use of nanofabrication techniques that have enabled the development of plasmonic structures for chemical sensing. When light of a specific wavelength illuminates a metallic nanostructure, it induces a collective and coherent oscillation of the free electrons within the metal, a phenomenon known as plasmon resonance. However, all these techniques lack portability and user-friendliness, as they still rely on reagents or expensive optical equipment like spectrometers, which prohibits their potential for widespread adoption.

Herein, we present a low-cost, easy-to-use, and label-free plasmonic colorimetric sensor that detects ammonia in water by correlating the color change in the sensor with the concentration of the target solution[3]. The plasmonic structure consists of a self-assembled layer of aluminum nanoparticles on an aluminum backplane coated with a thin transparent oxide supporting gap plasmons at visible wavelengths. Hence, when illuminated by surrounding

white light, the nanostructure absorbs certain spectral bands and reflects the rest, resulting in a specific color appearance. Interestingly, when the aluminum nanoparticles interact with ammonia in water, the nanoparticles oxidize, leading to a loss of color. Thus, by analyzing this color transformation, the ammonia concentration can be determined directly from the solution without additional reactants. Significantly, this colorimetric platform relies on a self-assembling technique for producing large-scale and low-cost structural color fully compatible with industrial standards, thus allowing for a cost-effective and high-volume production method for the sensors, essential for commercial success. We present a simple algorithm using a smartphone camera, and image recognition can eliminate the need for traditional bulky and expensive spectroscopic systems, simplifying color-reading[3]. Our colorimetric plasmonic platform only requires a sensor and a smartphone to determine ammonia levels as low as 8.5 ppm in water[3], eliminating the need for additional chemicals. This makes the sensor suitable for use in contexts where low cost and portability are required.

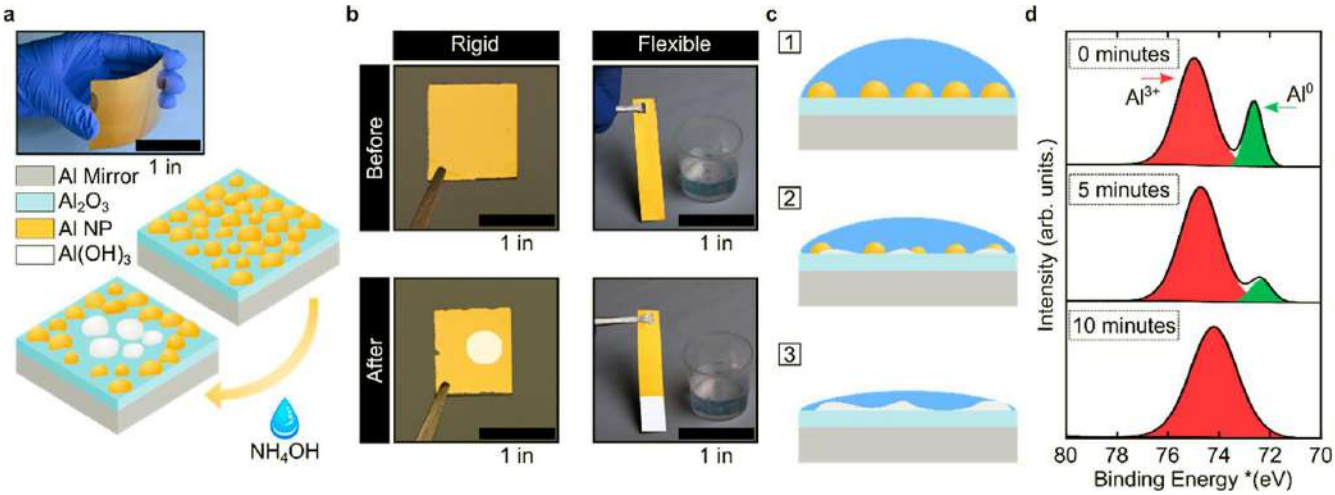

Figure 1. Chemical reaction-induced color change in nanosensor. (a) The plasmonic colorimetric sensor consists of an aluminum self-assembled layer over a thin Al_2O_3 layer over a back mirror on rigid (glass) and flexible (PET) substrates. (b) Nanoislands structural change causes observable color shifts before/after exposure to dissolved ammonia in water. (c) Al_2O_3 transforms to $Al(OH)_3$ after reaction with dissolved ammonia in water. Subsequent exposure to water cyclically prompts Al_2O_3 layer formation. (d) XPS measurements of the top surface of the sensor at different time intervals indicate aluminum nanoparticles oxidize during the reaction with aqueous ammonia.

Visualization of Thermal Extraction Process Achieved by Metamaterial Absorber

Wakana KUBO
Tokyo University of Agriculture and Technology (TUAT)
*corresponding author: w-kubo@cc.tuat.ac.jp

Abstract: We visualized how a metamaterial absorber extracts heat from surrounding objects for the first time. After a certain period of heating, we observed that the temperature of the Cu plate placed on the metamaterial substrate attached to the thermoelectric device decreased faster than that of the Cu plate placed on the control substrate.

The development of technologies to recycle waste heat is essential for establishing a decarbonized society. Thermoelectric conversion is a promising technology for recycling waste heat. However, due to its inherent limitations, power generation is impossible in an environment with uniform thermal radiation, meaning that conventional thermoelectric devices cannot collect and recycle the waste heat diffused in environments. To address this issue, we proposed and demonstrated metamaterial thermoelectric conversion capable of power generation even in an environment with uniform thermal radiation.[1-3] In this mechanism, a metamaterial absorber (MA) installed on one end of the thermoelectric element absorbs thermal radiation emitted from the surrounding environment, which is then converted into electricity by the thermoelectric element.

In previous studies, the ability of MA to absorb thermal radiation has been demonstrated through measurements of its absorption and emission spectra in far-fields and through direct observation of localized heat generation. Furthermore, we previously demonstrated that MA induces nonradiative cooling, reducing the air temperature in its vicinity.[4] However, the nonradiative cooling has been evaluated using thermistors, which measure the average temperature drop of the surrounding air in the vicinity of the MA electrode. Moreover, no prior study has visualized the process of MA extracting heat from surrounding materials. Therefore, we attempted to observe how MA extracts heat from surrounding objects using an infrared camera.

We fabricated a metamaterial thermoelectric device by attaching a MA substrate, composed of Ag disks, a calcium fluoride (CaF_2) layer, and a Ag layer, to one side of a thermoelectric element (Fig. 1(a-c)). The MA substrate is electrically isolated from the thermoelectric device using polymer double-side tape. The MA thermoelectric device and control device (with Cu electrodes only) were placed on a cooler maintained at 303 K, and a Cu plate bonded with polyimide (PI) was placed on the top electrodes of the devices.

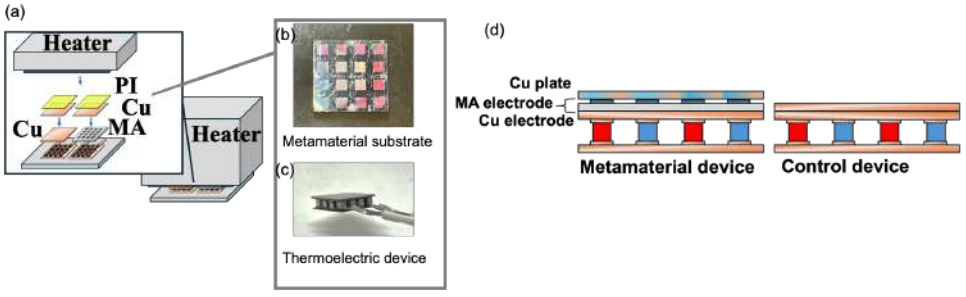

Figure 1. (a) Schematic of experimental setup. Photographs of (b) the metamaterial substrate and (c) thermoelectric device. (d) Cross-sectional experimental schematics of the metamaterial (left side) and control (right side) thermoelectric devices.

The PI film on the Cu plate is used to reduce reflectivity, leading to more accurate temperature measurements using an IR camera. The upper surfaces of the Cu plates were heated for 1 minute by a heater set to be 373 K. After removing the heater, we observed the natural cooling process of the upper Cu plate. The temperature reduction on the Cu substrate was measured using an infrared camera and thermistors, and the voltage and current of the thermoelectric devices were recorded.

Fig. 1(d) presents the expected mechanism that the MA extracted heat from the upper Cu substrate and gave it to the thermoelectric device. This caused the faster temperature reduction of the Cu substrate on the MA device than that of the Cu plate on the control device, leading to an increase in the output voltage generated by the MA device.

Figure 2(a) shows the time dependence of the output voltage generated by the MA and control thermoelectric devices. Figure 2(b) displays the voltage difference of the MA and control devices after 320 s, demonstrating that the MA device exhibited a higher output voltage. The absolute value of the temperature difference between the Cu plates on the MA and control devices is shown as red plots in Fig. 2(b), indicating that the temperature reduction of the Cu plate on the MA device occurred after the MA exhibited higher output voltage. Figure 2(c) presents the infrared camera images of the Cu plates on the MA and control devices. At 16 s after heating stopped, the temperature of the Cu substrate placed on the MA device was visually confirmed to be lower than that on the control device, indicating that the MA extracted heat from the Cu plate. This trend is also supported by the output voltage difference profile. These results support the cooling mechanism observed for the Cu plate placed on the MA device. In conclusion, we successfully visualized the process of MA extracting heat from the surrounding objects.

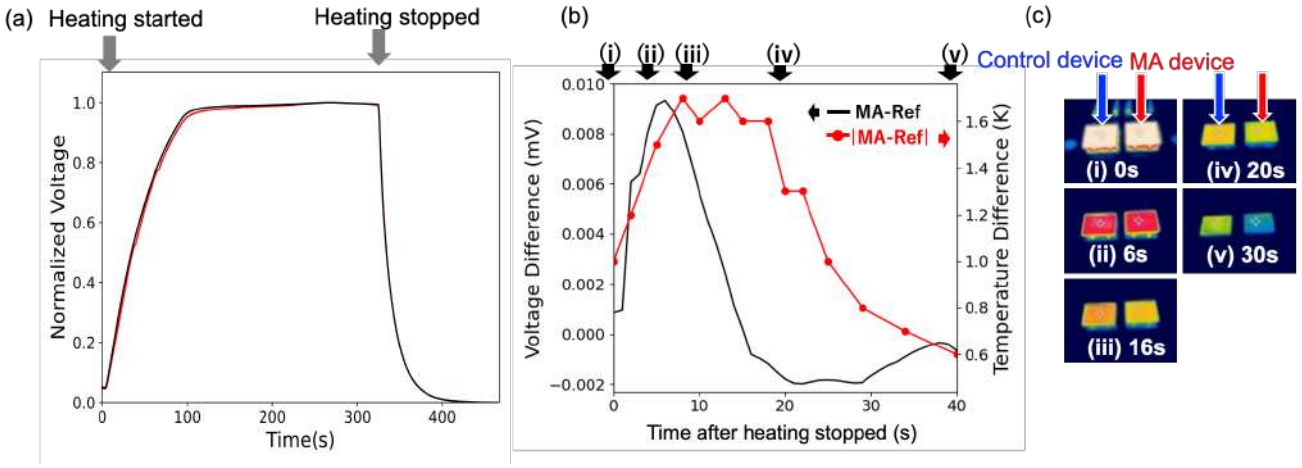

Figure 2(a) Normalized output voltage profile of the metamaterial (red line) and control (black line) thermoelectric devices. Heating was stopped at a time of 320 s. (b) Comparison of the voltage differences of the metamaterial and control devices, and the absolute value of temperature difference between the Cu plates on the metamaterial and control devices. (c) IR camera photographs of the Cu plates placed on the MA and control devices at (i) 0 s, (ii) 6 s, (iii) 16 s, (iv) 20 s, and (v) 30 s, respectively.

Twisted Moiré Metasurfaces with Emissive Gap Layers Enabling Giant and Tunable Chiral Emission

Zijie Jiang[1], Sun Zhao[1], Zhuofei Gan[1], and Wen-Di Li[1*]

[1]Department of Mechanical Engineering, The University of Hong Kong, Pokfulam, Hong Kong S.A.R., China
[*]corresponding author: liwd@hku.hk

Abstract: We present twisted moiré chiral metasurfaces (TMCMs) with tunable chiral emission using cost-effective and large-area fabrication combining nanoimprint and interference lithography. TMCMs achieve luminescence dissymmetry factor (g_{lum}) of −1.21. Chirality is tuned via twist angles and gaps, validated by reciprocity-based simulations. Compatibility with quantum dots and perovskites enables versatile chiral light sources.

Chiral light sources with direct circularly polarized emission are critical for sensing, imaging, and quantum technologies [1]. Conventional chiral metasurfaces rely on complex meta-atoms and costly electron-beam lithography, limiting their manufacturability and scalability. Twisted moiré metasurfaces [2,3] offer intrinsic chirality through lattice-level symmetry breaking but face challenges in emission performance and fabrication efficiency. Here, we demonstrate emissive TMCMs with a dye-doped polymer gap layer between reusable structural layers, fabricated via nanoimprint (NIL) and laser interference lithography (LIL). This method enables centimeter-scale production while maintaining high tunability and cost-effectiveness.

The TMCM design comprises two twisted gold nanopillar arrays separated by an emissive gap. The moiré lattice, dictated by the twist angle (α), breaks symmetry without intricate meta-atoms. A key innovation in our work is the reusable structural layers, fabricated using high-throughput and scalable techniques like interference lithography, UV-curable and thermal NIL, and electrochemical deposition. The thickness (g) of the emissive gap layer in the TMCM structure is controlled via spin-coating, enabling precise modulation of interlayer coupling.

Emission chirality was quantified by the g_{lum} factor, defined as $g_{lum} = 2\frac{I_{LCP}-I_{RCP}}{I_{LCP}+I_{RCP}}$, with the maximal value achieved to be −1.21 at 719 nm. Chirality tuning was demonstrated by varying α from 0° to 165° and g from 35 to 210 nm. For instance, reversing α beyond 90° inverted g_{lum}, while adjusting g shifted resonance wavelengths and flipped chirality. We also carried out reciprocity-based simulations, which revealed that the emission asymmetry correlates with field enhancement contrasts.

Notably, the TMCM platform supports diverse emissive materials. Replacing dye molecules with CdSe quantum dots or $CsPbI_3$ perovskites in the gap layer yielded comparable g_{lum} values. This versatility, combined with dynamic tunability, positions TMCMs as ideal candidates for applications like encryption, 3D displays, and spin-photonics.

In conclusion, our work addresses critical barriers in chiral metasurface fabrication and performance. The scalable fabrication method, high g_{lum}, and tunability via geometric parameters establish TMCMs as a promising platform for practical chiral light sources.

Abstract: This work presents a systematic optimization approach to develop efficient photonic structures with enhanced optical performance for CMOS image sensors. Adjoint sensitivity analysis (ASA) is used to optimize the structure for improved focusing and collection of light. The adjoint-optimized structure demonstrates enhanced performance compared to the conventional designs.

In recent years, there has been a great interest in advancing CMOS image sensors to achieve high resolution sensing and imaging. The broad integration of CMOS image sensors in various imaging and sensing technologies is largely driven by their miniaturized feature size, resulting in reduced pixel size. This reduced pixel size affects the light collection in the photoactive region, which degrades the intensity, angular response, and overall performance. Efficient photonic designs such as microlenses [1] or dielectric metasurfaces [2] can significantly improve the light collection and optical efficiency of CMOS image sensors. We use adjoint-driven optimization techniques to accelerate the development of efficient design of microlenses and metasurfaces to enhance the overall optical efficiency of CMOS image sensors.

In our study, we carried out shape optimization of CMOS microlenses using ASA [1, 3]. We utilize an optical stack for CMOS image sensor that includes conventional microlenses as initial design. The derivative-based optimizer perturbs the shape (or design parameters) of the microlenses to improve the figure of merit (FOM). The FOM sensitivities information is used during perturbation to determine the optimal design parameters. The FOM sensitivities with respect to all the design parameters are efficiently computed through only two simulations using ASA. We used Ansys Lumerical FDTD to carry out electromagnetic simulations. LumOpt [4], an open-source package, is utilized to perform adjoint-based optimization. We have substantially modified and extended the LumOpt framework, significantly enhancing its ability to integrate adjoint formulation for free-space photonic problems and incorporate FOM for new classes of photonic devices, such as microlenses [1] and dielectric metasurfaces [2].

In our work, the front-side illuminated (FSI) optical stack for CMOS image sensor is represented using an Si substrate with metallic interconnect embedded in a dielectric layer of SiO_2. The optimizable microlenses are positioned above the Bayer color filters. Each color pixel is 2 μm wide and a fill factor of 25% is used during the optimization. We aim to maximize the absorption of light at the Si surface for the central RGB wavelengths, i.e. 650 nm, 550 nm, and 450 nm, by defining a novel FOM for adjoint field formulation as follows:

$$FOM = \sum_{\lambda} w_{\lambda} \left| E(x,\lambda) \right|^2 , \tag{1}$$

where $E(x,\lambda)$ is the electric field at location x for wavelength λ and w_{λ} is the assigned weight for each λ .

Our study demonstrates significant improvement in the FOM and angular response (AR) through adjoint-assisted shape optimization of CMOS microlenses and outperforms the conventional microlenses, as shown in Fig 1. This work further accelerates the development of nonintuitive yet highly efficient 3D CMOS microlens for practical applications.

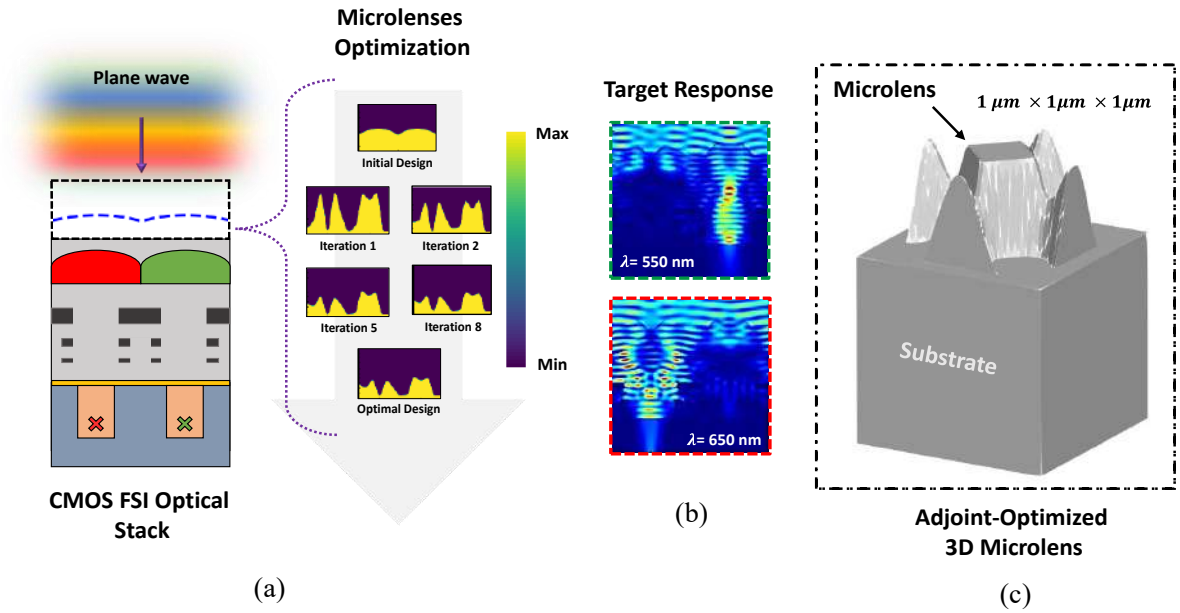

Figure 1. (a) Evolution of optimal microlenses for CMOS FSI optical stack during optimization process. (b) Intensity of incoming light at target wavelengths. (c) Optimization of 3D microlens for a quarter-unit cell on a substrate to maximize the light intensity at a target wavelength.

The contribution of our work is not only limited to the development of efficient designs of CMOS microlenses. The novel FOM developed in this work, supported by adjoint-driven optimization, enables the development of efficient optical devices to address the free-space photonic problems, presented in [2]. In [2], the adjoint-optimized dielectric metasurface (TiO_2–Si_3N_4), employed as color router, demonstrated improved optical efficiency (OE) over the visible spectrum and addressed the drawbacks associated with conventional color filters.

Modulation and amplification of waves by metasurfaces

I. V. Shadrivov
Research School of Physics and Australian Research Council Centre of Excellence for Transformative Meta-Optical Systems, The Australian National University, Canberra ACT 2601, Australia
ilya.shadrivov@anu.edu.au

Abstract: In this presentation I will overview our approaches to creating tunable metasurfaces for controlling amplitude, phase and polarization of electromagnetic waves. I will further discuss the parametric processes that allow amplification and up-conversion of electromagnetic waves.

First, we explore tunable polarization conversion in metasurface-assisted anisotropic slab waveguides using electro-optic modulation. We show that by an appropriate choice of the crystal axis, quasi-TE and quasi-TM modes in lithium niobate (LN) waveguide can be made degenerate. Using grating excitation of such modes and coupling between the modes, we enable efficient linear polarization conversion. The achieved broadband polarization conversion is demonstrated for varying crystal angles. Furthermore, voltage-induced refractive index changes in LN allow dynamic tuning of the conversion efficiency and phase. The study highlights the potential for versatile and tunable polarization conversion of light by a 1 micron thick structure.

In the second part of the presentation, we will focus on developing reconfigurable and time-varying metasurfaces, which can dynamically adjust their behaviour in response to external signals. This ability to change over time opens up exciting possibilities for new functionalities, such as real-time beam steering, enhanced signal processing, and advanced wave control mechanisms. Metasurfaces that change their properties with time are often referred to as time-varying or parametric metasurfaces. Unlike passive surfaces, which only redirect or filter incoming waves, parametric metasurfaces can actively amplify and convert the frequency of electromagnetic waves, enabling entirely new applications in signal processing and wireless communications. Recent studies have explored how time-varying metasurfaces can be used for nonreciprocal wave transmission (allowing waves to travel differently in opposite directions), the creation of so-called "time crystals," and the up-conversion of electromagnetic waves to higher frequencies.

Despite these exciting developments, most studies on time-varying metasurfaces have focused on either frequency conversion or wave amplification, but not both simultaneously. Only a few theoretical works have suggested that metasurfaces could achieve both amplification and frequency up-conversion at the same time, and even in those cases, the reported conversion efficiency was relatively low. Furthermore, previous designs often relied on reflective structures, making them bulky and less practical for integration into compact systems.

In this study, we propose a new type of parametric metasurface that overcomes these limitations. Our design is based on a dual-resonance structure consisting of two coupled split-ring resonators (SRRs), with an embedded varactor diode. By modulating the capacitance of this varactor, our metasurface can simultaneously amplify and up-convert incident electromagnetic waves. Through theoretical modeling, we demonstrate that our metasurface achieves an up-conversion efficiency exceeding 20 dB, surpassing conventional limitations set by the Manley-Rowe relations. Moreover, by tuning the phase of the external modulation, we gain precise control over the phase of the up-converted waves, offering additional possibilities for advanced wave manipulation.

Negative refraction of light using atoms instead of metamaterials

Abstract: Negative refraction has driven the development of metamaterials. However, due to material characteristics, the applications of this phenomenon, such as perfect lensing, have been constrained. Here, we demonstrate negative refraction of light in an atomic array without the use of artificial metamaterials, employing essentially exact simulations of light propagation.

Atoms primarily interact with light through electric dipole transitions, while magnetic dipole and electric quadrupole transitions are significantly weaker. Although atomic systems with well-developed quantum technologies otherwise provide a pristine optical medium where each atom possesses a precise resonance frequency, free from manufacturing imperfections or non-radiative absorption losses, these inherent constraints in the optical transitions have hampered any efforts to achieve unusual optical properties, such as negative refraction of light, in a natural medium. While negative refraction has driven the development of metamaterials, material characteristics of artificially engineered media have constrained the applications of this phenomenon, such as lensing that surpasses the diffraction limit.

Here we show that negative refraction of light can be obtained in atomic media without the use of artificially fabricated resonators [1]. This is made possible by harnessing and utilising cooperative, non-local atom responses that arise from strong light-mediated interactions at high densities. We achieve this controlled response by considering subwavelength atomic arrays [2] with unit filling, which can be experimentally realised in system sizes up to tens of wavelengths. Cooperative optical interactions in atomic arrays have recently been confirmed in transmitted light, as evidenced, e.g, by the spectral resonance narrowing below the fundamental quantum limit dictated by a single atom [3].

We demonstrate the negative refraction of light through microscopic, atom-by-atom simulations that exactly incorporate all recurrent scattering processes between stationary atoms in the low light intensity limit which accurately describes experimental conditions. The simulations uncover a distinct deflection of propagating light beams in the opposite direction to what normally occurs. This enables us to extract from microscopic simulations the negative value of refractive index. We demonstrate high-transmission negative refraction that is resilient to lattice imperfections, such as missing atoms and position uncertainty, over a range of laser frequencies, incident angles, and lattice constants by modelling 3D atom arrays as stacked infinite 2D planar layers when in each layer the scattering problem is represented in momentum space. Our findings, confirmed for finite-sized arrays in a few-layer scenario through large-scale simulations, reveal that such refraction aligns with the simple phenomenology of transverse Bloch band collective resonances. Notably, negative refraction can be realised by engineering and exciting such resonance bands whose in-plane group velocities are antiparallel to the excitation quasimomenta – which are a common occurrence in moderately subwavelength arrays. Intriguingly, the effective refractive index can be significantly enhanced through coupling with more subradiant

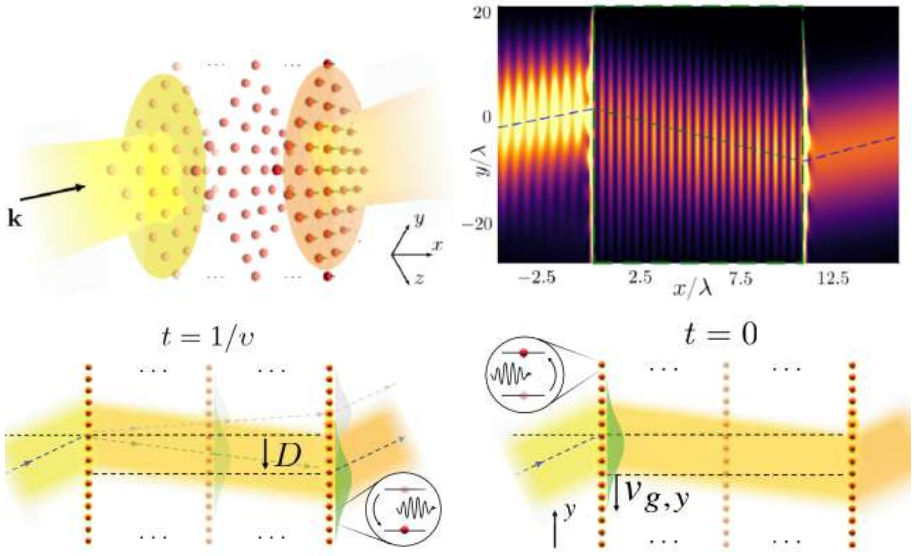

Figure 1: **Negative refraction and transmission of light through an atomic medium.** Top left: Light transmission through a cubic atom array, stacked in infinite planar lattices along the x axis. The transmitted beam undergoes lateral displacement D along the y axis. Top right: Negative refraction of a beam incident with the angle $\theta = 0.2 \times \pi$ and laser detuning $\Delta/\gamma = 0.73$ from the atomic resonance, in units of single-atom linewidth γ, through a 25-layer atomic lattice. Bottom row: Microscopic origin of negative refraction. An atomic polarisation wavepacket, excited by the incident beam, propagates along the y-axis over its lifetime $t = 1/\upsilon$, where $\upsilon = \upsilon^{(j)}(q_y, q_z = 0)$ is the collective linewidth, accumulating a transverse displacement of $D \simeq v_{g,y} \times 1/\upsilon$. The transverse group velocity component $v_{g,y} = \in \partial\delta^{(j)}(q_y, q_z = 0)/\partial q_y$ is derived from the collective line shifts $\delta^{(j)}(q_y, q_z = 0)$ for phase-matched quasimomenta q_y in resonant band j. Green and grey wavepackets illustrate cases of negative and positive displacement, respectively.

excitations.

In Fig. 1, we demonstrate cooperative negative refraction of light through a 25-infinite-layer atomic medium based on atom-by-atom simulations for the propagating beam incident at angle $\theta = 0.2 \times \pi$ relative to the array normal. The illustration also describes the microscopic origin of the negative refraction in this system in terms of lifetimes of the collective excitations. Targeting a resonance energy band with subradiant features can considerably enhance negative refraction.

Abstract: As an ideal platform for photonic integrated circuits, silicon nitride material is explored. In particular, we investigate residual stress and cracking limits in SiN_x films through experimental and computational approaches, as well as plasma-based SiN_x nanopatterning.

Silicon nitride (SiN_x) has become a key material for photonic integrated circuits (PICs) due to its ultra-low optical losses, broad spectral transparency, and compatibility with standard semiconductor processes. It plays a crucial role in telecommunications, nonlinear optics, quantum photonics, and biosensing. However, its widespread adoption remains limited by stress-induced cracking in thick SiN_x films and the challenges associated with precise nanopatterning and etch fidelity in plasma etching.

Our research group addresses these challenges by integrating experimental fabrication with computational modeling to advance SiN_x photonics. We investigate SiN_x deposition, stress control, and nanofabrication using a combination of low-pressure chemical vapor deposition (LPCVD) experiments and molecular dynamics (MD) simulations. Our experimental findings reveal that while LPCVD produces ultra-smooth (~0.16 nm roughness) and highly uniform SiN_x films, it also induces high tensile stress (>1 GPa), leading to crack formation in stochiometric compositions. To understand this, we use MD simulations to explore how deposition conditions—substrate temperature, deposition power, and precursor composition—affect intrinsic stress. We also investigate alternative deposition methods such as reactive sputtering to produce thick, low-stress, hydrogen-free SiN_x films, offering promising solutions for high-performance photonics.

Beyond stress control, our group develops advanced SiN_x etching techniques to improve fabrication precision. By optimizing fluorine-based plasma etching and investigating lithographic densification, we enhance etching selectivity, uniformity, and sidewall smoothness and angles. We systematically compare different mask materials, including SiO_2 and metal hard masks, to assess their impact on etch fidelity and feature resolution. Using inductively coupled plasma etching, we achieve precise, anisotropic patterning of SiN_x structures, enabling high-resolution, low-loss photonic devices with improved reproducibility. Our optimized process allows for the fabrication of square SiN_x waveguides with optical losses below 1 dB/cm and minimal birefringence, validating the platform's suitability for scalable, low-loss photonic integration.

Vectorial metasurface for polarization encoding and imaging

Fengjun Li[1], Zilan Deng[1], and Xiangping Li[1*]

[1]College of Physics and Optoelectronic Engineering, Jinan University, P.R.China
[*]corresponding author: xiangpingli@jnu.edu.cn

Abstract: With powerful wavefront manipulations metasurfaces emerge as a transformative platform for multifarious and ultra-compact optical devices. In this talk, we present the vectorial metasurface design that enables polarization encoding in the 2D parametric space of polarizations including both polarization rotation angle and ellipticity. In addition, we show the monolithic metasurface design by fusing vectorial grating and lens functions to enable ultra-compact polarization camera with large field-of-view of 14 degrees and full stokes polarization imaging capability.

Metasurfaces, composed of arrays of subwavelength meta-atoms with exquisitely tailored geometries, have offered unprecedented prospects for light management and wavefront shaping [1,2]. The upsurge in metasurfaces based on various meta-atom designs has impelled marvelous developments such as lenses, holograms, illusionary optics and color prints, which have demonstrated potentials as a transformative platform for lightweight, ultra-compact and multi-furious miniaturized optical devices. In this talk, we present the vectorial metasurface design that empowers full parametric control of diverse polarization states across the full Poincare sphere. Leveraging this polarization manipulation freedom, we introduce a method for polarization encoding information along trajectories on the Poincaré sphere using metasurfaces, based on a generalized Malus' law (GML) [3]. This generalized law facilitates universal 2D projections among any pair of elliptical polarizations over the entire PS. By custom-designing PS trajectories through either specific analytic functions or strategically aligned modulation grids, we enable a diverse set of polarization-based image transformation capabilities. In addition, we demonstrate a meta-grating-lens (MGL) based monolithic polarization camera that fuses polarization analysis, beam-splitting, and imaging functionalities within a singlet metasurface in a fine-grained pixel level [4]. The optimized MGL exhibits >80% diffraction efficiency with <0.1% zeroth-order noise for high performance polarization imaging. We envision that the vectorial metasurface approach provides an ultra-compact and miniaturized paradigm underpinning diverse polarization-dependent applications ranging from autonomous anti-spoofing imaging, 3D imaging, information encoding and defogging imaging.

Highly Sensitive CMOS Image Sensor Integrating Color-routing Nanostructures

C. Cho, S. Lee, S. Roh, S. Ahn, S. Lee, J. Lee, S. Song, S. Yun*

Samsung Advanced Institute of Technology, Korea
*corresponding author: seok.h.yun@samsung.com

Abstract: We present CMOS image sensor with tailored color-routing nanostructures, which significantly enhances sensitivity while preserving most of its spatial resolution as well. Furthermore, adjusting the arrangement of nanostructures based on relative position, enables mitigating oblique light incidence, enabling commercial CMOS image sensors.

With the recent advancements in CMOS image sensors, the demand for high-quality image resolution has led to smaller pixel sizes. As pixel downsizing results in an increased number of pixels in the same form factor, it suffers from low sensitivity, especially in low-light environments, as its light-receiving region becomes smaller [1]. To this end, image sensors employing color-routing nanostructures have been suggested [2-4]. While two third of light are dissipated in color filter in conventional image sensors, image sensors featuring color-routing structure enable separating lights by colors and then filter, thereby improve quantum efficiency (QE). Although color-routing nanostructures achieves high sensitivity or even color filter free image sensors, the diffraction mechanism dilute spatial resolution and corrupt the image quality. While image could be refined by running reconstruction algorithm, it consumes high power resources which is undesirable in real cases.

Here we present highly sensitive image sensor featuring color-routing nanostructure, preserving most of its spatial resolution compared to conventional microlens based image sensor. As illustrated in Fig.1, the color-routing structure consist of TiO_2 pillars embedded in a SiO_2 bilayer, which separates and focuses incoming light onto different locations based on wavelength. It achieves 15% improvement in average QE for RGB channels compared to conventional microlens image sensors in a 0.7um pixel-sized, 4-pixel binning configuration. Additionally the autofocus contrast ratio at a 10° incident angle reaches as high as 2.2 at the center of sensor. By adjusting the arrangement of TiO_2 pillars and shift of two layers with respect to the center of sensor, relative to the chief ray angle (CRA), performance is maintained in the high CRA. Furthermore, by arranging the pillars tightly, the sensors preserve more spatial resolution information by restricting uncontrolled light transmission through the layer. Under slanted edge illumination simulation, it shows MTF of 94.9% with respect to reference at 1/2 Nyquist frequency.

In summary, we developed a CMOS image sensor incorporating tailored color-routing nanostructures that significantly enhance sensitivity while maintaining most of its spatial resolution. Additionally, by optimizing the nanostructure arrangement relative to position, we effectively mitigate the impact of oblique light incidence, making color-routing nanostructure feasible for commercial CMOS image sensors.

Non-Lorentzian effects for exciton-plasmon systems at strong coupling

Tigran V. Shahbazyan

Department of Physics, Jackson State University, Jackson, MS 39217 USA
shahbazyan@jsums.edu

Abstract: We study non-Lorentzian effects in the scattering spectrum of quantum emitters strongly coupled to surface plasmons in metal nanoparticles. We develop a semiclassical approach incorporating optical dispersion and losses in the metal to show that non-Lorentzian effects cause a shift of the spectral weight towards the lower energy polaritonic band.

The shape of scattering spectra of quantum emitters (QE) resonantly coupled to localized surface plasmons (LSP) in metal nanoparticles (NP) as the system transitions to the strong coupling regime has been an actively debated issue as the relative spectral weight of polaritonic bands is determined by several competing processes. In general, the scattering spectrum of a hybrid system characterized by a broad spectral band is enhanced on the higher frequency side due to a faster radiation rate of upper-energy states, implying that, in the strong coupling regime, the spectral band associated with the upper-energy polaritonic state should be relatively enhanced. Such a spectral profile is consistent with the classical model of two coupled oscillators (CO), in which one of the oscillators (LSP) couples much stronger to the electromagnetic (EM) field due to a much smaller QE optical dipole moment [1]. However, recent experiments for excitons resonantly coupled to LSP in metal-dielectric structures [2,3] reveal the opposite asymmetry pattern characterized by enhanced lower polaritonic band. In this paper, we demonstrate that non-Lorentzian effects originating from the material optical dispersion and losses strongly affect the optical spectra of hybrid QE-LSP systems and, in the strong coupling regime, results in a shift of the spectral weight towards the lower-energy polaritonic band, consistent with the experiment. Using the non-Lorentzian LSP Green function for NP of arbitrary shape [4], we set up non-Lorentzian Maxwell-Bloch equations which include complex dielectric function of the metal rather than Lorentzian approximation for the LSP resonance. We show that the non-Lorentzian effects show up prominently in the optical spectra of plasmonic systems due to an interplay between the real and imaginary part of the metal dielectric function which define, respectively, the plasmon coupling to the EM field and the broad plasmon optical band. Specifically, the temporal dispersion of its real part, which originates from free-electron absorption is metals, leads to a spectral weight shift towards the lower frequency side of the spectra. In the strong coupling regime characterized by well-separated polaritonic bands, such non-Lorentzian effects result in an inversion of spectral asymmetry as compared to the CO model predictions.

In Fig. 1 we show the scattering spectra for a QE near an Au NP calculated using non-Lorentzian model for three different LSP frequencies. As the QE-LSP coupling increases, the system undergoes transition to strong coupling regime signaled by the emergence of Rabi splitting between polaritonic bands. In the higher-energy region, the spectrum exhibits enhancement of the lower-energy polaritonic band, consistent with the experiment [2,3], while for lower energies, the spectral weight shifts towards the upper energy band. In contrast, for scattering spectra calculated in the Lorentzian approximation shown in Fig. 2, the upper energy polaritonic band is enhanced in the entire energy range, as predicted by the CO model. This difference can be traced to the effect of metal temporal dispersion on the LSP optical dipole moment which results in a suppression of the LSP radiation efficiency for higher energies.

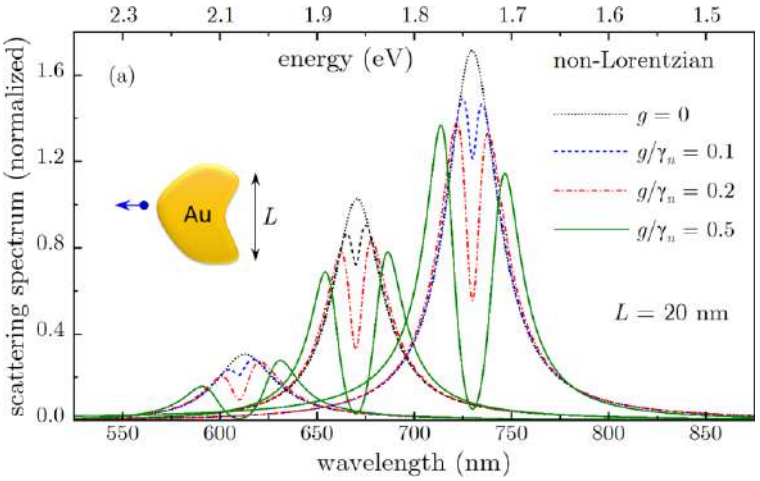

Figure 1. Scattering spectra for an Au NP coupled to a QE calculated using non-Lorentzian model.

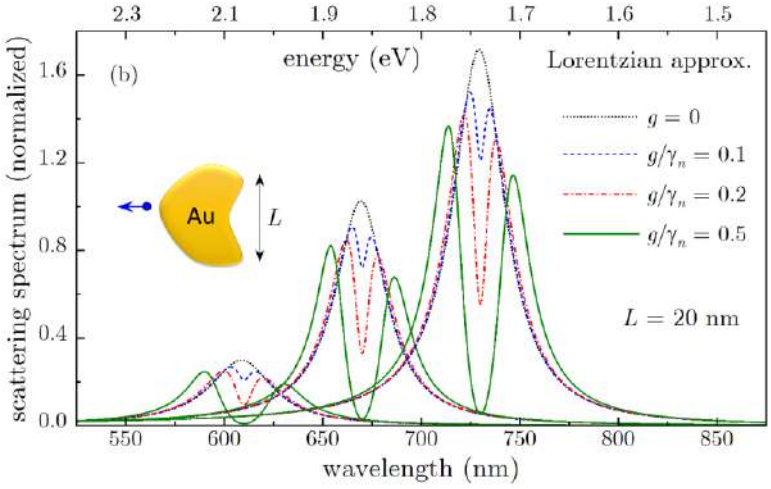

Figure 2. Scattering spectra for an Au NP coupled to a QE calculated using Lorentzian approximation.

Sub-1-volt, reconfigurable Gires-Tournois resonators for full-colour monopixel array

Young Min Song

[1]Electrical Engineering and Computer Science, Gwangju Institute of Science and Technology, Gwangju 61005, Korea
[*]corresponding author: ymsong@gist.ac.kr

Abstract: We present an electrically reconfigurable Gires-Tournois resonator integrated with polyaniline for full-colour, energy-efficient modulation at CMOS-compatible voltages. This system achieves vibrant colour shifts across the visible spectrum within a sub-1V range, supporting ultrahigh pixel densities and wafer-scale fabrication, with bistable memory-in-pixel functionality for low-power passive matrix addressing in display applications.

Ensuring uniform colouration and efficiency across pixel scales remains a key challenge in modern display technology, particularly for near-eye applications where micrometre-scale pixel precision is essential. Conventional approaches such as liquid crystal on silicon (LCoS) displays offer high spatial resolution and precise pixel control but require high operating voltages (~6 V) and suffer from sub-pixel configurations, light loss, and scalability issues due to crosstalk. Monopixel reflective displays, which integrate optically active materials within photonic architectures, have emerged as a promising alternative by enabling colour generation directly within the pixel. For instance, phase-change materials (PCMs) like Ge-Sb-Te enable sub-micrometre pixelation but face challenges related to heat dissipation, response-time fluctuations, and limited electrical addressability. Meanwhile, electro-optic (EO) materials provide high-speed modulation but require operating voltages exceeding 30 V and exhibit limited refractive index variation, constraining their colour modulation capacity. Conductive polymers such as polyaniline (PANI) and PEDOT:PSS offer a low-power solution (<1 V, <0.3 mW/cm²) with a significant refractive index change in the visible spectrum, yet their standalone implementation lacks the necessary light-matter interaction for achieving vibrant, broad-spectrum colour modulation. Plasmonic and Mie resonators have been investigated to enhance colour performance but introduce absorption-related losses and fabrication complexity, limiting practical scalability.

To overcome these challenges, we introduce an electrically reconfigurable Gires-Tournois (r-GT) resonator integrated with PANI, enabling full-colour modulation with ultra-low energy consumption (90 μW/cm²) at CMOS-compatible voltages (-0.2 V to 0.8 V). The r-GT resonator exploits sharp and strong resonance effects from impedance matching, achieving colour shifts that exceed complementary hue changes. By stabilizing the resonator interfaces during redox reactions, we mitigate chromatic degradation and scalability constraints, allowing operation across a wide range of pixel scales, from high-density micro-pixels (1.5 μm, ~16,900 PPI) to centimetre-scale image printing. Furthermore, PANI's bistable memory properties enable the memory-in-pixel feature, significantly reducing energy consumption compared to emissive-type displays, with energy savings up to 7.2 times greater. We demonstrate the feasibility of this technology with a passive matrix addressing system, validating its potential for scalable, high-performance reflective displays and other photonic applications requiring energy-efficient, high-resolution dynamic colour control.

Abstract: A metasurface-enabled weak measurement is devised for a single-shot observation of the spin Hall effect of light. By using a polarization beamsplitting metasurface, we achieve a real-time tracking of the spin Hall shift, thereby enabling high-precision optical sensing in dynamic environments.

The spin Hall effect of light (SHEL) manifests as a spin-dependent transverse shift when light undergoes refraction or reflection at an interface. When paired with a signal amplification method known as weak measurement [1], it offers nondestructive, high-precision metrology. However, conventional weak measurements require a multistep process, thus limiting their applicability in dynamic scenarios. Here, we introduce a metasurface-enabled single-shot weak measurement approach that allows real-time detection of the SHEL without the need for calibration [2].

Our method replaces the postselection polarizer, a component in the weak measurement, with a polarization beamsplitting metasurface. It functions as a beam splitter and two polarizers simultaneously and thus squeezes the two snapshots from traditional methods into a single capture. Two postselected beams with orthogonal polarizations reach the camera simultaneously at different positions, from which the transverse distance between them is extracted as a weak value. The spin Hall shift follows a linear relation with the weak value as $Y = 2\delta F/\sin 2\alpha$ where α is the postselection angle. The amplification factor of our setup corresponds to $1/\cos^2\alpha$ of that of the previous setup, which indicates that the amplification is even higher compared to the conventional method.

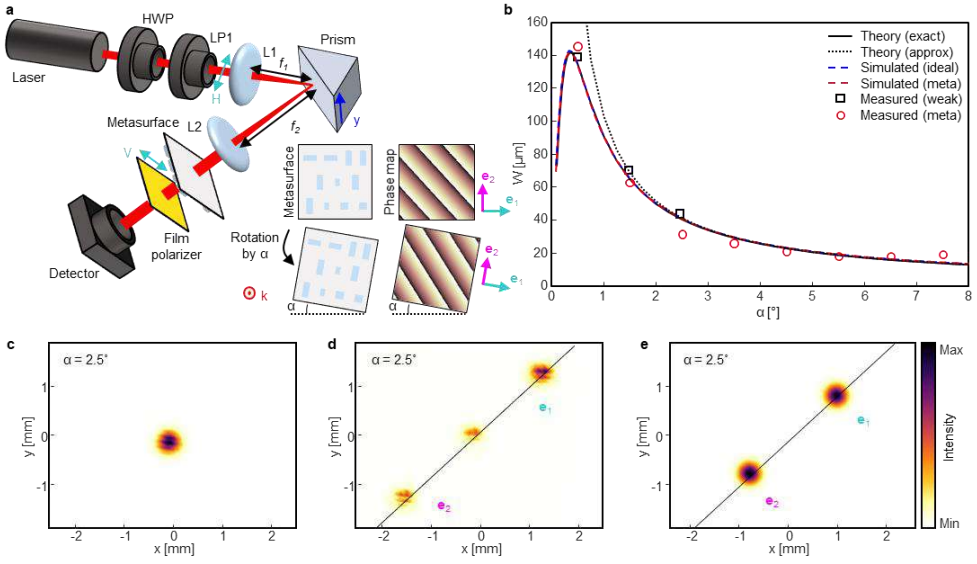

Figure 1. Comparison between conventional weak measurement and metasurface-enabled single-shot weak measurement. (a) Schematic of the experimental setup. (b) Measured weak values for various postselection angles. (c-e) Captured intensity distributions from conventional and single-shot measurements at the postselection angle is 2.5°.

This new measurement scheme simplifies the measurement process and enables a single-shot measurement of the SHEL even when the beam position fluctuates over time. It is tested for two cases, one static and the other dynamic. We first measure the SHEL at a static air-prism interface using both methods and compare them (Fig. 1). Our new method shows excellent agreement in comparison to the conventional one, even with a single capture. In a dynamic scenario, we track the SHEL in real time by continuously varying the tilt angle of an anisotropic interface over a range of 30° to 40°. Our setup provides measured weak values closely matching theoretical and simulation results.

The metasurface-assisted single-shot weak measurement technique enhances the feasibility of SHEL-based precision metrology in time-varying environments. Its potential applications include high-sensitivity optical sensing for biomedical diagnostics, chemical analysis, and environmental monitoring. By eliminating the constraints of conventional weak measurement techniques, our approach paves the way for real-time, high-precision optical measurements in a wide range of scientific and technological fields.

Abstract: We report plasmonic color printing through a femtosecond laser-induced modification of disordered metal-dielectric multilayer structures. The structures are fabricated by sequential deposition of subwavelength-thick dielectric layers and island-type layers of disordered metal nanoparticles. Colors are controlled by parameters of femtosecond laser pulses, e.g., fluence, polarization, repetition, and scanning parameters.

Disordered plasmonic nanostructures have been explored in plasmonic color [1–5] and other photonic applications [6]. Nano-island type or semicontinuous films can be deposited using industry-proven physical vapor deposition (PVD) processes [1,4]. They form through self-organization when a thin film of metal is deposited on a non-wetting substrate. Laser post-fabrication processing of disordered structures allows material modification at the nanoscale and local control of sample color, polarization selective response, diffractive structures formation, and diffuse reflectance component control [1–5].

Herein, we report a direct femtosecond laser modification of disordered metal-dielectric multilayer structures. These structures are composed of metallic nanoparticles embedded in a dielectric matrix. We fabricated these composites using the electron-beam PVD technique. In a single process, without breaking the vacuum, we sequentially deposited subwavelength-thick dielectric layers and island-type films composed of disordered metal nanoparticles. Such composites have been explored in the past, as their transmittance, reflectance, and absorption can be controlled by details of the fabrication process, number of layers and their thickness, and choice of constituent materials [7,8]. Next, we studied how laser modification parameters influence the optical properties of composites. We used a femtosecond laser with the following characteristics: pulse duration of 215 fs, wavelength of 1030 nm, fluence range of 1 - 100 mJ cm^{-2}. The laser pulses induce polarization selective color changes in modified regions of the metal-dielectric multilayer structure.

This technique allows high throughput and high-resolution color printing. It could be used in anti-counterfeiting, information encryption, hidden marking, and data storage applications.

The General Boundary Conditions for all interfaces, including arbitrary moving metasurfaces and instantaneous changes in constitutive relations.

Abstract: We present the most general boundary conditions, which satisfy basic physical constraints: linearity, causality and local to the boundary. Using relativity they are valid for all motions of the interface, including arbitrary moving metasurfaces and superluminal motion. We discuss the nature of causality for boundaries.

(a) An initially uniform homogeneous medium simultaneously changes its constitutive relations within a bounded region (indicated as a gray rectangle), before the constitutive relations revert back to their original form. The boundary of the gray region (blue) consists of the two spacelike hypersurfaces arising from the temporal change, plus the spatial boundary of the finite region. Note that, the region $U_{\boldsymbol{p}}$ which is both in Σ *and* in the past lightcone of $\boldsymbol{p}$, cannot influence $\boldsymbol{p}$ via the boundary conditions.

(b) Here the boundary initially is superluminal, it then becomes subluminal. Even though a lot of the boundary depicted lies in the past light cone of $\boldsymbol{p}$, only the red part is connected to $\boldsymbol{p}$ via curves which remain subluminal.

Figure 1: **Causality and spacetime boundaries:** In these two spacetime diagrams, there are places where the boundary (blue and red) moves instantaneously or superluminal and others where it is stationary or subluminal. The region of the boundary which can communicate with the event $\boldsymbol{p}$ is given in red.

As soon as one wishes to consider electromagnetic fields passing from one medium in one region of space-time to another, once has to consider what are the correct boundary conditions to impose. The natural boundary conditions for a static interface: continuity of perpendicular components of $\boldsymbol{E}$ and $\boldsymbol{H}$ and the tangential components of $\boldsymbol{B}$ and $\boldsymbol{D}$, have served us

well. However these are insufficient when one or both of the regions are spatially dispersive, when additional boundary conditions are required. Superluminal and instantaneous boundary conditions [1, 2] are required when an entire region of space suddenly changes its constitutive relations. Furthermore, metasurfaces can be modelled using more exotic boundary conditions. Thus similar to constitutive relations, the range of potential boundary conditions is limited only by the imagination of the researchers: the experimentalist's ability to manufacture them and the theorist's ability to model them. Instead of coming up with ever more complicated boundary conditions, in this talk, we present a general formula for all boundary conditions which satisfy a small number of conditions: linearity, causality and local to the boundary.

The result can be succinctly expressed as a number of integrals over the 3–dimensional spacetime hypersuface which represents the interface. The kernel within the integral may include δ–functions. The reason for the integral is that the boundary condition allow for temporal and spatial dispersion at the interface.

Many additional boundary conditions are considered, including all the standard boundary conditions both on a spatial boundary and on a temporal boundary. We also consider dispersive boundaries where polaritons propagate inside the boundary. Since these polaritons carry information, and boundaries can move subluminally, luminally and superluminally, there is a discussion of the nature of causality for boundary conditions. Since polaritons involve the actual movement of charges, they can only move subluminally (or luminally). As a result the integral for the boundary conditions at the point $\boldsymbol{p}$ can only be over regions of the spacetime boundary that lie in the past of a point and are causally connected to $\boldsymbol{p}$ via luminal paths that lie in the boundary. This can be visualised on a spacetime diagram, as in figure 1.

Abstract: In this study, we propose a comprehensive platform to harness the localized surface plasmon resonance of metasurfaces for achieving ultrafast all-optical modulation via carrier multiplication in the silicon substrate. Transmission changes in the picosecond time scale are demonstrated via single-color time-resolved pump-probe experiments using an infrared free electron laser, along with an impact ionization model and full-wave simulation. The findings can lead to high-speed optical modulation using low-photon energy light sources.

Plasmonic metasurfaces represent a fascinating frontier in nanotechnology, merging the principles of plasmonics with engineered surface structures to manipulate light at unprecedented scales [1]. These planar nanostructures exploit the unique properties of surface plasmons—collective oscillations of electrons at the interface of metal and dielectric—to achieve extraordinary optical phenomena. The ability to control light on the subwavelength scale opens up numerous potential applications, ranging from high-resolution imaging and biosensing to enhanced photovoltaics [1].

In this study, we explore the potential of plasmonic resonance in metasurfaces for ultrafast all-optical modulation applications. The most common method to modulate the optical characteristics of materials is via optical pumping through the semiconductor bandgap, which requires high photon energy and introduces additional losses into the system [2]. Our approach leverages on field enhancement that is localized at the subwavelength scale, efficiently accelerating free electrons to a sufficiently high kinetic energy to cause carrier multiplication [3, 4]. Carrier concentrations in certain regions of silicon change within picoseconds, leading to a strong modulation of optically transmitted signals. The crucial role of localized surface plasmon resonance in achieving ultrafast all-optical modulation is established, with a modulation depth that is on-resonance higher than 125%, which is unprecedentedly high considering the photon energy employed. These phenomena are further validated through an analytical model and numerical simulations, which clarify the roles of plasmonic field enhancement and impact ionization in shaping carrier dynamics. Our findings provide a comprehensive and robust understanding of carrier dynamics in plasmonic metasurface platforms occurring over several to a few hundred picoseconds, forming a foundation for developing time-variant media with potential applications in low-photon energy ultrafast all-optical modulators.

Injecting Physics Knowledge in Neural Networks for a Wide Range of Photonic Devices: QNM-Net

V. A. Lilja, A. J. Svärdsby, T. Gahlmann, and P. Tassin
Chalmers University of Technology, Department of Physics, Göteborg, Sweden

Abstract: We will present our work on QNM-Net, a physics-informed neural network for electromagnetic scattering. Our network incorporates physics knowledge through the quasi-normal-mode framework, which means it can model a vast range of (nano)photonic devices. By incorporating physics knowledge, we can achieve a tenfold reduction of training data needed.

In recent years, machine learning has been shown to be a powerful tool for the design of optical devices. Typically, a neural-network model is constructed to act as a fast surrogate for full-wave electrodynamics solvers, which is then used to search the design landscape through iterative optimization or through the training of inverse models such as tandem or generative-adversarial networks [1]. Indeed, since a neural network prediction is typically many orders of magnitude faster than a full-wave simulation, a trained neural network makes it possible to explore the design space efficiently.

However, obtaining a neural network that is accurate enough across the entire design space normally requires a very large training dataset, typically requiring thousands of full-wave simulations. This is a large computational cost, but is possible on high-performance computing clusters, because all the training data samples are independent and can be generated concurrently. Nevertheless, to advance the field, we need to reduce the need for training data.

One way to make neural networks modelling physical devices more data efficient is to incorporate physics knowledge into the network [2], significantly restraining the relationship between design parameters and device response. We show that this can be done for a large range of electromagnetic scattering devices using quasi-normal-mode theory. The resulting network, called QNM-net, contains a physics layer that calculates the scattering response of an optical device from the resonances of the system, preceded by a neural network that relates the properties of the resonances to the design parameters. This allows for a neural network with much fewer hyperparameters.

We will demonstrate the power of QNM-Net with two examples, a photonic crystal with free-form holes and a metasurface with free-form nanopillars on a substrate. QNM-Net let us incorporate a priori physical principles such as energy conservation and mirror symmetry. In comparison with standard neural network architectures directly modeling the relationship between the design parameters and the scattering response, QNM-Net requires an order of magnitude less training data and trainable parameters to achieve the same validation loss. This brings the data generation problem to the realm of the practical, with data generation times of days instead on months.

We acknowledge financial support from Chalmers' area of advance Nano (Excellence Grant) and from the Swedish Research Council under Grant No. 2020-05284. The training data generation and neural network training were performed on resources provided by the Swedish National Infrastructure for Computing (NAISS), at the Chalmers/C3SE and KTH/PDC sites, partially funded by the Swedish Research Council under Grant No. 2022-06725.

Abstract: We present our recent work on nonlinear optics in suspended AlGaAs waveguides/micoresonators, including fabrication of high-Q suspended AlGaAs microring resonators, microcomb generation in near and mid-infrared regime, and octave-spanning supercontinuum generation.

1. Introduction

Aluminum gallium arsenide (AlGaAs) is a promising nonlinear optical material with an enormous intrinsic third order Kerr nonlinearity $n_2 \sim 10^{-17}$ m^2/W [1], and its bandgap can be tailored by varying the Al content to avoid two photon absorption (TPA) at telecom wavelengths. However, to date, the fabrication of low-loss AlGaAs waveguides is mainly based on bonding process [2,3]. In this talk, we present our recent work on nonlinear optics in suspended AlGaAs waveguides/microresonators formed directly on GaAs substrate. Suspended AlGaAs microrings with intrinsic Q factor exceeding 10^6 have been fabricated with optimized plasma dry-etching and surface treatment, allowing efficient Kerr comb generation in the near- and mid-infrared regime. Furthermore, octave-spanning supercontinuum is demonstrated in a 2-mm-long suspended AlGaAs waveguide.

2. High-Q Suspended AlGaAs Microring Resonator for Kerr Comb Generation

Figure 1(a) depicts the schematic of our suspended AlGaAs microring, which is formed on the $Al_{0.2}Ga_{0.8}As$ waveguide layer by plasma dry etching based on BCl_3 and Ar mixture [4]. The underlying $Al_{0.8}Ga_{0.2}As$ sacrificial layer is selectively removed by chemical wet etching in diluted HF solution. After surface treatment in HCl, NH_4OH, and *N*-methyl-pyrrolidone solutions to ensure complete removal of residual etching products, the microring is encapsuled with 10-nm-thick Al_2O_3 by atomic layer deposition (ALD). The intrinsic Q-factor of the fabricated 50-μm-radius, 1800-nm-wide microring is measured to be 1.3×10^6 for TM_{00} mode, as shown in Fig. 1(b). Near-infrared Kerr comb generation with milliwatt-level pump power is recorded in Fig. 1(c).

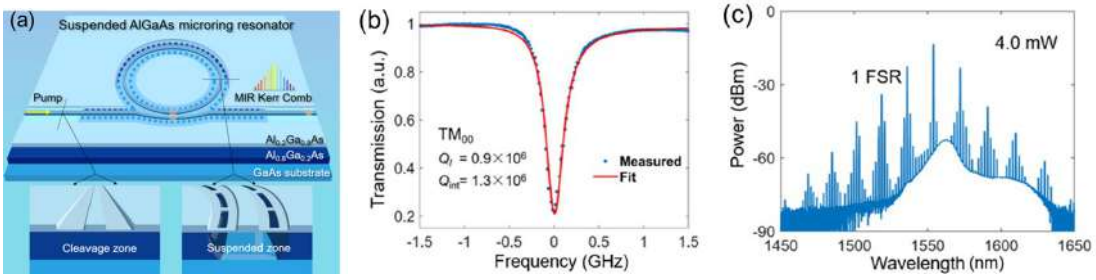

Fig. 1. (a) Schematic of the suspended AlGaAs microring. (b) TM_{00} mode resonance around 1550 nm. (c) Kerr comb lines generated with a TM polarized pump at 1550 nm.

The air-clad suspended AlGaAs microring is particularly suitable for mid-infrared (MIR) frequency comb generation. With the experimental setup shown in Fig. 2(a), MIR frequency combs covering from 1250 to 5450 nm are generated in an 80-μm-radius, 1800-nm-wide microring with a TE-polarized pump at 2.7 μm.

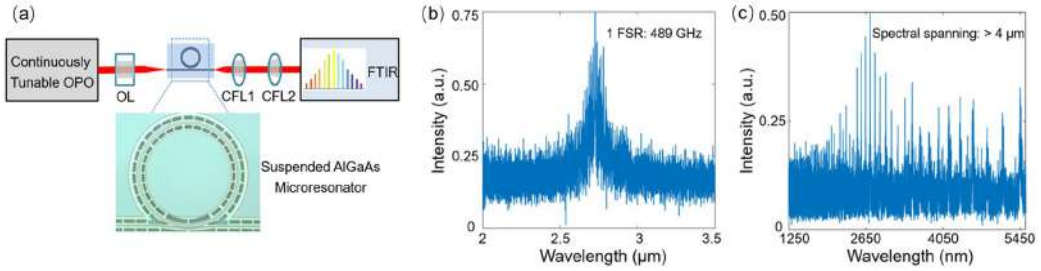

Fig. 2. (a) MIR frequency comb generation. (b) and (c) MIR frequency combs generated with a 2.7 μm pump.

3. Octave-spanning Supercontinuum Generation in Suspended AlGaAs Waveguides

The experimental setup for supercontinuum generation (SCG) in a 2-mm-long suspended AlGaAs waveguide is shown in Fig. 3(a), where an erbium-fiber-based femtosecond laser (pulse duration ~70 fs) acts as the pump. The evolution of output spectra with varying pump pulse energy is plotted in Fig. 3(b). The onset of SCG occurs near 7.9 pJ, and octave-spanning supercontinuum covering 1000-2250 nm is recorded with a pulse energy of 20 pJ, corresponding to an average waveguide-coupled power of 2 mW.

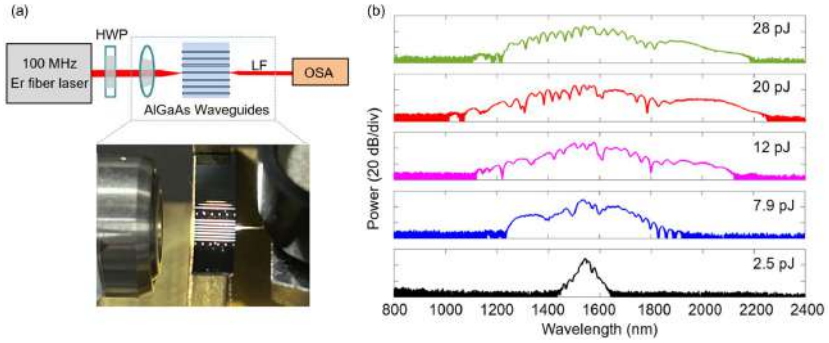

Fig. 3. (a) Experimental setup for SCG in suspended AlGaAs waveguides. (b) Output spectra for different pulse energies.

4. Conclusions

We have investigated nonlinear optics in low loss suspended AlGaAs microresonators/waveguides. Our demonstration opens up a new prospect for employing AlGaAs devices in integrated nonlinear photonics.

Abstract: We demonstrate the realtime observation of linear plasmonic fields by optical field sampling. Our findings also demonstrate the ability to manipulate the spectral properties of ultrashort laser pulses by plasmonic samples.

Plasmon excitation in nanosystems allows for extreme light confinement beyond the diffraction limit, therefore enabling a number of new applications in photonics, energy harvesting and biology. In this context, it is key to obtain a realtime characterization of the onset from plasmonic field and its ultrafast dephasing dynamics. Tunnel ionization with a perturbation for the time-domain observation of an electric field, short TIPTOE, is a recent established technique allowing for the optical sampling of ultrashort laser pulses based on strong field ionization. Subsequently, this ionization is modulated by a weaker pulse to be sampled. With this method it is possible to characterize arbitrary electric fields as long as ionization by the weak pulse itself does not occur. [1,2] Here, we implement TIPTOE for the optical sampling of linear plasmonic fields measured in the far-field regime.

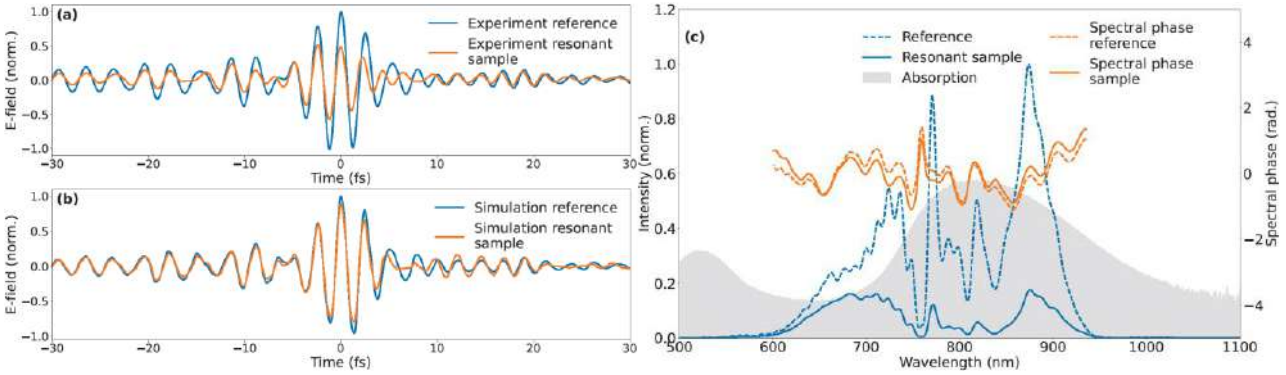

Fig. 1 Normalized (a) measured TIPTOE traces and (b) simulated traces for the electric field after interaction with the plasmonic sample. As reference the input field is depicted in blue, which was also used as the input for the FDTD simulation. (c) Retrieved spectrum (blue) and spectral phase (orange) via FFT for the plasmonic sample. The retrieved spectra were normalized to the reference. The dashed lines display the retrieved spectra and spectral phase of the input field respectively. The shaded area displays the absorption spectra of the plasmonic nanorods.

In our experiment, sub 5 fs pulses with a central wavelength of 780 nm are exciting plasmonic gold nanoparticles embedded on a fused silica substrate, the transmitted beam is then sent into a TIPTOE setup for the optical field sampling. While the latter sample displays a broadband plasmonic resonance, i.e. the longitudinal localized surface plasmon resonance (L-LSPR), covering a major part of the few-cycle spectrum, the plasmonic resonance of the spherical particles is located outside the exciting broadband pulse bandwidth.

The measured traces for the resonantly excited plasmonic samples strongly differ from the few-cycle input field, with a large deviation window in the trailing edge of the laser pulse and within a 15 fs decay range. The retrieved spectrum exhibits the expected strong reduction in intensity due to large absorption induced by the L-LSPR and remarkable effects in the spectral phase, which displays a crossing in the region of the plasmon resonance. These effects are not observed with the non-resonantly excited particles, therefore confirming that a strong signature of the resonant excitation persist in the far-field. The obtained results were compared with theory using finite difference time domain (FDTD) simulations, where the detection of the electric field is performed after the plasmonic sample to mimic the far-field conditions of the experiment. The simulations reproduce the same deviations observed in the experiment well, therefore confirming that a measurement in the far-field still carries crucial information on the excited plasmonic field. These results not only pave the way to realtime observation of plasmonic fields from arbitrary samples on the petahertz scale, but also opens interesting perspectives in the engineering of the spectral phase of ultrashort laser pulses using plasmonic metasurfaces.

Abstract: Maximum-chiral metasurfaces, selectively interacting with circularly polarized light, are designed by optimizing their photonic eigenstates. The design constraints are relaxed by employing uncoupled interfering and coupled hybridized eigenstates. Then freestanding planar structures become helicity-preserving chiral mirrors, while those stacked upon substrates perform as chiral filters, absorbers and reflectors.

Metasurfaces with strong and eventually maximum optical chirality facilitate emission and detection of chiral light, perform versatile nonlinear chiral light transformations and generally enhance chiral light-matter coupling. Maximum chirality can be achieved by tuning a specific photonic eigenstate to selective coupling with circularly polarized light of a particular handedness [1,2]. Depending on the metastructure symmetry (the presence of rotation axes and in- and out-of-plane mirror planes), different functionalities including chiral absorbers, reflecting filters and helicity-preserving mirrors can be realized [3]. Strong extrinsic chirality in oblique directions is available in structures with the in-plane mirror symmetry lacking optical chirality for normal incidence [4]. The origin of maximum-chiral properties allowed by the symmetry is conveniently explained by the phenomenological coupled-mode theory (CMT) and by the semi-analytical resonant state expansion (RSE) both treating the metasurface response as determined by the spectrum and spatial structure of its eigenstates.

Technologically convenient planar metastructures are photonic crystal slabs (PCSs) and arrays of particles of the same height. Their out-of-plane mirror symmetry determines spatial parity of the eigenstates which are denoted as even and odd according to the parity of their in-plane electric field components and resemble in-plane electric and magnetic dipoles respectively. Such states on their own have linearly polarized far field and provide achiral individual contributions to the metasurface response. Neglecting dissipation losses in CMT, the parameters of their coupling to free-space plane waves are expressed by the in-plane vectors [3]:

$$\mathbf{m}_{\mathrm{even}} = \mathbf{m'}_{\mathrm{even}} = \mathbf{e}_{\mathrm{even}} i\sqrt{\gamma_{\mathrm{even}}} e^{i\frac{(\alpha+\beta)}{2}} \quad , \quad \mathbf{m}_{\mathrm{odd}} = -\mathbf{m'}_{\mathrm{odd}} = \mathbf{e}_{\mathrm{odd}} \sqrt{\gamma_{\mathrm{odd}}} e^{i\frac{(\alpha-\beta)}{2}} \quad , \qquad (1)$$

where the unit vectors $\mathbf{e}_{\mathrm{even}}$ and $\mathbf{e}_{\mathrm{odd}}$ are the far-field polarization directions, and γ_{even} and γ_{odd} are the decay rates of the corresponding states. The primes denote coupling with light on the back metasurface side. The phases α and β characterize the background metasurface phase shift and transparency correspondingly ($\beta = 0$ for a transparent and $\beta = \pi/2$ for a fully reflective non-resonant response).

In a free-standing PCS, even and odd states are uncoupled, but their individual contributions to reflected and transmitted waves can peculiarly interfere. This interference is similar to that giving rise to the generalized Kerker effect [5], but here the state far field polarization is of key importance. Thus a pair of degenerate orthogonally polarized states with $\omega_{\mathrm{even}} = \omega_{\mathrm{odd}}$ and $\mathbf{e}_{\mathrm{even}} \cdot \mathbf{e}_{\mathrm{odd}} = 0$ and a transparent background with $\beta = 0$ build up an achiral mirror which resonantly reflects circularly polarized light preserving its helicity regardless of the handedness. Alternatively, a pair with the unit vectors $\mathbf{e}_{\mathrm{even}}$ and $\mathbf{e}_{\mathrm{odd}}$ building an angle of

$\pi/4$ combined with a semi-transparent background with $\beta = \pi/4$ constitutes a helicity preserving chiral mirror reflecting waves of one circular polarization and transmitting others inverting their handedness [6].

Placing a metasurface with degenerate eigenstates of different parity on a substrate induces their direct near-field coupling. The arising observable effects are truly remarkable, as a rotation-symmetric PCS can exhibit a pair of close maximum-chiral transmission resonances of the opposite handedness. The underlying mechanism of state coupling is quantitatively well explained by the RSE which explicitly shows the importance of the initial state degeneracy as well as of the state coupling through their twisted near-fields [7]. It is also possible to couple the states of different parity with $\mathbf{e}_{\mathrm{even}} \cdot \mathbf{e}_{\mathrm{odd}} \neq 0$ through their far field. Placing such a metasurface above a mirror establishes symmetry-breaking far-field coupling merging the states into chiral hybrids with the quality factor controlled by the distance to the mirror.

Structures with the in-plane mirror symmetry lack optical chirality for normally incident light but can exhibit remarkably strong extrinsic chirality in oblique directions. Here, for the normal incidence, one can establish degenerate states, even and odd with respect to the vertical symmetry plane. Tilting the direction of incidence breaks this symmetry and merges the states into rotating dipole combinations selectively coupled to circularly polarized light. This can be realized in meta-atoms of simple shapes, such as triangles, and their arrays exhibit remarkable chiral selectivity of resonant transmission in oblique directions. Combining such arrays with mirrors allows building extrinsically chiral metacavities. Filled with functional optoelectronic materials, the cavities become efficient electroluminescent sources of chiral light emitted in the opposite oblique directions [4].

Altogether, controlled interference and coupling of degenerate photonic eigenstates substantially broadens the palette of chiral optical properties available in planar metasurfaces convenient for fabrication by standard nanolithographic techniques.

Abstract: We experimentally demonstrated a non-Hermitian (NH) point gap in complex frequency space using NH photonic crystals. Furthermore, we propose unique light transport and the generation of orbital angular momentum enabled by the NH skin effect in nanophotonic systems.

In recent years, systems governed by non-Hermitian (NH) Hamiltonians have garnered considerable research attention. Studies exploring exceptional points in NH systems with parity-time (PT) symmetry have led to the discovery of various novel optical phenomena that do not appear in conventional nanophotonics [1-3]. Another key characteristic of NH systems is the presence of point gaps and the non-Hermitian skin effect (NHSE) [4-9]. A point gap arises when complex energy values encircle a specific reference point, forming a loop in complex energy space. This concept is fundamental to understanding the topological properties of NH systems and NHSE, where bulk states become localized at the system's boundaries.

In this presentation, we report the experimental observation of NH point gaps in nanophotonic systems [10] and the optical functionalities enabled by the skin effect [11]. In photonic crystals, point gaps and NHSE emerge when both anisotropy and material loss are present [7-9]. While NHSE has been experimentally observed, point gaps have remained elusive. To address this, we directly observed point gaps in complex frequency space. In the process, we discovered that point gaps and NHSE can be realized not through material loss but through radiation loss. In other words, a conventional silicon photonic crystal can be employed, and our band measurements [12] and analysis enabled the first successful observation of point gaps. Furthermore, we propose that the skin effect can arise even in uniform systems [9]. By leveraging the unidirectional propagation behavior of skin modes in two-dimensional systems, we demonstrate that skin modes facilitate anomalous light propagation and the generation of optical orbital angular momentum (OAM).

Abstract: We report on the experimental investigation of the electrically tunable third harmonic generation of mid-infrared pulses from grating-gate field effect devices fabricated on n-doped InGaAs/InP heterostructure. Our findings pave the way for future exploitation of free-electron nonlinearities in all-semiconductor photonic integrated circuits.

Photonic integrated circuits with implementation of nonlinear functions hold promises as future hardware for neuromorphic information processes. However, the development of nanoscale nonlinear elements in photonic integrated circuits is hindered by the physical limits to the nonlinear optical response of dielectrics [1]. Recently, we have shown that optical nonlinearities in heavily-doped semiconductors due to nonlinear collective behavior of free-electrons can exceed by several orders of magnitude the efficiency of conventional dielectric nonlinearities [2]. We measured third-harmonic generation (THG) of mid-infrared (mid-IR) pulses from plasmonic nanoantenna arrays made of heavily n-doped InGaAs with increasing levels of free-carrier density. A further distinctive advantage of using semiconductors is the possibility to tune nonlinearity by means of field effect. In this work, to demonstrate the electrical reconfigurability of optical nonlinearity by means of an applied DC bias, we measured THG of mid-IR pulses from heavily doped InGaAs layer with gold antenna gratings on top (sketch in Figure 1a), investigating the effect of the applied bias on the emission intensity.

Plasmonic metal grating-gates have been fabricated by electron beam lithography starting from a HfO_2/n-doped InGaAs/InP multiplayer. The 750 nm-thick n-doped InGaAs layer ($n = 8.8\times10^{18}$ cm^{-3}) has been grown by metal organic chemical vapor deposition (MOCVD) on a lightly doped InP substrate, and the 35 nm-thick HfO_2 layer has been evaporated by atomic layer deposition on the n-doped InGaAs to work as gate dielectric material. Plasmonic metal gratings consist of arrays of rectangular gold electrodes with equal pitch (2 μm) and varying electrode width from around 300 nm to around 900 nm. All gratings are connected to the same electrical pad, while on the bottom of the lightly-doped InP substrate a metal back contact was fabricated by depositing a 50nm-thick Ni/50nm-thick Au layer. Electrical characterization of the plasmonic grating-gates confirmed efficient InGaAs carrier density modulation. The grating-gates have been then characterized by linear mid-IR Fourier transform IR micro-spectroscopy, confirming that plasmonic resonances shift towards higher energies by decreasing the gate width (see extinction curves in Figure 1b), in agreement with computational results.

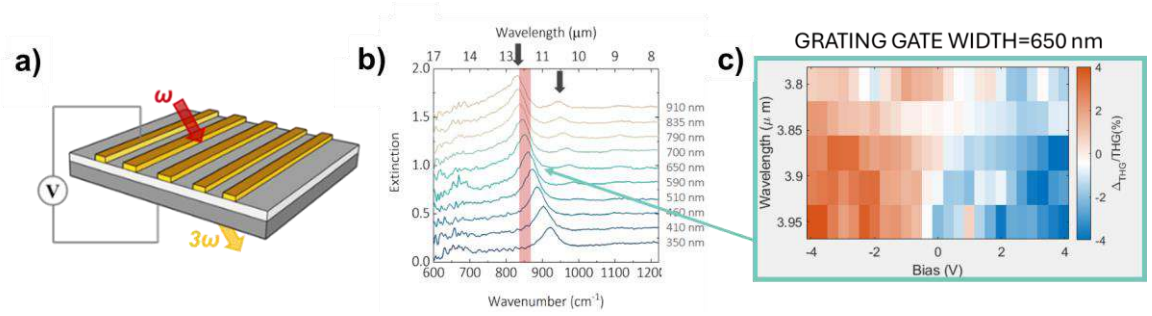

Figure 1 (a) Schematic of THG experiment with applied voltage bias on the n-doped InGaAs layer with gold antennas on top spaced with 35 nm HfO_2. (b) Extinction curves obtained by measuring both the reflection and the transmission of each grating (E=1-T-R). The red vertical band represents the optical pump spectrum used for the THG experiments. (b) Colormaps of the variation of THG emission intensity as a function of applied voltage bias for the grating with gate electrode width of 650 nm.

Finally, to assess the electrical reconfigurability of optical nonlinearity, we measured THG from the grating-gates with a mid-IR optical pump at approximately 12 μm, which corresponds with the main plasmonic resonance of many of the grating-gates (see Figure 1b), while varying the applied gate bias. We calculated the variation of THG spectrum ($\Delta_{THG}/THG_{0V} = (THG_V - THG_0)/ THG_0$) as a function of applied bias for the different grating structures. In all cases, we observe a change of the THG emission intensity depending on the applied bias. When the mid-IR radiation is resonant with the grating (grating width 650 nm, Figure 1c), which is the condition of optimal spatial overlap between gated semiconductor and plasmonic near-field, we observe an increase of the THG emission for negative bias, i.e. towards the depletion region of the n-doped InGaAs layer. Our results demonstrate that it is possible to modulate optical nonlinearity with an applied voltage bias by controlling the semiconductor carrier density. Having employed the common material platform InGaAs/InP that supports integrated waveguides, these findings pave the way for future exploitation of free-electron nonlinearities in all-semiconductor photonic integrated circuits.

Abstract: We present an overview of state-of-the-art materials for ultra-stable laser interferometers, focusing on thermal noise in various components. Investigated materials include NEXCERA for spacers, GaAs for highly reflective mirrors, metamirrors for ultra-low noise mirrors, and Eu^{3+}:Y_2SiO_5 for spectral-hole burning experiments.

Ultra-stable laser interferometers are key instruments in optical metrology, e.g., finding application in gravitational wave detectors [1] or optical lattice clocks [2]. The high precision is achieved through a laser source with ultra-stable frequency stability, typically ensured by stabilizing the laser to a high-finesse optical reference cavity [3]. A fundamental limitation of frequency stability arises from the reference cavity itself, or more specifically, from the thermal noise of its components—two high-reflectivity mirrors and a spacer [4]. An essential material parameter for quantifying Brownian thermal noise is the mechanical loss factor, which is linked to the intrinsic energy dissipation of a material.

In this study, we employ the mechanical ringdown technique to determine the mechanical loss factor of different materials, providing key insights into the reduction of thermal noise. Beyond conventional mirror technologies, we also investigate metamirrors, which offer an ultra-low noise performance and hold great potential for improving the frequency stability of next-generation ultra-stable lasers.

A material that has recently gained interest for use as a spacer in optical cavities is NEXCERA™, a ceramic-based composition. Its key feature is a coefficient of thermal expansion that crosses zero around room temperature, making it an ideal candidate for room-temperature cavities, as frequency fluctuations due to temperature variations are negligible. However, its thermal noise performance remains uncertain and could be a limiting factor if the Brownian noise level is high, even though thermo-optic noise is negligible. To address this, we measured the mechanical loss factor of NEXCERA and estimated the thermal noise for different spacer geometries and complete cavity configurations [5]. Our results indicate that NEXCERA exhibits lower Brownian thermal noise than ULE, the material currently used in the most stable optical cavity [6].

While the spacer plays a crucial role in stabilizing the optical cavity, the performance of the mirrors is also essential. For this purpose, a material currently under investigation is GaAs, combined with AlGaAs to form a stack of alternating layers, creating a highly reflective

crystalline Bragg mirror for ultra-high-finesse cavities [7]. Crystalline coatings offer a significant advantage: the mechanical loss factor is much lower than that of conventional amorphous coatings, resulting in a substantially reduced thermal noise limit. However, unexplained excess noise has been observed in these coatings, likely due to photoinduced effects, preventing them from outperforming traditional coatings [8]. In this work, we present our latest findings on photoinduced effects in elasticity and mechanical loss in GaAs. Our results indicate that laser illumination modifies both mechanical loss and elasticity, with effects persisting over timescales ranging from seconds to minutes [9].

While conventional Bragg mirrors achieve outstanding reflectivity through alternating layers, their main drawback is that increasing the number of layers also increases the overall thermal noise. Metamirrors provide a promising alternative by significantly reducing thermal noise while maintaining high reflectivity [10]. Unlike multilayer coatings, where each interface contributes to thermal noise, metamirrors rely on a single reflective surface, minimizing noise contributions and offering a highly stable solution for next-generation optical cavities.

Furthermore, in addition to cavity-referenced laser stabilization, the spectral-hole burning technique has emerged as a promising method. Here the stabilizing laser is locked to an ultra-narrow optical transition in an optical crystal, such as Eu^{3+}:Y_2SiO_5. Previous experiments have demonstrated significant potential for high-precision optical metrology, achieving frequency stability comparable to the most stable cavity-referenced lasers [11]. However, since the mechanical loss factor of Eu^{3+}:Y_2SiO_5 remains unknown, the fundamental thermal noise limitation in spectral-hole burning experiments is not yet well defined. In this work, we present cryogenic mechanical loss measurements, allowing us to estimate an upper limit for the Brownian thermal noise [12]. Our findings indicate that Eu^{3+}:Y_2SiO_5 could be a promising candidate for future ultra-stable laser applications.

In conclusion, our results highlight promising pathways for improving the frequency stability of next-generation laser cavities through the use of novel materials.

Abstract: Photoexcited plasmonic hot carriers unlock opportunities in applications ranging from nonlinear optics to photocatalysis. Here, we combine simulations and experiments to track these nonequilibrium carriers with spatial (sub-nm), temporal (few fs), and energy (meV) resolution, and then discuss an example of photocatalytic reaction leveraging hot carriers under ultrafast pulse illumination.

Plasmonic hot carriers – highly energetic electron-hole pairs with energy distributions far from equilibrium – photoexcited in metallic nanostructures hold great promise for a wide range of applications[1,2]. Their intrinsic spatial (a few nanometers), temporal (femto- to picoseconds), and energy (up to a few eV) scales offer unparalleled degrees of freedom for manipulating light-matter interactions. Effectively harnessing the large excess energy of these nonequilibrium carriers within their ultrafast lifetime has unlocked new opportunities for nanophotonic systems, with implications in fields ranging from nonlinear optics[5] to photocatalysis[6]. In this talk, we will first introduce an advanced technique for the real-time tracking of hot carries, and then discuss a photocatalytic reaction whose rate is modified by photoinduced nonlinearities under pulsed illumination.

When considering the ultimate limits of atomic-length scale structures, the ability to directly investigating hot carrier dynamics has remained out of reach until now, primarily due to the challenge of attaining simultaneous resolution in all the three domains – space, time and energy. Here, by combining time-dependent semi-classical modelling and two-colour femtosecond pump-probe microscopy, we present the real-time tracking of hot carriers in a well-defined plasmonic picocavity, formed in the tunnel junction of a scanning tunneling microscope (STM, sketched in Fig. 1a). The photoexcitation of hot carriers in the picocavity enables the ultrafast all-optical control over the broadband anti-Stokes (aS) electronic resonance Raman scattering (ERRS), and subsequent aS emission at the sub-nm scale. By leveraging the unique spatial confinement within the picocavity and ensuing spatio-temporal dynamics of hot carriers, the aS signal is generated in an active volume as small as 11 nm x 11 nm x 4 nm, and modulated with a sub-150-fs full recovery time, well before hot carrier relaxation.

The picocavity in unperturbed conditions emits aS photons over a broad spectrum (Fig. 1b, blue) following the illumination with a probe pulse (green in Fig. 1a) and excitation of its LSP (Fig. 1b, red), which decays to generate hot carriers. Finite element method-based simulations of the picocavity local density of photonic states (Fig. 1b, green), correlating with both the aS signal and the LSP, exhibit good agreement with measurements.

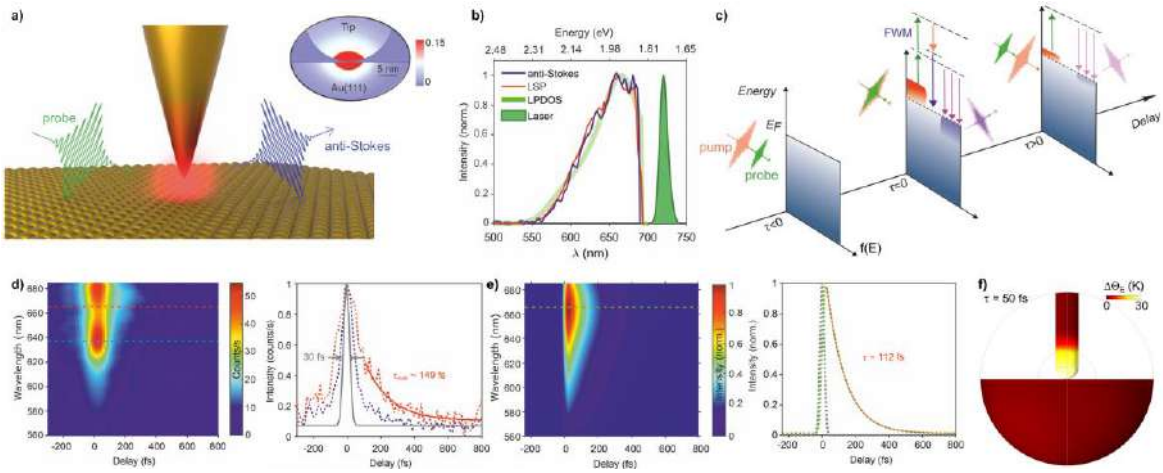

Fig. 1. a) Sketch of the picocavity excited by an ultrashort pulse (green) and generating aS photons (blue). Inset: simulated spatial distribution of the electromagnetic dissipated power. **b)** Measured aS spectrum (blue), local LSP (red), and the calculated local density of photonic states (green). **c)** Sketch of the temporal evolution of the hot carrier energy distribution as a function of the pump-probe delay τ. **d)** Experimental map (left) of the aS signal and ultrafast dynamics (right) of the signal at ~ 665 nm (red) and 640 nm (blue). **e)** Simulations for (d). **f)** Simulated spatial distribution of the electronic temperature across the metallic regions (tip and substrate), at 50 fs after the pump pulse arrival.

To dynamically modulate the aS emission, we conduct and model a pump-probe experiment, where the pump controls the hot carrier density, and the probe gives rise to aS ERRS (Fig. 1c). The recorded map of the aS signal is shown in Fig. 1d, with a section at 665 nm (red line), where the signal due to hot carriers is the strongest. Experiments are well explained by our simulations (Fig. 1e), reproducing both the spectral shape and temporal evolution of the measured aS modulation. The model combines a formulation of the ERRS cross-section with a rate-equation description of the hot carrier dynamics incorporating the ultrafast spatial carrier diffusion (Fig. 1f). Our time-resolved calculations indicate that the aS emission modulation is dominated by nonthermal hot carriers, while thermalised hot carriers (i.e., closer to the Fermi level) are drastically reduced by their spatial diffusion.

To conclude with an example of application exploiting the energy of hot carriers, we discuss the effects of pulsed illumination in driving a photocatalytic reaction (ammonia decomposition using CuRu antenna-reactors). By combining photothermal models and time-resolved measurements, we report a 20-fold increase in the reaction rate upon doubling the pulse repetition rate, for the same pulse energy and steady-state temperature. The effect is rationalised by light-driven transient nonlinearities modulating the reaction effective activation energy.

Abstract: The Photoacoustic spectroscopy is a technique that allow to study the local absorption of the sample. The new set-up allows for spatial and spectral mapping of absorption enabling the study of extrinsic chirality in nanostructured metasurfaces and the homogeneity of the nanostructures.

Circularly polarized light is conventionally used to probe the chirality of the sample , left and right circular polarization are absorbed differently, and this difference is defined as Circular Dichroism (CD). The chirality can be induced by combining the asymmetry of the sample and the optical set-up. This property is called extrinsic chirality and it is obtained by breaking the symmetry of the light-sample interaction by forming a non-planar triad of vectors between the light wave-vector, the normal of the sample's surface, and the vector of the sample's asymmetry. Previously, the chirality was studied by conventional techniques only for a single laser [1] wavelengths, however to measure the directly absorption response we can use unconventional photo-thermal techniques. Photo-acoustic spectroscopy (PAS) is a photothermal technique that exploits the interaction between an incident light beam and matter, inducing a non-radiative de-excitation process that generates heat. The fluctuations produce an acoustic signal, converted into an electrical signal and this approach enables direct measurement of local absorption, thereby detecting effects that might otherwise be obscured by other scattering-dependent techniques.

The PAS set-up, Fig. 1., used for the measurement consists of a widely tunable near-infrared laser, covering a wavelength range from 680 nm to 1080 nm. The light is modulated by a mechanical chopper at different frequencies. Before reaching the sample housed within the photoacoustic cell, the light beam, passes through a polarizer, a quarter-wave plate and the light can be focused on the sample in a closed PAS cell. The photoacoustic cell is equipped with a rotating stage, that enables examination of the sample at different angles of incidence relative to the surface normal, and a translation stage that allows the scanning of the sample in different areas.
This methodology allows us to study the homogeneity of the sample even on very small areas.

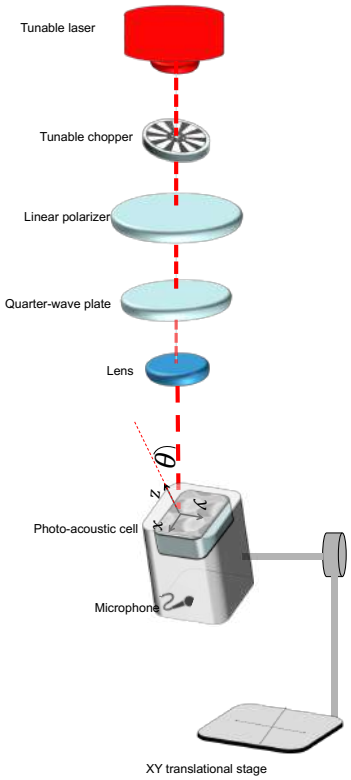

Figure 1- Photo-acoustic set-up positioned on rotational and translation stages allows for multiple tunable parameters

Abstract: Integrating photonic elements on multimode optical fibers combined with traditional wavefront shaping systems can enhance neural endoscope sensing. Here, we present our approaches to fabricating nano- and micro-photonic and plasmonic structures at the output of the fiber and achieve precise control over their coupling with thousands of guided modes.

Over the past 15 years, optical techniques have revolutionized the study of neuronal activity and connections within the brain, enabling all-optical observation of neuronal dynamics through electrical and chemical sensing[1,2]. The integration of endoscopic methods to excite and collect functional fluorescence has emerged as a promising approach for investigating local microcircuits[3] and mapping neural activity[4] in deep brain regions in a minimally invasive fashion. In this framework, multimode optical fibers (MMFs) represent an excellent platform for endoscopic sensing, thanks to the small cross-section, their inherently light-couple nature, and the possibility to shape the multimode fiber to engineer the emission and collection volume. This presentation will describe our approach to improving and extending the detection capabilities of MMFs for neural endoscopy applications, based on the use of photonic structures at the fiber output to exploit light-matter interactions to better interface with brain tissue[5]. To fully access the potential of this approach, we developed a set of methods to optimize and dynamically control the coupling of thousands of guided modes in the MMF of either dielectric elements or plasmonic systems.

Firstly, we will describe how wavefront shaping offers a dynamic solution to optimize the incident phase profile on a system composed by a MMF hosting at the output a meta-lens fabricated by two-photon lithography. By iteratively refining the wavefront, the optical response of the photonic structures can be maximized, enabling sub-diffraction spatial confinement by tailoring the near field, and selecting a working point of the coupled system's dispersion diagram by acting on the far field reciprocal plane[6]. By designing a diverging meta-lens that increases the numerical aperture of the fiber, it was possible to generate a scanning focused spot beyond the diffraction limit while simultaneously improving the collection volume of the probe. The same concepts were also applied to plasmonic MMFs, featuring gold nanoslit arrays or nanoparticles to integrate molecular sensing capability through spatial-resolved surface-enhanced Raman spectroscopy (SERS).

An alternative method to control the coupling between guided modes and plasmonic resonances on MMFs is to operate directly onto the shape of the fiber optic and the geometry of the plasmonic structures. The second part of the presentation will describe how this approach enhances the performance of a SERS probe. SERS offers significant advantages

to the neuroscience community by providing a label-free alternative for molecular sensing[7,8] and complements genetically encoded indicators which have been pivotal in neuroscience but are limited to animal models. To increase the probe sensitivity, we explored two complementary strategies: modifying the fiber itself and tailoring the design of the plasmonic structures. Tapered optical fibers (TFs) offer a unique advantage in SERS-based biosensing due to their modal demultiplexing properties and the co-existence of both radiative and evanescent field on the output surface[9], which enhance the coupling with plasmonic structures and the collection of the generated vibrational signal. To integrate plasmonic structures on TFs we employed physical vapor deposition, enabling the spontaneous nucleation of gold nanoparticles on the highly curved surface. This process leads to a transition from a rough gold nanofilm to a uniform layer of spherical nanoparticles with inter-particle gaps of less than 5 nm. The resulting plasmonic sensor exhibits remarkable detection capabilities, enabling the detection of serotonin dispersed in an aqueous solution at the physiological resting concentration (10^{-9} M) even in a through-fiber measurement scheme. Additionally, repeated measurements at varying concentrations reveal the detection of different stereoisomeric forms of serotonin.

Incident light selective metasurfaces

K. Y. Yang[1*]

[1]BrightEST Technology, Taiwan

Abstract: Photonic nanostructures can tailor the scattering phase from various polarizability induced by incident light. By introducing subwavelength meta-atoms with selective response of incident light, we have demonstrated additional design freedom to engineering dispersion, birefringence, wavevector selection and enhancement of second harmonic generation beyond arbitrary wavefront shaping for metasurfaces.

The development of nanophotonics has enabled tailoring the optical scattering phase in subwavelength photonics elements, so called meta-atoms. Thanks to the enrichment of mode and near-field coupling, meta-atoms can generate varying electromagnetic polarizability for different incident wavelength, polarization and illumination angle.

In this talk, we will first demonstrate the design of meta-atoms that can support independent scattering phase for horizontal and vertical linear polarizations. The meta-hologram arranged the polarization-selective meta-atoms as the building block of computer-generated meta-hologram, which can provide distinguish wavefront reconstruction and thus holographic images with different incident polarizations.

Besides the incident polarization, we have also realized the wavelength-selective metasurface which supports diffraction-free beam steering within 100 nm operation bandwidth at 750 nm central wavelength. To achieve optical phase engineering without introducing unwanted inhomogeneous broadening, plasmonic dark mode in meta-atoms supported Fano resonance plays a key role. This work demonstrates the color-routing metasurface can provide diffraction-free wavefront shaping beyond conventional bandpass filtering or grating with a subwavelength device thickness.

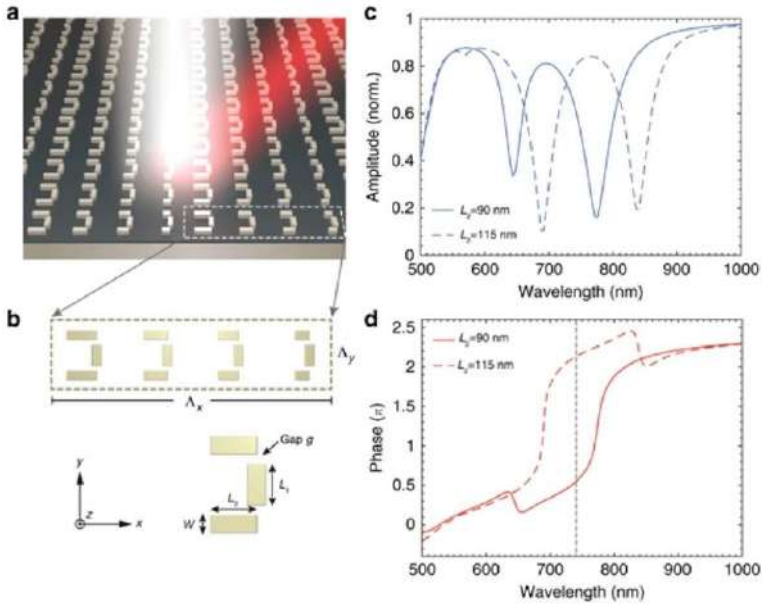

Figure 1. Design principle of a narrowband metasurfaces composed of plasmonic Fano resonators.

In the following, we will present our 2 works to achieve the selective response of incident angle for second harmonic (SH) generation (SHG). For SHG in plasmonic nanostructures, the second-harmonic dipole is enhanced by spatially overlapping fundamental hot spot to the area where centro-symmetric is broken. The unique 3D gold nanopillars with different tilted angles can support fundament plasmonic resonance only when incident angle is such that the polarization is paralleled to the nanopillars. Therefore, allows the subwavelength-thickness metasurface exhibits wavevector-selective SH enhancement.

Furthermore, we demonstrate a reflective type metasurfaces that can efficiently couple incident planewave to a hybrid plasmonic mode propagating along the interface of gold backplate of metasurfaces. A pronounced SH enhancement can be detected when the hybrid mode is excited by corresponding incident angle. Importantly, the SHG is at least 230 times higher than other angles that only localized plasmonic mode is excited at fundamental wavelength. These results underline the fascinating physics of SHG in the symmetry of fundamental plasmonic mode. The wavevector-selective nonlinear response in metasurfaces can find applications in the field of vacuum ultra-violet (VUV) super-resolution imaging, silicon photonics, etc.

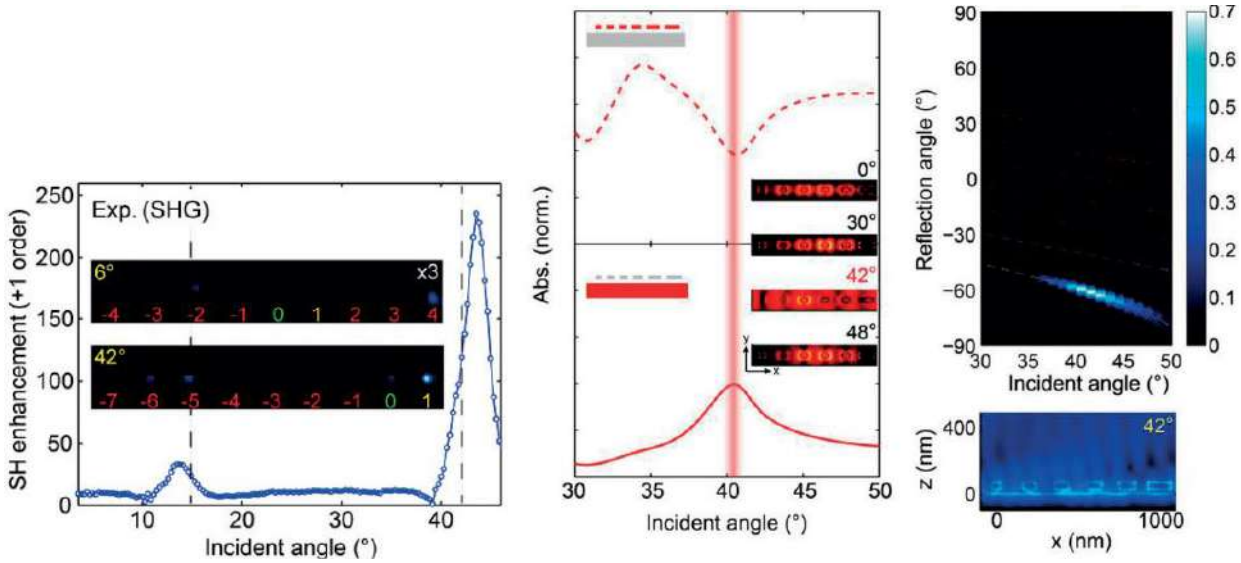

Figure 2. The experiment and simulation of SH enhancement from a hybrid plasmonic mode propagating along silver backplate of reflective metasurfaces with specific incident angle at fundamental wavelength.

Finally, I would like to acknowledge my Ph.D. advisor Prof. Olivier Martin, Dr. Jeremy Butet in EPFL and M.Sc. advisor Prof. Din Ping Tsai in National Taiwan University who provide endless support in completing the research of this talk.

Abstract

A new method for fabricating fluorescent nanostructures with defined magnetic dipolar transitions is presented. Electron beam lithography exposes a negative tone resist embedded with Europium complexes, achieving emitter diameters as small as 80 nm, which facilitates investigations of magnetic local density of optical states in nanophotonics.

1 Introduction

In studies of spontaneous emission modification, the magnetic component of light is often neglected in light-matter interactions due to its amplitude being 10^{-5} times smaller than that of the electric component. However, this is not the case when we engineer nanostructures with strong magnetic field localization [1]. To study the magnetic-field mediated light-matter interactions a magnetic emitter is utilized. Magnetic dipolar (MD) transition dominates when because of selection rules, the electric dipolar transitions are forbidden. These types of transitions occur primarily in lanthanides such as Europium; specifically we consider the $Eu^{3+}(^5D_0) \rightarrow Eu^{3+}(^7F_1)$ transition. Therefore, a Europium-based emitter enables us to study the often neglected magnetic component of light.

Previous works show that high refractive-index dielectric nano-antennas have great potential for the modification of magnetic transitions. However, the magnetic field localizations are much sub-wavelength, thus; we need a localization method for the magnetic emitters with nanometer precision. We introduces a fabrication method to deterministically create nanoscopic europium emitters which can be used to probe nanoscopic photonic environments [2]. The method utilizes electron beam lithography (EBL), and provides nanometer precision for the deterministic placement of magnetic emitters.

To create the nanoscopic emitters, we embed metal-organic complexes $Eu(TTA)_3$ into negative-tone electron beam resist series ma-N at a mass percentage of 0.1%. The mixture is filtered with a 0.2 μm filter and rested for 24 hours before spin-coating onto the substrate. To investigate

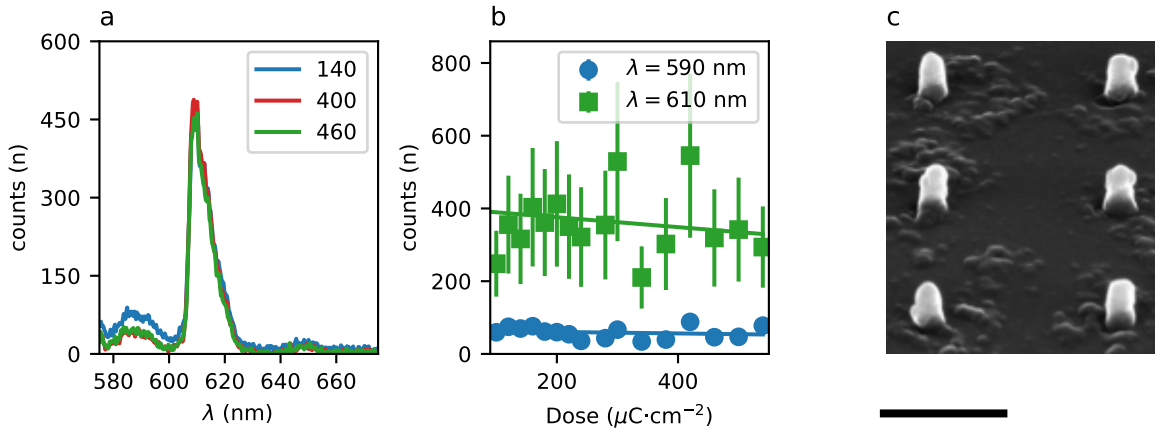

Figure 1: (**a**) Fluorescence spectra taken form exposed resist: Blue, red, and green lines correspond to doses of 140, 400, and 460 $\mu C \cdot cm^{-2}$, respectively. (**b**) Intensities of the $\lambda = 590\,nm$ transition (blue circles) and the $\lambda = 610\,nm$ transition (green squares) for different exposure doses. The solid lines are linear fits to the data. (**c**) Tilted electron microscope image showing the nanodot array. The scale bar is 400 nm.

the exposure properties, it is exposed to doses ranging from 100 $\mu C \cdot cm^{-2}$ to 540 $\mu C \cdot cm^{-2}$ in steps of 20 $\mu C \cdot cm^{-2}$, and after development, the fluorescence properties of the nanostructure are examined. In Figure 1a, some representative spectra are shown, and Figure 1b displays the intensity of the $\lambda = 590\,nm$ and $\lambda = 610\,nm$ transitions versus the exposure dose. We find that the fluorescence of the europium emitters is not altered by exposure to the electron beam. Additionally, we demonstrate the creation of fluorescent nanodots with a diameter of 80 nm using point exposures with a dose of 5 fC, see Figure 1c.

In conclusion, a new negative-tone fluorescent EBL resist ma-N : $Eu(TTA)_3$ with a mass percentage of 0.1% is demonstrated. The resist has good exposure properties and exhibits the fluorescence characteristics of Eu^{3+}. Considering the high flexibility of EBL, with multi-layer alignment, the new resist allows for the creation of hybrid photonics devices where the precise placement of emitters showing magnetic dipolar is critical.

Abstract: Electrophoretic deposition provides a feasible route to form closely packed, crack-free nanoparticle thin films as the emissive layer in a LED device. Herein, we present a method to monitor the film growth in real time and obtain information on film thickness and morphology without resorting to advanced microscopy techniques.

Electrophoretic deposition (EPD) is a method to form particle films on a solid substrate from a charged particle solution assisted by an external electric field. EPD has been widely used in industrial applications such as forming protective coatings on flat surfaces,[1] or inner surfaces of tubes that are otherwise difficult to have access to.[2] More recently, EPD was used to form various structured nanomaterials and films that can still take advantage of the unique properties of individual nanoparticles (NPs).[3,4] In this work, we propose a EPD model considering the finite volume of the NP solution and the dissolution of the NPs back to its solution. The mass of deposited NP film and the concentration change of the NP solution can be described by the following coupled equations:

$$\begin{cases} \dfrac{dw}{dt} = R_{dep} - R_{dis} & (1) \\ c_c = c_0 - \dfrac{\int R_{dep}\,dt}{V} & (2) \\ c_n = \dfrac{\int R_{dis}\,dt}{V} & (3) \\ c = c_c + c_n & (4) \end{cases}$$

where w is the deposited mass on the substrate, R_{dep} the deposition rate, R_{dis} the dissolution rate, c_c and c_n the concentrations of charged and neutral particles in solution respectively, V the volume of the solution and c_0 the initial concentration of charged particles. The plots below show how deposition current, charged particle concentration and deposited mass vary with time when a limited volume of particle solution is used.

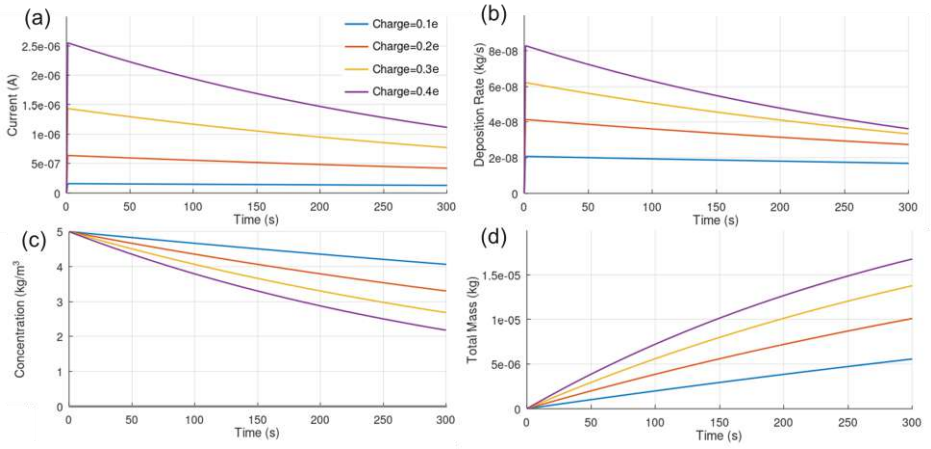

Figure 1: Modelling of I, R_{dep}, c_c and w vs. time with an initial charged NP concentration c_0= 5 mg/ml

We show that with appropriate assumptions, analytical solutions to the coupled equations can also be obtained. By measuring the deposition current vs. time trace, we can predict the single particle charge in solution and the deposition thickness of NP film as a function of time.

We employed this EPD method to form closely packed, vertically aligned CdSe/CdS core/shell nanorods (NRs) as the emissive layer in an inverted light emitting diode. Following an organic-inorganic architecture, the device fabricated yields an external quantum efficiency (EQE) of 6.3 % and a maximum luminance of 4320 cd/m^2 at 11 V.[5] This good performance can be attributed to the vertically aligned NR layer enhancing the charge transport through the long axis of NRs as it requires less hopping from NR to NR compared to a QD film of the same thickness. Achieving vertically aligned NR-LEDs can therefore maintain high current density. The EPD technique may prove useful to the development of a vast class of nanocrystal-based optoelectronics, including solar cells and laser devices.

Classical–quantum correspondence in photonic temporal crystals

Bumki Min

Department of Physics, KAIST, Daejeon 34141, Republic of Korea
*corresponding author: bmin@kaist.ac.kr

Abstract: We present a quantum electrodynamics model of photonic temporal crystals (PTCs) that connects classical and quantum pictures. A localization–delocalization phase transition takes place in a Floquet-photonic synthetic lattice, causing a two-level atom's Rabi oscillations to irreversibly decay into a mixed state, driven by photonic delocalization.

In this work, we develop a quantum electrodynamical framework for photonic temporal crystals (PTCs), bridging classical momentum gaps and fully quantum phenomena within a single theoretical model. Building on previous studies of non-Hermitian band structures in time-periodically modulated media [1-4], we show that a PTC can be quantized through a Floquet Hamiltonian where the photonic modes form a synthetic lattice in momentum–Floquet space. A key insight is that the exponential field growth seen in classical PTCs corresponds, quantum-mechanically, to a localization–delocalization transition of photon wavefunctions. At critical momenta (i.e., the edges of the momentum gap), photon number states become delocalized, triggering exponential increases in photonic energy.

Notably, when a two-level atom couples to these modes in a single-frequency cavity, conventional Rabi oscillations can be dramatically altered by the large continuum of Floquet–photonic states. Rather than exhibiting recurrent population exchange, the atomic state irreversibly decays into a half-and-half mixed state, even though there is only one nominal cavity resonance, illustrating how time-periodic modulation effectively expands the available photonic Hilbert space [4]. These results highlight that, despite the overall Hamiltonian being Hermitian, classical pseudo-Hermitian features emerge through Floquet band folding and interplay with quantum light–matter interactions. Beyond clarifying the classical–quantum correspondence of PTCs, this framework opens avenues for exploring photon pair creation, squeezing, and tailored non-equilibrium light-matter interactions [4, 5].

Abstract: Plasmonic nanostructures offer a powerful strategy for selective CO_2 reduction, overcoming challenges in conventional catalysis. By leveraging dendritic morphologies to enhance plasmonic effects, we drive efficient C-C coupling under light excitation. This talk explores our integrated approach combining simulations, spectroscopy, and nanoscale modelling to advance scalable, energy-efficient CO_2 conversion into valuable multi-carbon products.

Reducing CO_2 is essential for tackling climate change, but capturing it is only part of the solution. Transforming CO_2 into valuable chemicals offers a pathway to carbon-neutral fuels and essential industrial products. In particular, converting CO_2 into C_2+ products, such as ethylene and ethanol, is highly desirable due to their energy density, versatility, and economic significance. However, achieving high selectivity for these products remains a major challenge. The CO_2 molecule is highly stable, requiring multiple electron and proton transfers for reduction, and competing side reactions such as hydrogen evolution or CO formation often lower efficiency[1]. Traditional catalytic methods struggle with selectivity and require substantial energy input, limiting their scalability.

Plasmonic photocatalysis offers a promising alternative by using light to drive chemical reactions in a more controlled. When light interacts with plasmonic nanostructures, it excites localized surface plasmons, generating strong electromagnetic fields and energetic charge carriers. These effects can be harnessed to influence reaction pathways, steering CO_2 reduction toward multi-carbon products with greater precision. Unlike conventional approaches that rely solely on thermal or electrochemical activation, plasmonic excitation has the potential selective energy transfer to key reaction intermediates, modifying adsorption dynamics and enhancing reaction rates[2]. By tuning the optical and electronic properties of plasmonic nanostructures, we aim to improve both the efficiency and selectivity of CO_2 reduction, unlocking new possibilities for sustainable chemical production.

In this talk, I will give an overview of our investigations into plasmonic light-matter coupling and how it can be used to modify photocatalytic (PC) and photo-electrochemical (PEC) reactions. Our approach combines insights from nanoscale characterization and modeling of plasmonic resonances (BEM, FEM), and in situ monitoring of chemical reactions using surface-enhanced Raman spectroscopy (SERS) to probe underlying mechanisms. In addition, I will discuss how insights from atomistic studies and model molecule-nanoparticle systems can be leveraged to design practical photoelectrodes and photocatalysts for large-scale CO_2 reduction based on self-assembled dendritic structures.

Building on this foundation, we present a strategy using plasmonic dendritic nanostructures to drive selective CO_2 reduction. These self-assembled dendrites, fabricated via a scalable electrodeposition

process, exhibit sharp tips and intricate morphologies that amplify plasmonic effects[3]. By tuning their structure, we seek to optimize hot carrier generation, near-field localization, and local reaction conditions, which could provide a platform for C-C coupling. We will examine how these properties influence the reaction landscape and whether they enable new pathways for multi-carbon product formation with improved selectivity under light-driven conditions. This work contributes to the development of more efficient and scalable approaches to CO_2 utilization, with potential implications for sustainable chemical production.

Complex modulation of light in polarization and space using laser-written multi-plane light conversion

Multi-plane Light Conversion (MPLC) [1-3] is a technique for performing complex transformations of a set of light modes by propagating them through multiple phase modulations thereby transforming them into desired set of output modes. The phase modulation profiles are optimized using a wavefront matching algorithm [4] and are typically implemented with a spatial light modulator. However, practical limitations of MPLC - such as losses and lack of polarization control - necessitate new implementation approaches.

Recent studies have demonstrated that full-vectorial mode conversion can be achieved using the MPLC concept by replacing phase masks with locally varying birefringent metasurfaces, which a fabricated using demanding nanofabrication methods [5]. Hence, having more compact designs with similarly high efficiency, great flexibility in polarization control and no need for cleanroom facilities are desirable.

In this work, we present a novel method for MPLC systems based on low-loss, transmissive silica slides, which locally modulate the polarization of light with high resolution resulting in a global modulation of the full vectorial light field, i.e. its polarization, phase, and amplitude. The design of the required modulation planes is found via a numerical optimization algorithm based on Jones formalism, wavefront matching, and gradient descent. The modulations are physically implemented as waveplates with a fixed retardance but locally varying orientation angles of the optical axis.

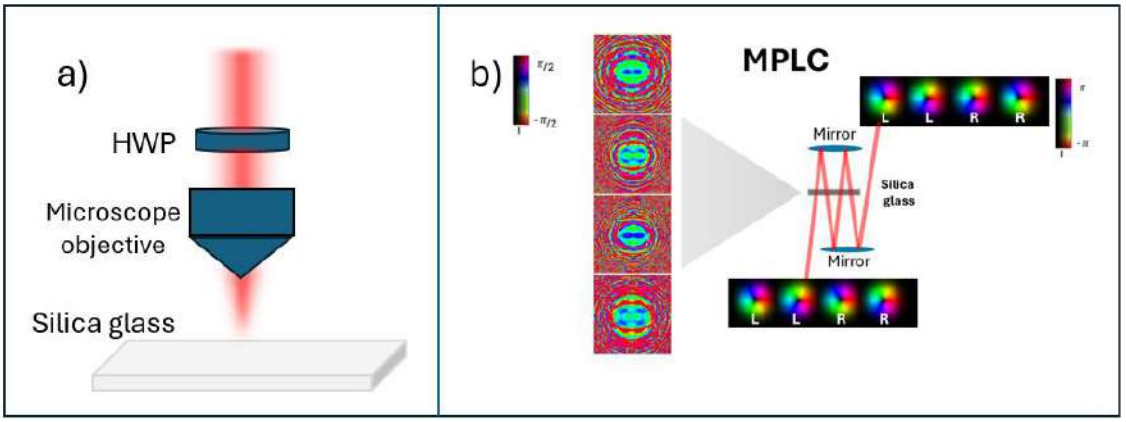

Fig. 1: (a) Simplified sketch of the laser direct writing technique used to fabricate waveplates with self-assembled nanogratings in silica glass. (b) Sketch of the MPLC implementation of 4 half waveplates with locally varying orientation angles of the optical axis. An example of a Single-photon CNOT gate is illustrated using circular polarization as a control qubit for the manipulation of OAM modes with masks

To fabricate the desired spatially varying waveplates with high resolution and low loss, we utilized the technique of direct laser writing of self-assembled nanogratings in silica glass [6], see Fig. 1 a). Through optimizing the

fabrication parameters such as writing speed, laser power, and repetition rate, we obtained a spatial resolution of around 1-2 μm per pixel and a efficiency of around 90% transmission per plane, which in principle can be as high as 99% [7]. Instead of realizing the MPLC system along a straight beam line with individual consecutive silica slides, we implement the scheme in a compact multi-pass design. A sketch of the setup can be found in Fig. 1b). In this scheme, all modulations are laser-written into one slide, with each modulation plane being 2x2 mm in size and separated from adjacent modulations by 2 mm. We note that owing to the high modulation resolution of our polarization modulation technique the sizes of the modulation can be further downscaled in future implementations enabling a smaller footprint of the MPLC system.

In our experimental demonstrations, we use an 808 nm laser beam that is simultaneously shaped in polarization and spatial structure through four modulations planes each acting as a complex structured half-waveplate (retardance of π). As a first test, we demonstrate the ability of our scheme in advanced full-field modulations and implement a mode de-multiplexer capable of decomposing the input light field into its spatial modes as well as polarization components. We further show that our scheme allows a unitary operation between sets of orthogonal spatial vector beams, i.e. spatial modes with transversely varying polarizations structure, and leverage this to demonstrate high-dimensional quantum gates. Finally, we show the ability of a polarization dependent spatial mode manipulation, which can be utilized as a single-photon controlled-NOT operation in which the two qubits are encoded in the two degrees of freedom of polarization and spatial structure.

In summary, our laser-written realization of an MPLC system shows great promise in advanced modulations of the full vectorial transverse spatial structure of light, thanks to it high-resolution and high-efficiency. I also enable increasingly complex modulation tasks possibly also including the modulation of the light's frequency components, which would result in the modulation of all degrees of freedom of light using an efficient single modulation scheme. As such, we are confident that using laser-written MPLC modulation schemes, will be a beneficial tool in various fields such as optical communications, imaging, sensing, and laser processing.

Abstract: We present our integration technique of low-power-consumption III-V lasers on Si. We use a directly bonded III-V membrane on SiO_2 as an integration platform and perform epitaxial growth to fabricate a buried-heterostructure. Based on this technique, direct modulation of membrane lasers and photonic crystal lasers with low-power consumption are reported.

The explosive increase in traffic within data centers requires the micro- and nano-lasers that are suitable for short-range optical transmission. A key to achieving high speed and low power consumption is the use of directly modulated lasers (DMLs) with strong optical confinement in a small active region. The power consumption of the laser is proportional to the volume of the active region, and the modulation speed of the DML is limited by a relaxation oscillation frequency determined by the optical confinement factor. To satisfy both, we have developed a heterogeneous integration technique of III-V nanostructure on SiO_2/Si platform using epitaxial growth after direct bonding of III-V membrane structure on Si with SiO_2 interlayer [1]. The III-V membrane structure (typically 250 nm thick) sandwiched between low-index materials provides strong vertical (*y*-direction) optical confinement. The active region is buried with InP by epitaxial regrowth to provide high lateral (*x*-direction) optical confinement. We have fabricated the lateral p-i-n structure by ion implantation of Si and thermal diffusion of Zn into the InP layer, allowing the lasers to be driven by lateral current injection.

Figure 1 shows the schematic drawings of the membrane lasers on Si. Longitudinal (*z*-direction) optical confinement was achieved by a surface grating fabricated by etching InP channel waveguides. For data transmission over a few kilometers, we developed a distributed feedback (DFB) laser with an active region of ~100 μm long, as mW-class optical output power is required. The membrane laser array demonstrated 2 km transmission of 56 Gbps (28 Gbaud) PAM-4 signals at 50°C with an energy cost of ~645 fJ/bit [2]. On the other hand, the energy cost required for chip-to-chip optical communication is much lower, while the optical output power required is lower. Therefore, we have also developed distributed Bragg reflector (DBR) membrane lasers. A high reflectivity of the DBR mirror enabled us to reduce the active region length to 5-μm. The laser was directly modulated by a 25.8 Gbit/s non-return-to-zero (NRZ) signal with a bias current of 600 μA and a bias voltage of 1.63 V, resulting in an energy cost of 38 fJ/bit [3].

To further reduce power consumption, we have also developed photonic crystal lasers that provide ultra-high optical confinement in an active region. Figure 2 shows a schematic drawing of the two types of photonic crystal lasers. The two-dimensional (2D) photonic crystal laser uses photonic crystals to increase both *z*- and *x*-directional optical confinement. The size of the buried heterostructure was only $2.5 \times 0.3 \times 0.15$ μm^3. We achieved 10 Gbit/s NRZ direct modulation with a bias current of 60 μA and a bias voltage of 1.71 V, corresponding to an energy cost of 10.3 fJ/bit. An on-chip optical link between a 2D photonic crystal laser and a membrane photodiode via the integrated Si waveguide has been demonstrated [4]. We have also demonstrated a 1D photonic crystal laser. The laser uses the photonic crystal only for *z*-direction confinement, and a deep-etched rib waveguide structure provides very high *x*-direction optical confinement. The optical output can be obtained

from the InP channel waveguide, which is directly butt-jointed to the active region. Thanks to the high optical confinement factor, we have achieved 40 Gbit/s NRZ direct modulation with a bias current of 180 μA [5]. We believe that these micro- and nano-lasers and their integration technology will pave the way for the fabrication of short-range optical links for the data centers of the future.

New materials for metaoptics from infrared (IR) to deep-ultraviolet (DUV)

Zeng Wang[1]

[1] Institute of Materials Research and Engineering (IMRE), Agency for Science, Technology and Research (A*STAR), Singapore
Corresponding author: wang_zeng@imre.a-star.edu.sg

Abstract: Our study investigates novel materials for metaoptics applications across a broad spectral range, from infrared (IR) to deep-ultraviolet (DUV). We focus on cavity-enhanced excitonic metaoptics utilizing two-dimensional transition metal dichalcogenides (TMDCs) for visible and IR applications, showcasing significant advancements in tunability, absorption enhancement, and excitonic effect control. These findings underscore the potential of TMDCs as a transformative platform for optoelectronic devices. Additionally, we demonstrate the use of aluminum nitride (AlN) for DUV metaoptics, highlighting its suitability for applications in this challenging spectral regime. Together, these developments pave the way for next-generation metaoptical systems with enhanced performance across diverse wavelengths.

Excitons in two-dimensional transition metal dichalcogenides (TMDCs) are quasiparticles formed by electron-hole pairs, exhibiting strong binding energies due to reduced dielectric screening and enhanced Coulomb interactions within their atomically thin layers, which give rise to exceptional optical characteristics for advanced optoelectronic devices[1]. Leveraging these unique excitonic properties, we first demonstrate atomically thin metaoptics operating in the visible spectrum by harnessing the robust excitonic resonances in MoS_2 multilayers[2]. Next, we extend the utility of MoS_2 to the infrared (IR) range by implementing cavity enhancement and subtle doping for band engineering, enabling strong absorption in the IR spectrum and broadening the scope of MoS_2-based metaoptical applications. Furthermore, we achieve a significant enhancement in exciton-trion conversion in atomically thin WS_2, facilitated by an optical cavity and electrical modulation. This results in a 40% modulation in reflectivity for excitons and 7% for trions at room temperature, paving the way for tunable, ultra-compact optical devices based on two-dimensional materials[3]. Finally, we report a breakthrough in metalens technology using aluminum nitride (AlN), achieving sub-200 nm resolution in the deep-ultraviolet (DUV) range. This advancement highlights the potential of AlN-based metalenses for high-resolution DUV applications, such as lithography and bio-spectroscopy, where precision at the nanoscale is critical. Collectively, these findings underscore the versatility of TMDCs and AlN in advancing metaoptics across a wide spectral range, from visible to DUV, with significant implications for next-generation optical technologies.

Abstract: We investigate the excitation and probing of hybrid light-matter electromagnetic modes (polaritons) using a fast electron beam and a metallic tip. By employing these localized probes, we are able to excite and spatially map strongly coupled systems that are challenging to access using conventional far-field optical spectroscopy techniques.

Polaritons are hybrid light-matter electromagnetic waves that arise from the coupling between photons and dipolar excitations in matter, such as phonons in polar materials, plasmons in metals, or excitons in semiconductors [1]. The strong field confinement induced by polaritons can produce electromagnetic fields that are orders of magnitude more intense than the incident field, leading to a variety of applications. A major challenge of polariton physics, however, stems from their large momentum mismatch with free-space photons, thus preventing their excitation using conventional far-field optical techniques. Among the variety of techniques to circumvent this limitation, scattering-type scanning near-field optical microscopy (s-SNOM) and electron energy-loss spectroscopy (EELS) in scanning transmission electron microscopy (STEM) are unique techniques for probing polaritons due to their ability to access their near field and provide information not accessible in the far field [2,3].

In this work, we present a numerical and experimental analysis of the excitation of polaritons in the near field using a fast electron beam or a metallic tip. Specifically, we analyze the near-field spectra of various polaritonic systems being excited by the localized probes (Fig. 1). We demonstrate that a metallic tip is capable of probing the hybrid polaritonic modes of single hexagonal boron nitride (h-BN) nanorods partially covered with a molecular layer [4]. Additionally, we theoretically describe how fast electrons couple to polaritonic modes in h-BN and the metallic delafossite oxide $PdCoO_2$ by analyzing their electron energy-loss spectra. Due to the optical anisotropy of h-BN and $PdCoO_2$, we show that the excitation of the polariton modes is strongly related to the electron velocity and highly dependent on the angle between the electron beam trajectory and the anisotropy axis [5]. Finally, we discuss the excitation of optical anapoles and anapole-exciton hybrids in transition metal dichalcogenides (TMDCs) tungsten disulfide (WS_2) nanodisks using EELS. We identify prominent dips in the electron energy loss (EEL) spectra of the WS_2 disks and demonstrate that they are associated with the excitation of various optical anapoles supported in the nanodisk [6].

The optical properties of semiconducting TMDC are dominated by excitons, which are electron-hole pairs that are tightly bound by Coulomb interactions. Excitons exhibit a large oscillator strength making TMDCs appealing for exploring exciton-polaritons. Thus, in the final section of the presentation, we briefly discuss recent findings on excitons in TMDC coupled to both photons and phonons, leading to the formation of a

three-body quasiparticle known as phonoritons [7].

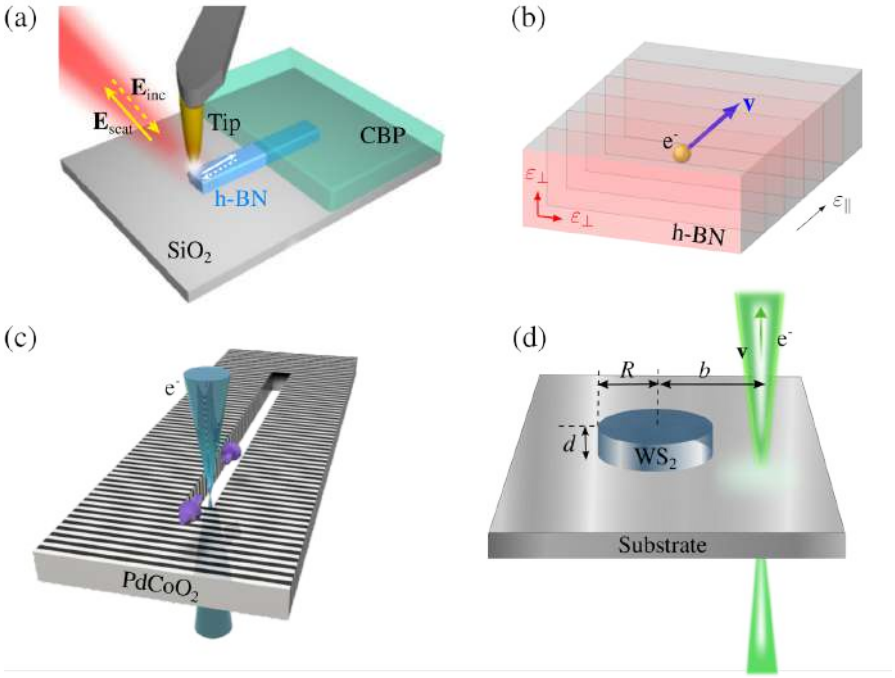

Figure 1: Sketch of the systems under study. (a) A s-SNOM tip (yellow conical structure) is positioned on top of the molecules-free part of an h-BN antenna (blue rod) half-covered by a molecular layer (green structure). (b) A fast electron traveling through h-BN. The red planes illustrate the stacking of single h-BN layers along the optical axis. (c) A fast electron passing through a $PdCoO_2$ slit, close to one of the sidewalls. (d) A WS_2 nanodisk (blue cylinder) excited by a focused electron beam (green ray) traveling along the vertical direction at a distance *b* with respect to the nanodisk center.

In summary, our results offer insights into the use of near-field spectroscopic techniques for exciting, probing, and mapping strongly coupled systems that cannot be easily accessed by far-field optical spectroscopy techniques.

Abstract:
In this work, a multi-objective, automated design process is presented to optimize one-dimensional photonic crystals for the purpose of exciting planar fields with enhanced optical chirality over a range of wavelengths. Using this procedure, we show the surprising result that designs composed of polymeric materials offer significantly superior performance.

Summary:

Chiral molecules are abundantly found in natural and engineered materials. Biomolecules ranging from DNA to synthetically engineered drugs are well known for having a chiroptical property where a molecule and its mirror image are non-superimposable. Despite having identical chemical composition, the effects of different handed chiral biomolecules (called enantiomers) can differ drastically, making the determination of the handedness crucial [1]. Optical sensors are prolifically used to determine the handedness of enantiomers, through circular dichroism with circularly polarized light, due to their non-invasive behavior and rapid detection schemes. However, due to the small size of typical biomolecules and the relatively large diffraction-limited focal spot of lasers in the optical regime, standard circular dichroism measurements require measuring a relatively large density of chiral biomolecules limiting its applicability. To match the increased demand by the pharmaceutical industry for improved chiroptical sensors, scientists have turned to the field of nanophotonics.

Optical sensors with enhanced chirality rely on the idea that confined light improves the interaction of circularly polarized light with chiral matter. That is to say that confining light containing both vertical and horizontal polarization states simultaneously with the appropriate phase offset will increase the optical chirality coefficient and thus improve the sensitivity of the optical sensor to the presence of chiral matter. A plethora of nanophotonic solutions have proposed such sensors which utilize different physical mechanisms to achieve the increased optical chirality such as SPP, metasurfaces, Bloch Surface Waves (BSWs), etc. [2]. However, it remains a challenge to produce a sensor with an enhanced optical chirality that is uniform over a large surface area which can be easily switched from left- to right- hand circularly polarized light. Additionally, to move from chiral sensing to chiral spectroscopy, the sensor must have a large and relatively even optical chirality enhancement over a significant operating wavelength range. In the past few years, exciting BSW inside specially designed one-dimensional photonic crystals (1DPCs) has shown a route towards developing such a nanophotonic solution [3]. However, designs remain elusive which allow for large, uniform chiroptical enhancements over extended wavelength ranges. To accommodate for these challenging design criteria, in this work we propose the use of an automated design process to optimize the structure of a 1DPC which can generate broadband, superchiral light. We use this optimization method to investigate the effect of using polymeric materials on the sensor's performance.

To generate superchiral light in 1DPCs, one must design structures to excited BSW which confine light to the surface of the 1DPC due to the presence of a photonic band gap and being in total internal reflection. While previous methods have generated such structures by hand tuning a 'defect' layer at the termination of a 1DPC, to support the superchiral enhancement over a large wavelength range an automated design can be very beneficial.

For our automated design, we used a multi-objective genetic optimizer, specifically a two-objective genetic optimization algorithm called “non-dominant sorting genetic algorithm”. In this optimization scheme, we have the freedom to choose the parameters to optimize and the evaluation functions to evaluate the individuals of the population. One example optimization is shown in figure 1, where the parameters of the evaluation were the thicknesses of each layer in the multi-layer dielectric stack for both a standard design, using SiO_2 and Ta_2O_5 for the layers, and a polymeric platform that used polystyrene and cellulose as the materials for the layers. The criteria used to evaluate the individuals were the maximum optical chirality calculated at 400 nm and 500 nm. As can be seen in figure 1b, a Pareto front forms at the end of the optimization, representing all the optimal designs and possible tradeoffs between the two evaluation criteria.

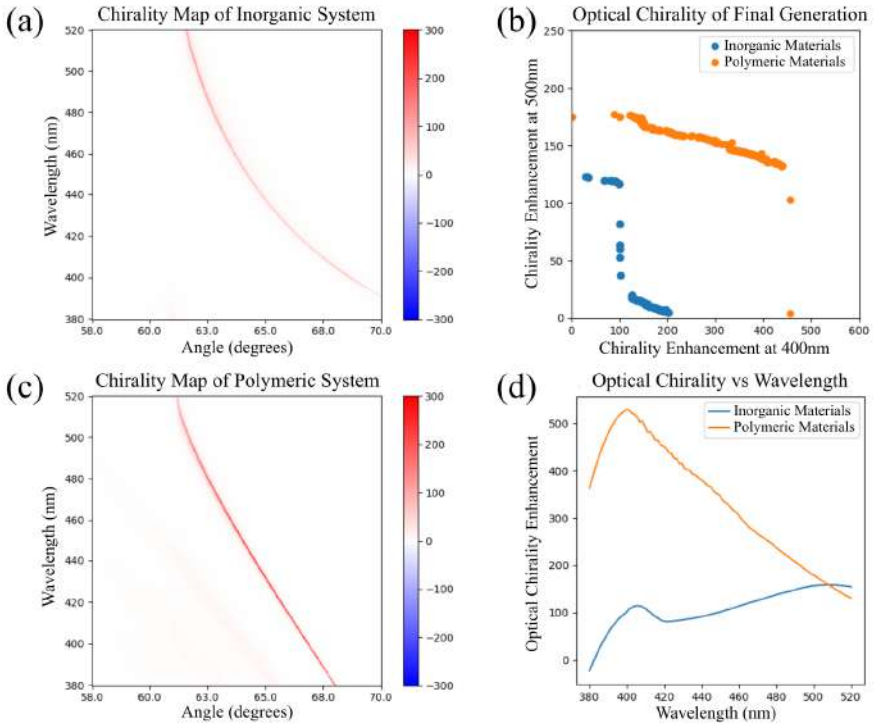

Figure 1: a) and c) show the optical chirality enhancement as a function of wavelength and incident angle for an optimized 1DPC design with inorganic and polymeric materials, respectively. b) shows the Pareto front from the last geneation of the optimizations. d) shows the optical chirality enhancement as a function of wavelength to visually compare the results of the inorganic and polymeric designs.

The optical chirality enhancement factor was calculated as a function of wavelength and incident angle to compare the two designs, as shown in figure 1a and 1c. The demonstrated possibility to employ low-index polymeric platforms without compromising but rather improving the performance of the device in terms of optical chirality enhancement paves the way to a class of low-cost and recyclable chips for optical chiral sensing.

Abstract: We examine the sensitivity of non-Hermitian photonic lattices with asymmetric couplings by exploring the underlying pseudospectral scalings. We show that the extreme lattice nonnormality leads to exponentially sensitive eigenvalue spectra and power growth, suggesting a route for designing ultrasensitive systems without relying on exceptional points.

A key characteristic of non-Hermitian Hamiltonians $\mathbf{H}$ is the presence of exceptional points (EPs), unique singularities where both eigenvalues and eigenvectors coalesce [1]. Systems operating near an EP exhibit strong sensitivity to perturbations [2], enabling applications such as microresonators [3] and gyroscopes [4], to name a few. Alternatively, ultrasensitivity appears in lattices with asymmetric couplings, which typically display the non-Hermitian skin effect (NHSE) [5], i.e., the localization of all eigenstates at one lattice end. It has been shown that the spectra of such asymmetric lattices exhibit exponential sensitivity with respect to the lattice size when the boundary conditions are varied, and this sensitivity has been linked to the lattice's topological properties [6]. In this work, we analyze the exponential sensitivity of asymmetric lattices by applying the pseudospectra theory [7]. We show that not only the spectra, but also the growth of an initial state exhibit exponential variations with N, and that this effect is due to the extreme lattice nonnormality [8].

Our results are schematically illustrated in Fig. 1. We investigate the Hatano-Nelson model [see Fig. 1(a1)], where the Hamiltonian matrix is given by $\mathbf{H} = \sum_{j=1}^{N-1} \left(t_L |j\rangle\langle j+1| + t_R |j+1\rangle\langle j|\right)$, with $|j\rangle$ denoting the state localized at lattice site j, t_R as the hopping amplitude for transitions from site $j+1$ to j, and t_L as the hopping amplitude in the reverse direction. We note here that $\mathbf{H}$ is a nonnormal matrix, meaning that $[\mathbf{H}, \mathbf{H}^\dagger] \neq 0$, which leads to nontrivial amplification effects as discussed in the following. The evolution of the amplitude ψ_n at each lattice site $n = 1, \ldots, N$ is

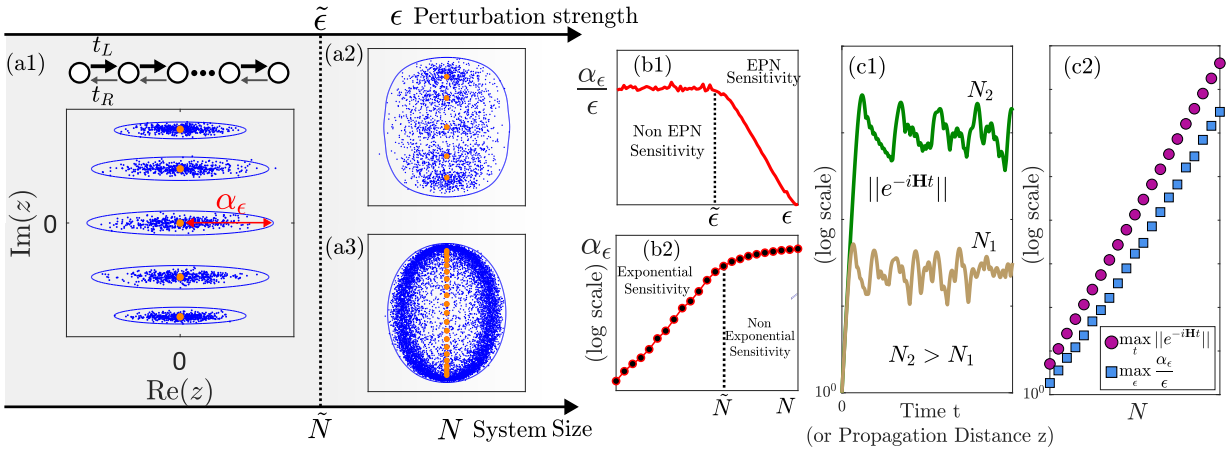

Figure 1: Spectrum (orange dots) and pseudospectrum (blue dots) of $\mathbf{A} = \in i\mathbf{H}$, for (a1) small N and ϵ, (a2) large ϵ and moderate N, and (a3) large N and moderate ϵ. (b1), (b2) Variation of the pseudospectral abscissa α_ϵ with (b1) ϵ and (b2) N. (c1) Time (or spatial) growth dynamics for light propagation through cavities (or waveguides) and for two lattice sizes $N_2 > N_1$. (c2) Power growth and Kreiss constant scaling with N.

described by $\dot{\boldsymbol{\psi}} = \mathbf{H}\boldsymbol{\psi}$, where dot denotes differentiation with respect to time t (distance z) for light propagation in cavities (in waveguides) and $\boldsymbol{\psi} = [\psi_1, ..., \psi_N]^T$. Figure 1(a1) shows the spectrum σ (orange dots) and the pseudospectrum σ_ϵ (blue dots) of the matrix $\mathbf{A} = \in i\mathbf{H}$. The pseudospectrum [7] is defined as the set with the eigenvalues of perturbed matrices $\mathbf{A}+\mathbf{E}$, with $\mathbf{E}$ being a complex random matrix with 2-norm less than ϵ. Note that for small N and ϵ, the pseudospectrum consists of N disks centered at the N eigenvalues of $\mathbf{A}$ [Fig. 1(a1)]. As the perturbation strength ϵ [Fig. 1(a2)] or lattice size N [Fig. 1(a3)] increases, the pseudospectrum extends into the complex plane. The variation of the pseudospectrum size — measured by the pseudospectral abscissa $\alpha_\epsilon = \max \Re[\sigma_\epsilon(\mathbf{A})]$ — with ϵ and N is shown in Figs. 1(b1) and 1(b2) respectively. We observe that α_ϵ scales as a power law (exponentially) beyond a (up to a) critical perturbation strength $\tilde{\epsilon}$ (critical lattice size $\tilde{N}$). These results show the extreme sensitivity of the spectrum to perturbations of the Hamiltonian.

We will now illustrate the sensitivity of the HN model in relation to power growth dynamics. We note first that the evolution of an initial state $\boldsymbol{\psi}_0$ is given by $\boldsymbol{\psi}(t) = e^{-i\mathbf{H}t}\boldsymbol{\psi}_0$, where the matrix $e^{-i\mathbf{H}t}$ is refereed as the propagator or evolution matrix [7]. A measure of the power dynamics is the maximum growth at any given time t, defined as $\max_{\boldsymbol{\psi}_0} \frac{||\boldsymbol{\psi}(t)||}{||\boldsymbol{\psi}_0||}$, which corresponds to the 2-norm of the propagator matrix $||e^{-i\mathbf{H}t}||$. Figure 1(c1) shows the time evolution of the propagator norm for two lattice sizes $N_{1,2}$. Amplification is observed ($||e^{-i\mathbf{H}t}|| > 1$), which results from the nonnormality of $\mathbf{H}$. Additionally, the maximum amplification $\max_t ||e^{-i\mathbf{H}t}||$ increases with N. Specifically, $\max_t ||e^{-i\mathbf{H}t}||$ scales exponentially with N, as illustrated in Fig. 1(c2), highlighting the exponential sensitivity of the growth. Furthermore, the pseudospectrum offers an estimate of this growth through the Kreiss matrix theorem, which states that $\max_t \left\|e^{-i\mathbf{H}t}\right\| \geq \max_{\epsilon>0} \frac{\alpha_\epsilon}{\epsilon}$. The right-hand side of this inequality, known as the Kreiss constant, is shown in Fig. 1(c2) to also increase exponentially with N.

In conclusion, we have conducted a scaling analysis of pseudospectra in exponentially sensitive lattices. Considering recent experimental realizations of such asymmetric optical lattices in non-Hermitian photonics [5], our results could facilitate the efficient design of ultrasensitive devices without the need for higher-order exceptional points.

Abstract: Subwavelength metamaterials have significantly driven silicon photonic integrated circuits since their inception in 2006. In this invited talk, we will provide an overview of our latest findings, with particular emphasis on the development of high-performance building blocks engineered for highly-efficient modal manipulation and power distribution.

Patterning of a subwavelength grating (SWG) onto a silicon wire with periods between 100–150 nm provides unprecedented control of the flow of light in photonic chips [1]. Such periodic structures suppress diffractive effects and behave as homogeneous metamaterials whose optical properties (refractive index, dispersion profile and anisotropy) can be tailored by modifying geometrical design parameters [2]. This versatility has enabled the demonstration of several ground-breaking devices as well as the enhancement of nonlinear effects in silicon nanophotonic waveguides [3-5], exhibiting remarkable prospects for overcoming the prevailing challenges of photonic integration, including suboptimal performance of key building blocks such as power splitters and mode converters. In this invited contribution, we will review our recent advances in the development of subwavelength-engineered metamaterial devices for high-performance power and modal control.

Firstly, we present two distinct architectures based on symmetric Y-junctions and SWG metamaterials for efficient power division: i) a Y-junction with SWG nanostructured stem and arms [6], and ii) a Y-junction assisted by SWG metamaterials between the arms [7]. The first power splitter has been optimized for two different lithographic resolutions, namely 50 and 100 nm. Experimental measurements demonstrated excess loss <0.3 dB for the fundamental transverse-electric (TE_0) mode considering the high-resolution process (i.e., 50 nm) and <0.5 dB for the 100 nm resolution scenario. The device is also robust against fabrication errors of up to ±10 nm. The second power splitter (i.e., SWG-assisted Y-junction) achieves one of the broadest operating bandwidths reported to date. Full 3D finite-difference time-domain (FDTD) simulations predict excess losses <0.2 dB for TE_0 and TE_1 modes over an ultra-broad bandwidth of 700 nm, while the TM_0 power splitting also yields a remarkably broad bandwidth of 500 nm. Experimental results confirm the broadband operation of the device for all three modes within a bandwidth of 250 nm (limited by our measurement setup).

Regarding modal management, we propose a novel mode converter based on two symmetric Y-junctions that are connected in a back-to-back arrangement through their arms. These arms include SWG metamaterials, enabling precise control of mode exchange to broaden the operating bandwidth [8]. The device was rigorously

simulated using a 3D FDTD solver, predicting insertion loss (IL) <0.3 dB and extinction ratio (ER) >20 dB over the wavelength range of 1472 – 1622 nm. The fabricated device shows an excellent agreement with simulation results, showcasing IL <0.5 dB and ER >18 dB over 150 nm bandwidth. To the best of our knowledge, this device achieves one of the broadest experimentally demonstrated bandwidths for TE_0-TE_2 conversion.

These devices underscore the significant potential of SWG metamaterials in advancing the next generation of high-performance functional building blocks. Notably, the power splitters and mode converter presented in this work are particularly suited for state-of-the-art on-chip applications, including programmable photonics, multi-target spectroscopy, nonlinear photonics, and quantum computing.

Abstract: We investigate a time-vaying dispersive interface. We discuss unconventional effects supported by this system: the generation of frequencies at the system's natural resonances, the direct excitation of confined wave modes, and unusual spin-dependent effects.

We investigate a time-varying, dispersive interface that features Lorentzian dispersion, whose parameters are modulated in time. Specifically, we consider a time-varying interface, i.e., a dispersive dielectric layer of thickness L (with $L << \lambda$, and λ denoting a characteristic wavelength) sandwiched between two homogeneous, stationary and non-dispersive half-spaces (see Fig.1(a)). We investigate transverse-electric (TE) modes of the kind $Re[E(z,t)e^{ik_x x}]\hat{e}_y$, where k_x is the conserved transverse wavenumber, $\hat{e}_y$ is an y-directed unit vector. The interface lies on the plane $z = 0$, and its response can be modeled in terms of sheet transition conditions, i.e., $\Delta E = 0, \quad \Delta H = \frac{dP(t)}{dt}$, with $\Delta G = G(z = 0^+, t) \in G(z = 0^-, t)$ $(G = E, H)$ and where H, and P denote the z-component of magnetic field and the y-component of the surface polarization, respectively. We assume that any field component G is of the form $Re[G(z,t)e^{ik_x x}]$. The dynamics of the surface polarization is governed by

$$\frac{d^2P(t)}{dt^2} + \gamma\frac{dP(t)}{dt} + \omega_0^2 P(t) = \varepsilon_0 L\omega_p^2(t)E(0,t), \tag{1}$$

where ε_0 is the vacuum permittivity, ω_0 and γ are the resonance frequency and damping parameter, respectively (constant over time), whereas ω_p is the time-varying plasma frequency. In the scenario where the system exhibits a temporal boundary (i.e., the plasma frequency undergoes a sudden switch), we derive analytical solutions (see [1] for details). In the stationary scenario (constant plasma frequency), the metasurface can support discrete bound modes that propagate along the x-axis and exhibit evanescent decay along the z-axis. In the standard scenario, these bound modes cannot be directly excited by a propagating wave, whereas the temporal boundary activates the natural resonance modes supported by the interface when interacting with an incident wave packet.

As a relevant example, we consider a scenario where a wave packet impinges at oblique incidence on the time-varying interface. Specifically, we assume that the incident electric field is $E_i = E_0 e^{-(t-t_0)^2/\sigma^2 - i\omega_i(t-t_0)}$ at a reference plane $z = \in L_1 \simeq \in 35c/\omega_0$, with $t_0 \simeq 53/\omega_0$, $\sigma = 4/\omega_0$, $\omega_i = 2.5\omega_0$, and $k_x \simeq 1.44\omega_0/c$ (corresponding to an incidence angle of 24° from the z-axis at the carrier angular frequency ω_i). Moreover, we set $\omega_p^2 = \omega_0^2 A(t)$, where $A(t) = A_1 + (A_2 \in A_1)U(t)$ [$U(t)$ is the standard unit step function] with $A_2 = 1.2$, $A_1 = 1$, $L = 0.16c/\omega_0$, $\varepsilon_L = 2$, $\varepsilon_R = 1$, and $\gamma = 5 \cdot 10^{-3}\omega_0$. Results are reported in Fig.1. Fig.1(b) shows the normalized electric-field map associated with bound resonant modes excited through a propagating wave

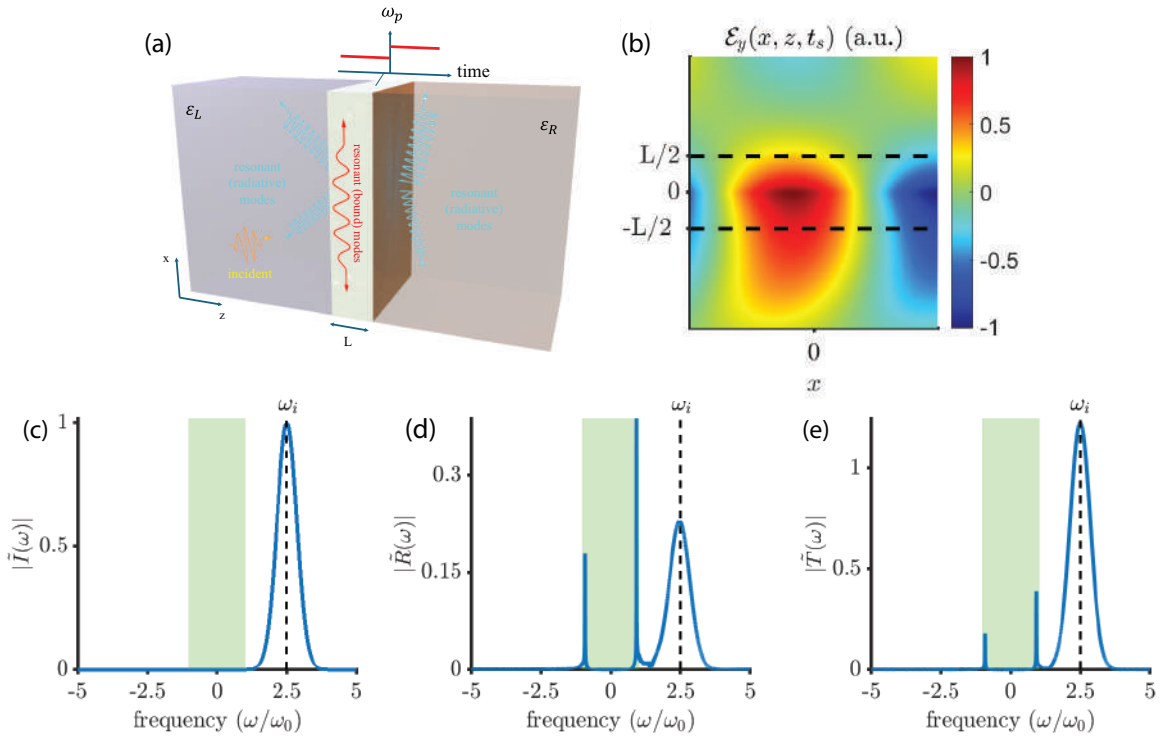

Figure 1: (a) A time-varying dispersive interface is represented as a thin dielectric layer between two homogeneous, stationary half-spaces with relative permittivities ε_L and ε_R. (b) Normalized electric-field map at time $t_s \simeq 61/\omega_0$, showing the excitation of a bound resonant mode (surface wave). The horizontal dashed lines delimit the thin layer interfaces at $z = \pm L/2$. Normalized spectra of the incident (c), reflected (d), and transmitted (e) wave packets; the dashed vertical lines represent the carrier frequency of the incident field. All spectra are normalized with respect to the peak value of incident one.

packet. Figures 1(c), 1(d) and 1(e) display the incident, reflected and transmitted spectra, respectively. For the chosen parameters, the resonant modes are bound since their eigenfrequencies lie within the evanescent spectral range (highlighted with green shading in Fig.1). Therefore, the excitation of the natural resonance modes induced by the temporal boundary enables the coupling of a propagating wave packet with bound modes (surface waves), without the need for any spatial subwavelength structuring or extended time-periodic modulations. The occurrence of this phenomenon is also confirmed through full-wave simulations (see [1] for additional details).

Finally, we note that a time-varying spatial interface can support other intriguing effects due to the unconventional interaction of the electromagnetic field with both temporal and spatial boundaries. In our presentation, we will also discuss these effects, highlighting their unexpected polarization dependence.

Abstract: We report our progress on single-photon emitters in materials for integrated quantum photonics, focusing on silicon nitride (SiN) and aluminum nitride (AlN) photonic platforms. We study emitter characteristics, defect origins, and site-controlled fabrication. We also discuss coupling emitters with resonant nanostructures to enhance emission efficiency.

Quantum photonic technologies rely on scalable and coherent single-photon sources integrated into photonic circuits. Silicon photonics, including SiN, enables photonic integrated circuits (PICs) compatible with CMOS processes. SiN is particularly advantageous, offering ultralow-loss waveguides, broad spectral transparency, and fabrication processes compatible with standard semiconductor foundries.

Our work demonstrated single-photon emitters in silicon nitride (SiN) fabricated via high-density plasma chemical vapor deposition (HDPCVD) [1] and plasma-enhanced chemical vapor deposition (PECVD), followed by thermal annealing. Emitters form primarily at interfaces between SiN and silicon dioxide (SiO_2), exhibiting stable room-temperature emission with high brightness, single-photon purity, and linear polarization [1]. These characteristics of single-photon sources are suitable for quantum key distribution protocols employing polarization encoding [2]. At cryogenic temperatures, emitters exhibit distinct zero-phonon lines (ZPL) around 548 nm [3]. Current research involves resonant excitation studies aimed at achieving lifetime-limited linewidths of ZPL essential for indistinguishable photon generation.

We integrated single-photon emitters into SiN waveguides [4] and proposed a scalable, site-controlled fabrication method compatible with semiconductor foundry processes [5]. Comprehensive materials characterization and modeling were used to identify potential defect complexes responsible for single-photon emission. Metasurfaces and resonant nanostructures enhance emission rates and enable efficient generation and control of quantum states of light [6]. We recently demonstrated bullseye cavity-enhanced single-photon emission in SiN, achieving improved emission rates and directionality. Future studies will focus on further optimizing bullseye and other resonant cavity structures to enhance the performance and integration potential of SiN-based single-photon emitters.

We also explored single-photon emitters in AlN, a promising platform for integrated quantum photonics, using heavy-ion irradiation followed by thermal annealing [7]. The emitter density showed a direct correlation with ion fluence. Zirconium (Zr) ions were used to generate theoretically predicted optically addressable spin defects. Ongoing studies aim to experimentally verify their spin-related optical properties.

In summary, our work highlights the capabilities of SiN and AlN with single-photon emitters for integrated quantum photonics, addressing emitter formation, defect origins, and scalable integration with photonic circuits and resonant nanostructures. Future research will focus on deepening our understanding of emitter photophysical properties and improving integration methods with nanophotonic components.

Optical fiber microstructure devices inscribed by femtosecond laser and their sensing applications

Xuewen Shu[1] (Invited)

[1]Wuhan National Laboratory for Optoelectronics, Huazhong University of Science and Technology, Wuhan, 430074, China

Abstract: We hereby report our recent progress in the fabrication of various in-fiber microstructures, such as interferometers and gratings, by using femtosecond laser, and then discuss their sensing applications.

Optical fiber-based devices have witnessed remarkable advancements in recent decades, driven by their extensive applications in diverse fields such as optical communication, environmental monitoring, and biomedical sensing. Among the various techniques for fabricating fiber-optic devices, femtosecond laser inscription has emerged as a powerful and versatile approach. Femtosecond lasers, characterized by ultra-short pulse durations and high peak powers, enable precise and minimally invasive modification of the fiber's internal structure. This unique property allows for the creation of in-fiber microstructures, including interferometers and gratings. Fiber interferometers are crucial for measuring physical parameters such as temperature, strain, and pressure with high sensitivity. Fiber gratings, on the other hand, have revolutionized the field of fiber-optic sensing by providing wavelength-selective reflection or transmission. Despite the significant progress made in this area, there remains a continuous need to develop novel fabrication methods and explore new applications. In this context, our research focuses on leveraging femtosecond laser inscription to create a variety of in-fiber microstructures. We hereby report our recent progress in the fabrication of these microstructures and then discuss their potential sensing applications. This work not only contributes to the fundamental understanding of femtosecond laser-fiber interactions but also holds great promise for the development of next-generation fiber-optic sensing technologies.

Figure 1 shows a specific example of a complex fiber grating structure fabricated by femtosecond laser. The fabricated grating is a kind of small-period long-period fiber gratings (SP-LPFGs) [1-3]. We use a femtosecond laser to inscribe a series of annuli inside the fiber, forming the grating. The annuli grating structure enables flexible adjustment of the transverse refractive index (RI) modulation region and the duty cycle along the axial direction. Additionally, the annular tracks effectively enlarge the scale of the RI modulation region. As a result, greater resonance intensity can be achieved with fewer cycles. Therefore, the gratings produced using this method can be relatively short, with a length of around 3 mm. By inscribing multiple adjacent annuli in each period, we can improve the axial duty cycle of the grating. We studied the effects of different annuli radii and the number of annuli in each period on the transmission spectrum. It was found that the SP-LPFG with annuli radii of 3μm and 4 annuli in each period exhibits distinct Bragg resonance dips and cladding mode resonance dips in its transmission spectrum. We also tested the RI and temperature sensing performances of the grating. The results show that the cladding mode resonances are sensitive to both RI and temperature, while the Bragg resonances are only sensitive to temperature. This indicates that the annular SP-LPFGs can be used for the simultaneous sensing of RI and temperature.

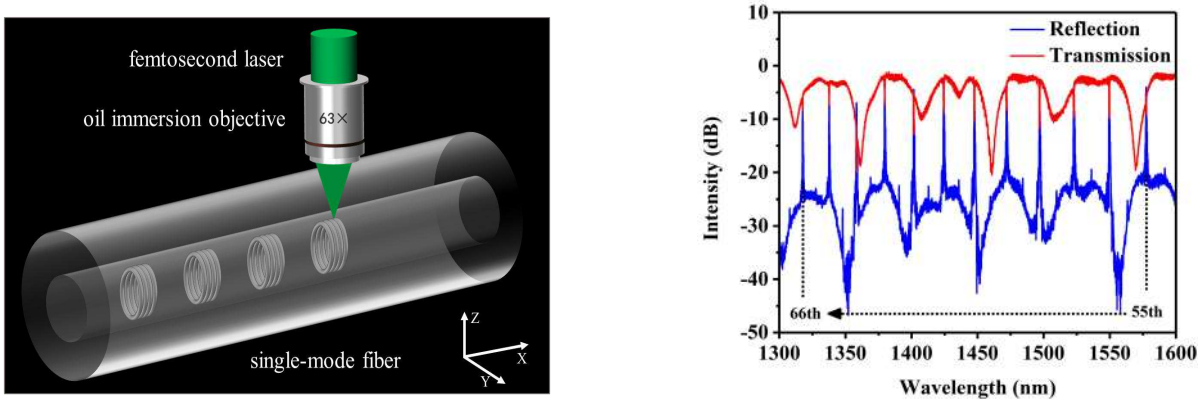

Fig. 1. (a) Schematic diagram of the annular SP-LPFG fabrication, (b) Reflection and transmission spectra of the annular SP-LPFG with annuli radii of 3μm and 4 annuli in each period.

Abstract: Photonic metastructures can be made reconfigurable and switchable via hot carriers photogenerated by fs-laser pulses. Here we show how multi-temperature modeling of hot-carrier dynamics can be exploited to design active metastructures made of plasmonic or dielectric media for a variety of applications, including ultrafast all-optical modulation and pulsed photocatalysis.

Hot carriers represent an unparalleled channel for manipulating photoinduced phenomena on the picosecond timescale [1]. When combined with the flexibility of photonic metastructures in moulding electromagnetic fields [2], the control of light-matter interactions can be achieved in subwavelength regions and at unprecedented speed, offering renewed degrees of freedom for ultrafast nanophotonics. An open challenge remains the active reconfiguration of the optical response of metasurfaces, whose properties are most often irreversibly fixed at the fabrication stage.

Here, we review our recent results in the field of dynamic metaphotonics. In particular, we show how multi-temperature modeling of the hot carrier dynamics combined with a semiclassical description of light-matter interactions at the nanoscale offers a versatile tool for the study and design of reconfigurable and switchable photonic metastructures based on noble metals, degenerate semiconductors and even all-dielectric media. Our modeling, based on a rate-equation approach, is validated by quantitative comparison with transient absorption spectroscopy measurements in a variety of configurations and for different functionalities, including ultrafast giant light amplitude modulation, dichroism and birefringence modulation [3], ultrafast diffraction management, and the tailoring of the modulation dynamics [4].

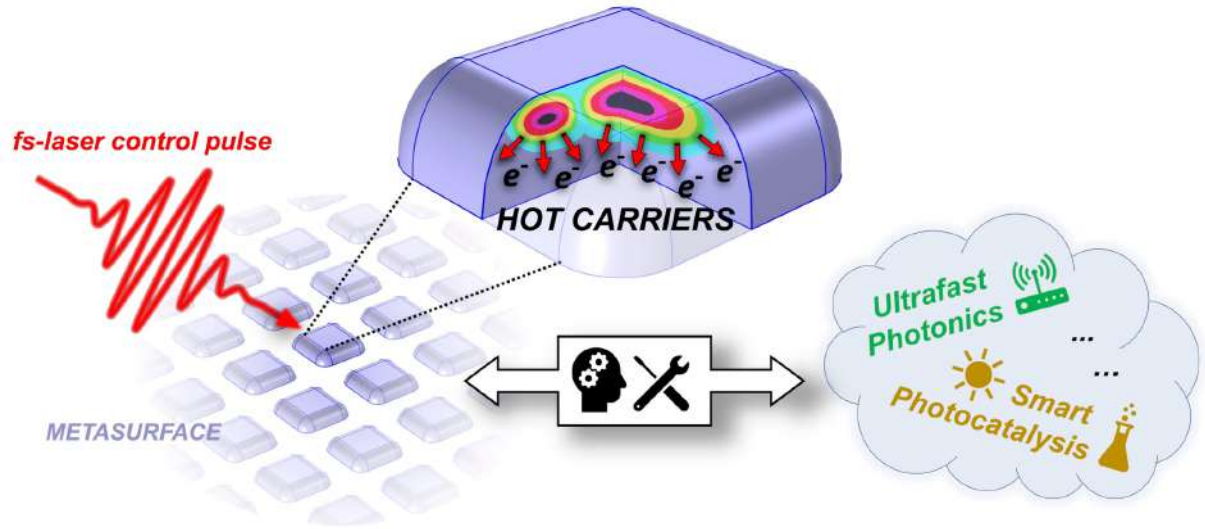

Figure 1: Sketch of the photoinduced hot-carrier spatial inhomogeneities at the metaatom level to be engineered for novel advanced functionalities, with applications ranging from ultrafast photonics to pulsed photocatalysis.

Moreover, shaping at the deep sub-wavelength scale the spatio-temporal evolution of nonequilibrium carriers can be crucial to disclose unprecedented possibilities for ultrafast all-optical modulation of light [5] and even to envisage new advanced functionalities (Fig. 1). For example, when carrier injection takes place besides internal relaxation, metallic metastructures provide the energy needed for photocatalytic conversion, and photoexcited nanoparticles can promote/alter chemical reactions, both through thermal and non-thermal pathways. In this context, we propose an original approach extending the model previously introduced, to investigate numerically with spatial, temporal, and energy resolution the ultrafast dynamics and ensuing effects of hot carriers across plasmonic nanostructures in the presence of adsorbed molecules resonantly accepting energy from photoexcited electrons [6].

Abstract: Complete photonic band gaps are frequency domains where light cannot enter a material from any angle. Here, we generate network-like photonic crystals with varying coordination numbers and correlate their photonic density of states to local and global statistical quantifiers that characterize the structural variantions.

Photonic band gap (PBG) materials have attracted attention for the past decades thanks to their ability to control the scattering and localization of light. A (complete) PBG is a frequency domain where destructive interference prevents propagating light states inside a photonic material [1]. Incident light within the PBG is totally reflected. Inside the material, PBGs can lead to light localization and altered spontaneous emission properties [2], [3]. These stunning phenomena have driven past research to understand and tailor the emergence of PBGs. For periodic photonic materials, so-called photonic crystals, the mechanism giving rise to a PBG can be understood using Bloch theory. In analogy to electronic crystals' valence and conduction bands, the Bloch modes in the *dielectric* bands below a gap concentrate light in the dielectric region, in contrast to the *air* bands above, giving rise to a frequency separation [1]. Several properties facilitate this separation, such as interpenetrating network topologies of high and low index and if the product of the fill fraction and the refractive index is the same in both domains.

While these general rules also apply to disordered materials [4], [5], the emergence of PBGs becomes more challenging to model and interpret. Nevertheless, some general theoretical observations have been made. Large PBGs are favored by a high statistical homogeneity on large length scales, which is maximal for so-called stealthy-hyperuniform systems [6]–[9]. In a hyperuniform medium, density fluctuations are absent in the limit of infinite-length scales, and thus long wavelength scattering is suppressed. Furthermore, tetravalent and trivalent networks of diamond-like and gyroid-like simplices create the most significant known PBGs. This superiority is traced back to the equality of all bond angles and lengths through the concept of local self-uniformity [10].

Here, we investigate the isolated effects of different kinds of disorders on the PBG of 3D photonic networks. We generate a statistical population of disordered networks with a well-established WWW Metropolis Monte Carlo algorithm [11], [12]. We vary the character and strength of the disorder by varying the initial network configuration, the weight of the bending energy β compared to the bond length energy in the associated Keating energy, and the temperature profile governing the network's evolution. We correlate the isolated effects of disorder in bond angles and lengths to the networks' PBG using a principle component analysis. Disorder in the photonic networks can be quantified using a plethora of order metrics that measure primarily short- or long-range order. The bond angle and bond length standard deviations σ_{angle} and σ_{length} of 420 networks generated at seven different values of β are presented in fig. 1. We additionally use the networks' pore size distribution [13], clustering, anisotropy, and local bond order [14]. We study the influence of the different order metrics on the photonic density of states simulated for rod-connected networks.

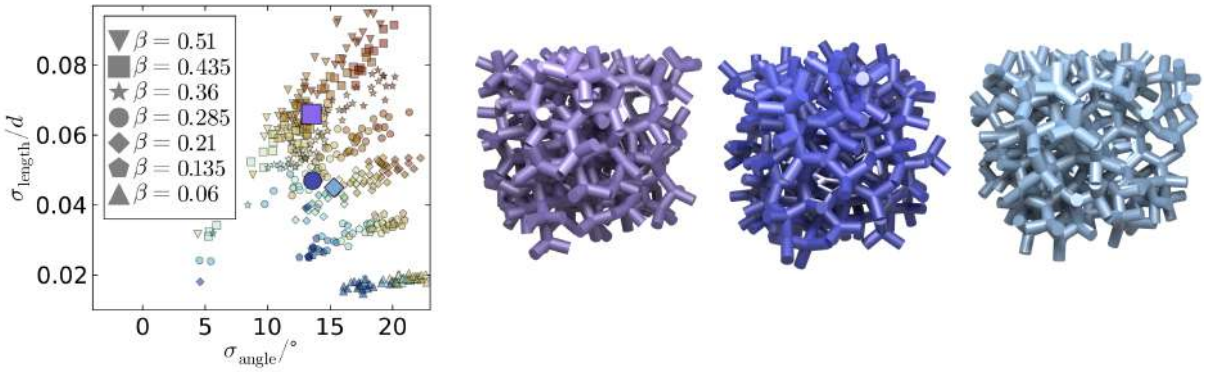

Figure 1: Bond length standard deviation σ_{length} as a function of the bond angle σ_{angle} for disordered networks generated at different values of the β parameter that tunes the bending energy contribution to the Keating energy. The color indicates the maximal temperature of the temperature profile to generate the disordered networks, ranging from $T_{\text{max}} = 0.06$ (dark blue) to $T_{\text{max}} = 0.27$ (dark red). Three exemplary networks are highlighted and depicted on the right.

Abstract: Nano-optomechanical disks are great candidates for sensing applications due to their capacity of simultaneously support very high quality optical and mechanical modes. In the last decade, different applications have been proposed. In this talk, we will review these applications, explain their operating principles, and discuss their future potential.

In the recent years, optomechanical systems stand out among nanomechanical resonators for their high sensitivity to displacement due to the strong interaction between optical and mechanical vibration modes. As a consequence, they provide high sensitivity to adsorbed particles even when operating in air and liquid [1], which is ideal for sensing of biological analytes.

Here we will talk about nano-optomechanical disk resonators (Figure 1(a,b)), a specific optomechanical device that optically supports whispering gallery modes. These optical modes strongly couple with mechanical radial breathing modes. We will review the operating principle of this kind of resonators, focusing on their potential for sensing applications. Particularly, we will talk about environmental monitoring [2], nanoparticle and pathogen detection and characterization [3, 4] (Figure 1c), and finally we will consider the future potential of these devices as biological sensors [5].

Ab initio simulation of nonlinear optical response in periodic semiconducting nanostructures

M. Uemoto[1]

[1]Graduate School of Engineering, Kobe University, JAPAN
*corresponding author: uemoto@eedept.kobe-u.ac.jp

Abstract: First-principles electron dynamics simulation has become a practical approach to describing light-matter interactions, including linear and nonlinear optical phenomena. We use a multiscale method that combines electron dynamics simulation with electromagnetics to predict harmonic generation enhancement in an all-dielectric, periodically structured nanostructure array and analyze the influence on geometric parameters.

In the field of nanophononics, the artificial nanoscale structures, particularly semiconductor-based all-dielectric nanoparticles and metasurfaces, have been intensively studied as a new platform for nonlinear optics, such as optical wavelength conversion, waveform shaping, second harmonic generations (SHGs) and high harmonic generations (HHGs). For the design of such nanophotonic devices above, the computational electromagnetics simulations based on Maxwell's equations, such as the time-domain finite difference (FDTD) method, have been utilized as an powerful tool. However, the conventional method requires empirical optical constants of media and is limited to light intensity with linear and low-order perturbative nonlinear optical responses. To overcome the limitations, we investigate a theoretical and computational method of electron dynamics based on time-dependent density functional theory (TDDFT) [1] and apply it to various material systems [2-3], such as atoms, molecules, and bulk solids. The TDDFT can successfully predict linear dielectric function [3], low-order nonlinear susceptibilities [4], and non-perturbative nonlinear phenomena such as tunnel ionization, saturable absorption, and HHGs. In addition, we also developed the coupled method, the first-principles TDDFT, and the electromagnetic simulation, the so-called "Maxwell+TDDFT multiscale method," which enables us to simulate light–matter interaction in nanoscale materials self-consistently [5]. We couple Maxwell's wave equation involving the current density J in this electron system and calculate the time evolution.

$$\nabla \times \nabla \times \mathbf{A}(\mathbf{r},t) + \frac{1}{c^2}\frac{\partial^2}{\partial t^2}\mathbf{A}(\mathbf{r},t) = \frac{4\pi}{c}\mathbf{J}(\mathbf{r},t)$$

where the current J is given by the microscopic electron dynamics. At each grid point R, the individual electron dynamics governed by time-dependent Kohn-Sham (TDKS) equation:

$$i\frac{\partial}{\partial t}u_{b\mathbf{kR}}(\mathbf{r},t) = \left\{\frac{1}{2}\left[-i\nabla_{\mathbf{r}} + \mathbf{k} + \frac{1}{c}\mathbf{A}_{\mathbf{R}}(t)\right]^2 + V_{\mathbf{R}}(\mathbf{r},t)\right\}u_{b\mathbf{kR}}(\mathbf{r},t)$$

where u_{bkR} are the Bloch orbitals of electrons and V_R is the effective potentials including the ionic, Hartree and exchange-correlation terms. Figure 1 illustrates the conceptual framework of the Maxwell+TDDFT multiscale coupling method.

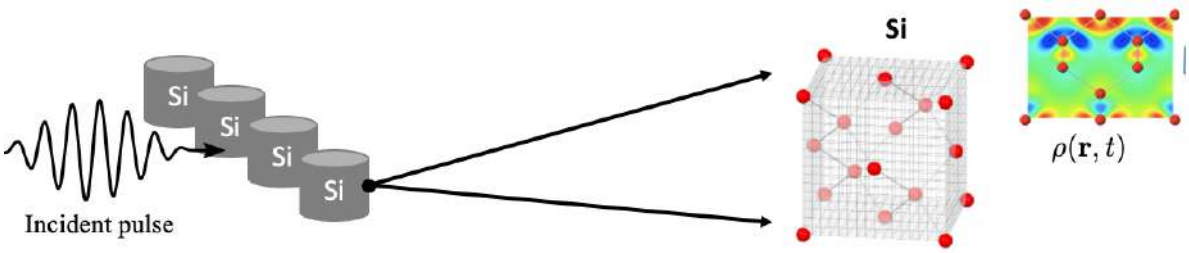

Figure 1: illustration of multiscale coupling between macroscopic nanostructure and microscopic electronic system

Besides, it is possible to improve the electrodynamics calculation to semiconducting Bloch equation:

$$\mathrm{i}\frac{\partial}{\partial t}\rho_{ij}^{(\mathbf{k})}(t) = \frac{1}{c}\mathbf{A}(t)\cdot\left[\sum_l \mathbf{p}_{il}^{(\mathbf{k})}(t)\,\rho_{lj}^{(\mathbf{k})}(t) - \sum_l \rho_{il}^{(\mathbf{k})}(t)\,\mathbf{p}_{lj}^{(\mathbf{k})}(t)\right]$$

,

where ρ is the density matrix, p is the transition dipole moment, and A is the vector potential. The calculation result by Maxwell+SBE agrees well with that by Maxwell+TDDFT because ρ and p are given by first-principles calculations using DFT in both methods. Owing to SBE's less computational cost than TDDFT, the Maxwell+SBE is capable of large-scale device models.

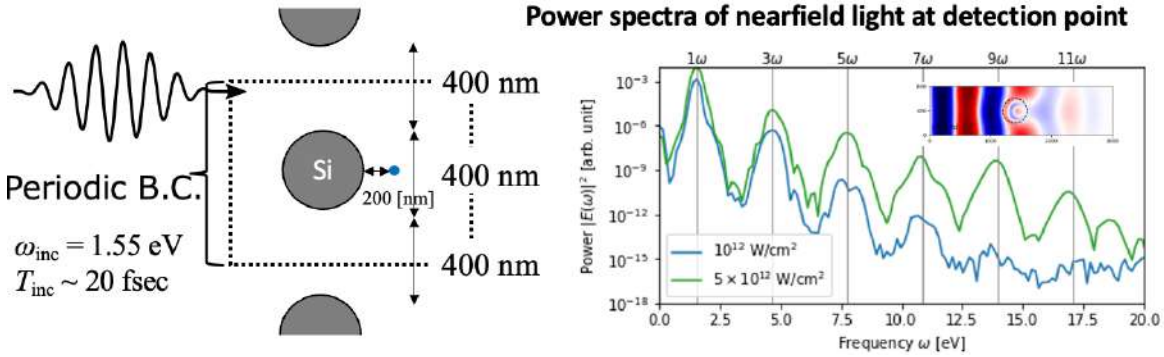

Figure 2: Result of harmonic generation spectra from semiconductor nanocylinder array.

Figure 2 shows the power spectrum of the near-field light in a silicon nanocylinder array under high-intensity laser excitation pulse. We observe higher-order harmonic components enhanced by light confinement and Mie resonances. The simulation also shows that cylinder geometry significantly affects the field intensity and harmonic generation efficiency. Besides, we also analyzed the influence on field amplitude which represents the drastic change of scattering filed distribution by nonlinear change of dielectric properties. These results pave the way for designing advanced nanophotonic devices that exploit nonlinear optical effects at the nanoscale.

Abstract: We demonstrated lasing action in quasi-BIC all-dielectric metasurfaces integrated with a slab waveguide containing laser dyes. Our system offers both single and multimode lasing emission directed toward true zeroth-order and oblique angles with the ability for passive tunability of the emission wavelength within the spectral range of the gain medium.

The precise control over the laser emission properties, such as wavelength and directionality, is crucial for numerous applications, including quantum sensing, biomedicine, and optical communication. Achieving efficient coherent light emission necessitates strong light-matter interaction, which can be realized through high-quality-factor (Q-factor) optical cavities that enhance localized electromagnetic fields within the gain medium.

One promising approach to achieve high-Q resonances involves the integration of symmetry-broken all-dielectric metasurfaces with slab waveguides [1]. This configuration supports quasi-bound states in the continuum (quasi-BIC) and guided mode resonances, enabling the engineering of lasing modes within the spectral range of the gain material. In addition, all-dielectric metasurfaces provide an excellent platform for nanoscale lasing due to their low absorption losses and compatibility with a variety of gain media [2]. By carefully designing the geometrical parameters of these metasurfaces, specific resonant modes can be tailored, allowing for precise spectral and directional control of lasing emission.

Recent studies [3] have demonstrated multimode lasing emission in dielectric nanocylinder arrays, predominantly propagating in the near-normal direction. Here, we present both single and multimode lasing emission directed toward true zeroth-order and oblique angles, with the additional capability of passive wavelength tunability within the spectral range of the gain medium. This is achieved through the integration of symmetry-broken all-dielectric metasurfaces with slab waveguides, which exhibit high-Q resonances essential for generating coherent light emission.

To this end, we designed and fabricated broken symmetry titanium dioxide (TiO_2) metasurfaces supporting high Q-factor resonances in the visible range and covered the metasurfaces with a Rh6G doped SU8 film using spin-coating. Figure 1A shows the focused-ion beam (FIB) cross-section of one of the fabricated metasurfaces after spin coating. Next, we characterized the power-dependent behavior of the fluorescent emission as well as its directionality using momentum-resolved fluorescence spectroscopy. Varying the metasurface geometry parameters and leveraging both quasi-BIC and guided mode resonances within this configuration, we achieved lasing emission over the broad spectral range of the gain medium from 550 nm to 600 nm, emitting into both normal direction and oblique angles.

Figure 1B and 1C represent the momentum-resolved spectra of a metasurface with a lattice constant of 380

nm below and above the lasing threshold, respectively, featuring a triple-mode lasing emitted normally out of the plane of the metasurface. The spectral positions of the three lasing peaks are marked with green arrows and numbers.

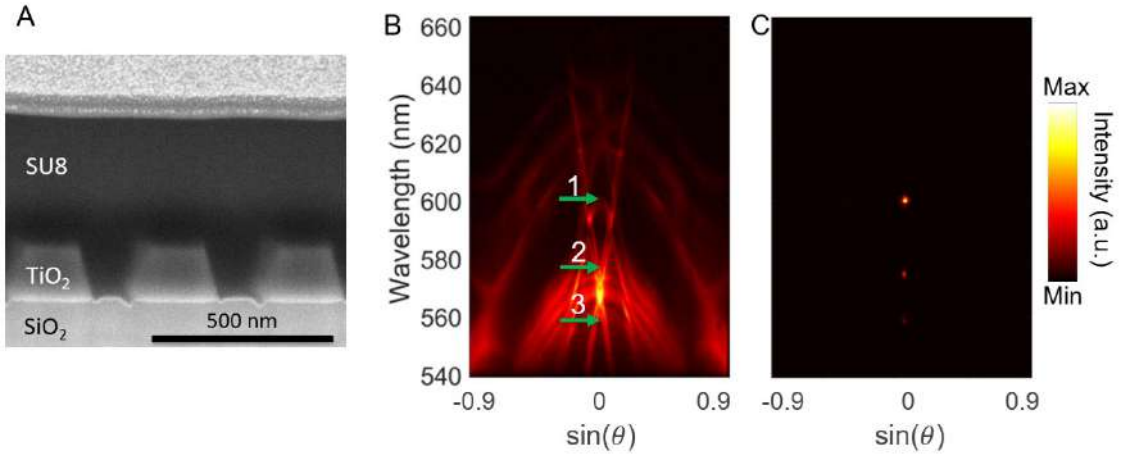

Figure 1: (A) The FIB cross-section of the fabricated metasurface coated with dye-doped SU8 film. (B) The measured momentum-resolved spectra of the metasurface below lasing threshold. The spectral positions of the three lasing modes are marked with green arrows and numbers. (C) The measured momentum-resolved spectra of the metasurface above lasing threshold, showing a triple-mode lasing emitted normally out of the plane of the metasurface, at: 1. 600 nm, 2. 580 nm, and 3. 560 nm.

Our experimental results demonstrate passively tunable single and multimode lasing across a broad spectral range, with emission directed both normally and at oblique angles, highlighting the potential of this approach for advanced on-chip laser applications.

Real-space Renormalization Group on Topological Scattering under Strong Disorder

Z. Zhang[1] and R. Fleury[1]

1 École Polytechnique Fédérale de Lausanne (EPFL), LWE, CH-1015, Lausanne, Switzerland

Abstract: Strong disorder typically induces trivial Anderson insulating phases. We introduce a real-space renormalization group approach for unitary scattering networks, uncovering robust scattering attractors that distinguish trivial from anomalous Floquet Anderson insulators hosting chiral edge states. Numerical and microwave experiments confirm our method, enabling prediction and design of topologically resilient photonics.

Anomalous Floquet topological phases uniquely host chiral edge states spanning all quasienergy gaps, exhibiting remarkable resilience against strong disorder[1-5]. While disorder typically induces trivial Anderson insulating states by localizing all modes, certain unitary scattering networks sustain robust, delocalized edge states, which are of anomalous Floquet Anderson insulating (AFAI) phase. Traditional band and scattering invariants fail to characterize these strongly disordered topological regimes. To overcome this, we introduce a real-space renormalization group (RG) scheme utilizing iterative block-scattering transformations. Our RG framework identifies stable scattering attractors distinguishing trivial and AFAI phases, significantly advancing theoretical understanding and enabling efficient prediction and engineering of disorder-resilient Floquet topological states.

Our real-space RG procedure systematically analyzes topological scattering networks under strong disorder via iterative block-scattering transformations. Unlike traditional momentum-space or Hamiltonian-based approaches, our method directly manipulates real-space scattering matrices, naturally accommodating strong disorder and real-space topological physics. The RG approach contains three key steps (Fig. 1a). First, for an arbitrary scattering network composed of unitary scatterers $S_0(\xi,\eta)$ interconnected by reciprocal phase-delay links, we partition it into triangular subnetworks (left panel). Second, we perform block-scattering transformation: Each triangular block is replaced by an effective three-port scatterer described by a smaller, 3×3 unitary matrix S'. Crucially, this transformation preserves three essential physical features: flux conservation, reflection, and chirality, ensuring macroscopic scattering characteristics are accurately captured. Newly simplified scatterers are reconnected, producing a progressively coarse-grained network (middle panel). Finally, by iterating this RG procedure, the network's size shrinks systematically, ultimately converging to a single three-port unitary scattering matrix called the scattering attractor S_F (right panel). Upon successful convergence, S_F encodes the macroscopic topological nature of the original network[5]. Specifically, two distinct attractors emerge: (i) **Trivial Anderson insulating attractor** S_F, which is a fully reflective unitary scattering matrix, signifying complete localization with no edge transport; and (ii), **Anomalous Floquet Anderson insulating attractors** S_{CW} or S_{CCW} which are perfectly chiral circulator matrices, revealing robust unidirectional edge transport immune to disorder-induced localization.

Applying our RG scheme extensively over the parameter space defined by the microscopic scatterers $S_0(\xi,\eta)$, we systematically derive the RG topological phase diagram (Fig. 1b). This diagram categorizes disordered scattering networks with strong, distributed phase-delay disorder into distinct topological regimes according to the corresponding attractor they approach[5]. The resulting phase diagram clarifies the critical boundaries between trivial

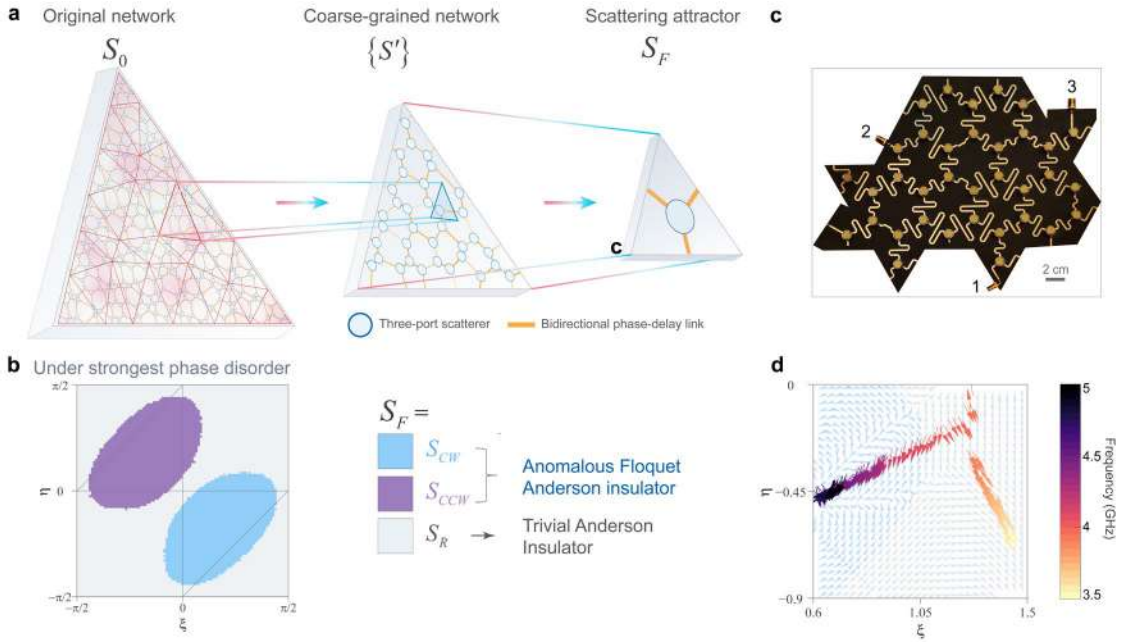

Fig. 1. Real-space renormalization group (RG) of a unitary scattering network with phase-link disorder[5]. a, RG scheme. Starting from a scattering network composed of three-port unitary scatterers (S_0, left), iterative block-scattering transformations simplify triangular subnetworks into three-port scatterers S′ (center), eventually yielding a single scattering attractor S_F (right). The attractor classifies the network as either trivial (trivial Anderson insulator) or topological (anomalous Floquet Anderson). **b,** RG topological phase diagram by summarizing scattering attractors for networks built from $S_0(\xi,\eta)$ with fully random phase-delay links. Attractors S_{CW} or S_{CCW} indicate anomalous Floquet Anderson insulating phases, while attractor S_R indicates trivial Anderson insulators. **c, d,** Experimental validation of RG flow.

Anderson phase and AFAI. These results underscore the remarkable ability of certain strongly disordered systems to preserve topological robustness despite the complete destruction of crystalline order. Independent validations through localization-length scaling analysis confirmed the accuracy of our RG predictions[5]. Additionally, experimental validations using microwave scattering networks closely matched theoretical results, further validating the RG scheme as shown in Figs. 1c and d.

We introduce a real-space renormalization group for strongly disordered topological scattering networks using iterative block-scattering transformations, independent of Hamiltonian methods. Our numerical analyses yield a clear RG phase diagram differentiating trivial Anderson insulators from anomalous Floquet Anderson insulating phases, offering a powerful tool for predicting and engineering disorder-resilient topological waves.

Photodegradation of dyes using Fe_3O_4-Au-Pd hybrid nanoparticles synthesized liquid-phase

Y. Yokota[1*], T. Uehara[1] and Mao. Takeda[1]

[1] Department of Materials and Life Sciences, Faculty of Science and Technology, Sophia University, 7-1Kioicho, Chioyoda, Tokyo 102-8554, Japan
[*]corresponding author: y_yokota@sophia.ac.jp

Abstract: We focused on iron oxide nanoparticles that can be recovered using magnets. and synthesized Iron oxide-gold-palladium nanoparticles (Fe_3O_4-Au-Pd hybrid nanoparticles) were prepared in the liquid phase under different synthesis conditions. The catalytic activity of these hybrid nanoparticles was investigated in dye degradation reactions.

The fabrication of metasurfaces and metamaterials using visible and near-infrared light requires precise control of the 2D or 3D alignment of noble metal nanoparticles. We focused on magnetic iron oxide with magnetic properties to enable controllable aggregation and arrangement. We are also pursuing chemical applications and expect that iron oxide can be used as a plasmonic catalyst for simple collection with magnets and reuse. Composite nanoparticles combining gold nanoparticle surfaces, which induce localized surface plasmon resonance, with palladium nanoparticles as an auxiliary catalyst are expected to be used as visible and near-infrared photocatalysts to promote organic chemical reactions and other applications. We have already synthesized Fe_3O_4-Au-Pd hybrid nanoparticles (hybrid nanoparticles), which can be recovered by a magnet. [1] In this study, the synthesized hybrid nanoparticles were used as catalysts for photochemical decolorization reactions.

Based on a previous study [1], iron oxide nanoparticles were synthesized by liquid phase co-precipitation. Then, iron oxide-gold core-shell nanoparticles were synthesized by adding sodium gold chloride. The core-shell nanoparticles were then covered with palladium by adding palladium chloride solution, and hybrid nanoparticles were synthesized and collected with a magnet. The synthesized nanoparticles were collected with a magnet, measured for absorbance, and observed for shape by scanning electron microscopy (SEM) and transmission electron microscopy (TEM). For the degradation reaction, the synthesized hybrid nanoparticles were added to an aqueous solution of methyl violet (MV) as a dye, and the mixture was stirred in the dark, under 300 W Xe lamp (wavelength 440 nm-740 nm) and under table-top white LED irradiation, respectively, and the absorbance was measured at regular intervals.

The synthesized hybrid nanoparticles had an average particle size of 220 nm. The shape was a sphere with an uneven surface. When the synthesized hybrid nanoparticles were added to the aqueous MV solution and reacted in the dark, the peak intensity at an absorption wavelength of 580 nm derived from MV remained unchanged after 72 hours, and the solution also remained purple and did not decolorize. Under Xe lamp irradiation, decolorization progressed with a decrease in the value of the absorbance peak at 580 nm wavelength. The color of the solution became clear after 6 hours. Under LED irradiation, a slight decrease in the peak was observed with time. From these results, the synthesized hybrid nanoparticles acted as a photocatalyst under visible light irradiation. Since the photodegradation was promoted even under weak light sources such as household tabletop white LEDs, the hybrid nanoparticles are expected to be applied as visible light

photocatalysts.

Photonic Antiferromagnetic Topological Insulator with a Single Surface Dirac Cone

Yihao Yang[1]

[1]Zhejiang University, Hangzhou 310027, China.

*corresponding author: yangyihao@zju.edu.cn

Abstract: We report on the realization of a three-dimensional (3D) photonic antiferromagnetic topological insulator (AF TI) configured as a *z*-directional stack of two-dimensional (2D) Chern insulators. This photonic AF TI features symmetry-protected single-Dirac-cone surface states, which have been demonstrated to be resilient against random disorder of any type on the surface.

Topological metamaterials/photonic crystals have provided a revolutionary platform for manipulating the flow of light. Among them, Chern photonic crystal with time-reversal symmetry broken have been extensively studied due to their chiral edge states (CESs) located at the boundary of structure which are completely immune to the disorders or defects existing in the propagation channel thus considered as an ideal candidate for realizing broadband slow light. On the other hand, stacking two-dimensional (2D) Chern photonic crystals along the third direction to construct three-dimensional (3D) structure has also been demonstrated exhibiting fantastic phenomena such as torus knots or links of topological surface states. Here, in this report, I will introduce some achievement with Chern photonic crystal.

Specifically, in 2D Chern photonic crystal, we have experimentally demonstrated the multiple Brillouin zone winding of topological CESs to slow down light over a relatively wide range of frequencies [1]. We experimentally show that by coupling to the resonance-induced nearly-flat bands, the CESs can wrap many times around the BZ. Thus, their group velocity can be significantly slowed down, and the fractional bandwidth with a reduction of the group velocity of more than 50% relative to the original CESs is 5.7%. Impressively, the winding number can be up to five in experiments and has no strict limit in theory. Finally, we demonstrate the robustness of such broadband topological slow light against obstacles and defects, as well as the smooth transport through slow-light regions with different group velocities.

Further, we stack the 2D Chern photonic crystals with opposite Chern number alternatively along z direction to construct a 3D photonic antiferromagnetic topological insulator (AF TI) featuring a single gapless *S*-protected Dirac surface state [2]. The nontrivial $\mathbb{Z}_2$ bulk topological invariant is numerically confirmed by tracking the evolution of Wannier centres in first-principles simulations. By directly mapping out both bulk and surface band structures, we have unambiguously verified the existence of a single symmetry-protected surface Dirac cone at the $k_z = \pi/a_z$ plane, the defining characteristic of bosonic AF TIs. Our photonic AF TI can also be regarded as the first realization of a 3D strong photonic TI in terms of the odd number of surface Dirac cones. Additionally, our experiments have demonstrated the remarkable resilience of the single-Dirac-cone surface state against random magnetic disorders that, on

average, respect the *S* symmetry. Our findings pave the way for further realizing and engineering novel magnetic topological phenomena in photonic systems, which are inaccessible in electronic systems.

Abstract: We created a tunable one-dimensional photonic crystal with strong polarization dependence by embedding a uniform lying helix (ULH) structure in a planar optical microcavity. The voltage-controlled orientation of liquid crystal molecules modifies the photonic band gaps and induces spin-orbit coupling, which can be interpreted as a synthetic non-Abelian gauge potential. Additionally, doping with dyes enables tunable polarized lasing.

Unlike spin-orbit coupling (SOC) in solid-state materials, which is inherently difficult to manipulate, liquid-crystal (LC) optical cavities offer significant tunability of photonic modes. The behavior of polarized electromagnetic waves propagating through one- or two-dimensional structures can be effectively described using a two-mode Hamiltonian, representing a massive spin-½ particle via Pauli matrices. By employing Green's function techniques and k·p perturbation theory from semiconductor physics, we obtained results interpretable as effective cavity-mode spin-orbit coupling and non-Hermitian Hamiltonians [1].

To further develop this analogy, we engineered a one-dimensional photonic crystal with strong polarization dependence, tunable via an applied electric field. This was realized by embedding a cholesteric liquid crystal into a planar optical microcavity, which spontaneously formed a uniform lying helix (ULH) structure (Figure). The orientation of LC molecules was controlled electrically, allowing us to tune the strength of a polarization-dependent periodic potential. This voltage-induced control resulted in the opening and closing of photonic bandgaps in the dispersion of massive photons within the microcavity.

Furthermore, when the ULH structure possessed a molecular tilt, it induced interband spin-orbit coupling (ISOC) between lattice bands of different parity. This ISOC is analogous to optical activity and can be interpreted as a synthetic non-Abelian gauge potential. Finally, we demonstrated that doping the LC with dyes enabled lasing, which inherited all the tunable features of the LC microcavity – including dual and circularly polarized emission [2].

Beyond traditional lithographic methods, our approach enables the self-organization of macromolecular photonic structures, with geometry controlled by temperature or applied electric fields. These periodic architectures allow for precise manipulation of optical modes, offering new possibilities for photonic device engineering.

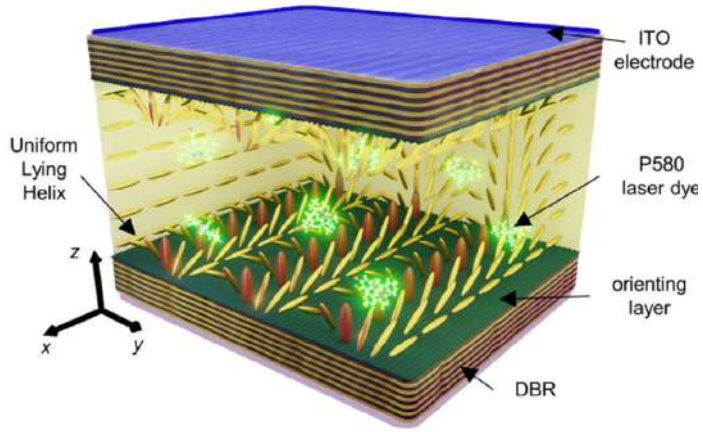

Figure. ULH texture inside optical microcavity. Schematic of the dye-doped optical microcavity with an embedded, stabilized ULH structure. Rows of molecules whose directors are oriented vertically are colored red to indicate the periodicity of the lattice.

Room-temperature Exciton-polariton Condensation in Prism-shaped GaN Microcavity Structures

Yong-Hoon Cho

Department of Physics and KI for the NanoCentury,
Korea Advanced Institute of Science and Technology (KAIST), Daejeon, Republic of Korea
*corresponding author: yhc@kaist.ac.kr

Abstract: We fabricated GaN-based hexagonal and triangular microcavity structures by using selective area growth. We formed room-temperature exciton-polariton condensation with whispering gallery mode and superscar mode in the hexagonal and triangular microcavities, respectively. Angle-resolved micro-photoluminescence experiments with varying excitation power were conducted to investigate the processes of polariton formation and condensation.

Group III-nitride semiconductors are promising materials for studying exciton-polaritons at room temperature due to their large exciton binding energy and high oscillator strength. It has been reported that exciton-polaritons can be observed in hexagonal-shaped GaN microrod structures at room temperature using whispering gallery mode cavities [1, 2]. However, the whispering gallery mode shows a relatively lower quality factor, which is a major obstacle for the room-temperature polariton devices. The superscar mode is an optical cavity mode found in polygonal structures, which has higher quality factors and a longer optical path compared to the whispering gallery mode. Here, we successfully fabricated prism-shaped GaN structures by selective area growth method and metal-organic chemical vapor deposition [3]. From the prims-shaped cavity structures, the superscar mode polaritons are observed at room temperature. Spatially-resolved and angle-resolved micro-photoluminescence experiments are performed with varying excitation beam spot sizes and excitation power densities. The detailed emission characteristics are analyzed and compared in real and momentum spaces. We could adjust the dominant mode between whispering gallery mode and superscar mode for the condensation by changing the opening shape on the GaN template for the selective area growth.

High-Temperature Superfluorescence in Perovskites

K. Gundogdu

[1]Physics Department, NC State University, USA
*corresponding author: kgundog@ncsu.edu

Abstract: In this presentation, I will introduce the superradiance mechanism that leads quantum coherence in lead-halide perovskites and its implications for designing new materials that exhibit macroscopic quantum coherence at high temperatures.

The formation of coherent macroscopic states and the manipulation of their entanglement using external stimuli are essential for emerging quantum applications. However, the observation of collective quantum phenomena such as Bose–Einstein condensation, superconductivity, superfluidity and superradiance has been limited to extremely low temperatures to suppress dephasing due to random thermal agitations. In this presentation I will talk about room-temperature superfluorescence (SF) in hybrid perovskite thin films [1,2]. In SF an optically excited population of incoherent dipoles develops collective coherence spontaneously. This emergent collective state forms a giant dipole and radiates a burst of photons. Because electronic transitions dephase extremely fast, observation of SF in semiconductors is extremely rare and under high magnetic fields and at very low temperatures. Therefore, the discovery of room temperature SF in perovskites is very surprising and shows that in this material platform, there exists an extremely strong immunity to electronic dephasing due to thermal processes. To explain this observation, we propose that the formation of large polarons in hybrid perovskites provides a quantum analogue of vibration isolation to electronic excitation and protects it against dephasing even at room temperature. Understanding the origins of sustained quantum coherence and the superfluorescence phase transition at high temperatures can provide guidance to design systems for emerging quantum information technologies and to realize similar high-temperature macroscopic quantum phenomena in tailored materials.

Abstract: We fabricated hybrid nanobeam cavities with high Q-factor and integrate the pristine hBN-encapsulated 2D materials with controllable cavity-material overlap. This allows the observation of novel light-matter interactions for the unique quantum emitters in 2D materials

2D materials such as monolayer transition metal dichalcogenides host a variety of excitonic transitions with rich exciton-photophysics, and thereby, are ideally suited as the active emitters for nanophotonic cavities. Moreover, 2D materials can be assembled into heterostructures via van der Waals bonding, and the atomical thickness of material results in the sensitivity and strong coupling to the multi-physics local environment. Therefore, 2D-material nanophotonic cavity paves the way to the coupling between different physical degrees of freedom. However, the common pick-and-place method introduces disorders that perturb the excitonic quality in 2D materials. Meanwhile, perforating nanophotonic structures in 2D flakes results in complex effects and limits the cavity Q-factor ~10^3. We fabricated hybrid nanobeam cavities with high Q-factor (>10^4) and integrate the pristine hBN-encapsulated 2D materials with controllable cavity-material overlap [1]. Based on this platform, we observed novel light-matter interactions for the unique quantum emitters in 2D materials [2]. Moreover, the photonic crystal is also phononic crystal, and thereby, the nanophotonic cavity also hosts the nanomechanical modes with phonon vibrations. We observe the phononic hybridization between the atomic lattice phonons and cavity nanomechanical phonons in the light-matter interaction [3]. Such multi-modal couplings provide novel methods to interface emitters, photons, and phonons as a hybrid solid-state quantum system [4].

Abstract: The objective is to provide guidelines for the engineering of Fano resonances and metasurfaces composed of coupled antenna-like resonators, possibly integrating gain and loss. The large number of degrees of freedom of these systems allows for great design versatility, allowing to tailor on demand spectral properties.

The objective of this work is to address the spectral response engineering of Fano resonances and metasurfaces, placing it in the general context of non-Hermitian open systems composed of the coupled antenna-like resonators possibly incorporating gain and loss. Following this approach, we have shown in our recent study that the natural frequency solutions obtained for a particular case of scattering matrix are rather general and valid for arbitrary values of the antenna radiative rates, thanks to an appropriate transformation of the coupling-detuning parametric space by simple linear expansion and rotation [1]. The universality of the obtained solutions thus provides a general recipe for an infinite diversity of optimal metasurface designs, meeting the requirements of tailor-made sensors with target spectral responses.

Specifically, the control of the asymmetry and sharpness of the Fano resonance achieved by navigating between the Parity-Time symmetry phase transition path and the Bound State in Continuum (BIC) path representing the natural hidden axis of universal scattering matrix solutions in the parametric coupling-detuning plane has been demonstrated. The validity of the analytical model has been confirmed by comparison with experimental and full 3D numerical simulation results reported in the literature for a metasurface with a unit cell composed of two asymmetrically split ring resonators operating in the THz domain [2].

Furthermore, the conditions required to achieve the superscattering regime corresponding to a passive metasurface, such as the one shown in Figure 1a, have also been established. The obtained solutions are then extended to the case where one resonator experiences a gain and another a loss. The superscattering regime in this case corresponds to the onset of laser emission. It is shown that modulation of the medium gain and loss level within realistic parameters is an efficient approach for implementation of tunability. This two-antenna configuration can serve as inspiration for the implementation of high-contrast resonance tunable metasurfaces.

The large amount of degrees of freedom offered by a coupled resonator system: near field coupling strength - κ, detuning of the resonance frequency - δ, the resonators' radiative decay rates- γ_i, the resonators gain and/or absorption losses - χ_i, opens the way to a great versatility of designs with the possibility of adjusting the spectral properties of this type of metasurface on demand.

Additional features can be obtained by introducing the third dimension into the system by considering a Fabry-Perot cavity formed by metasurfaces A and B with detuned resonance frequencies that exhibit absorption losses. Generally, their presence results in a decrease in the Fano resonance contrast and is considered detrimental. Figure 1b shows an example where the intentional introduction of absorption losses can result in a

high-contrast narrowband $S_{11\,A}$ reflection dip associated with a narrowband X_A absorption peak close to 100% for an electromagnetic wave incident on this Fabry-Perot cavity from the side of metasurface A. This coherent perfect absorption (CPA) results from a combination of interference and dissipation. The portion of the incident beam reflected by metasurface B destructively interferes with that transmitted through metasurface A, and vice versa, so that the radiation is trapped in an interference pattern in the cavity and entirely suppressed by dissipation. This CPA mechanism is reciprocal but substantially asymmetric. As shown in Figure 1b, the $S_{11\,B}$ reflection and X_B absorption spectral responses are completely different for a beam incident on the metasurface B side. It is worth noting that, as expected, the $S_{12\,A}$ and $S_{12\,B}$ transmissions on both sides are perfectly identical. This type of structures, exhibiting narrowband spectral characteristics despite absorption losses, is also of great interest for sensing applications. In turn, narrowband CPA can be used to suppress the transmission of a given wavelength in diverse applications.

The power of the developed analytical approach lies in its ability to provide, on the basis of a mathematical formalism, the prediction of the spectral behavior of the system without going through more complex and time-consuming full-wave 3D numerical simulations which are still necessary, but rather at next stages, when translating the mathematical model into a practical design.

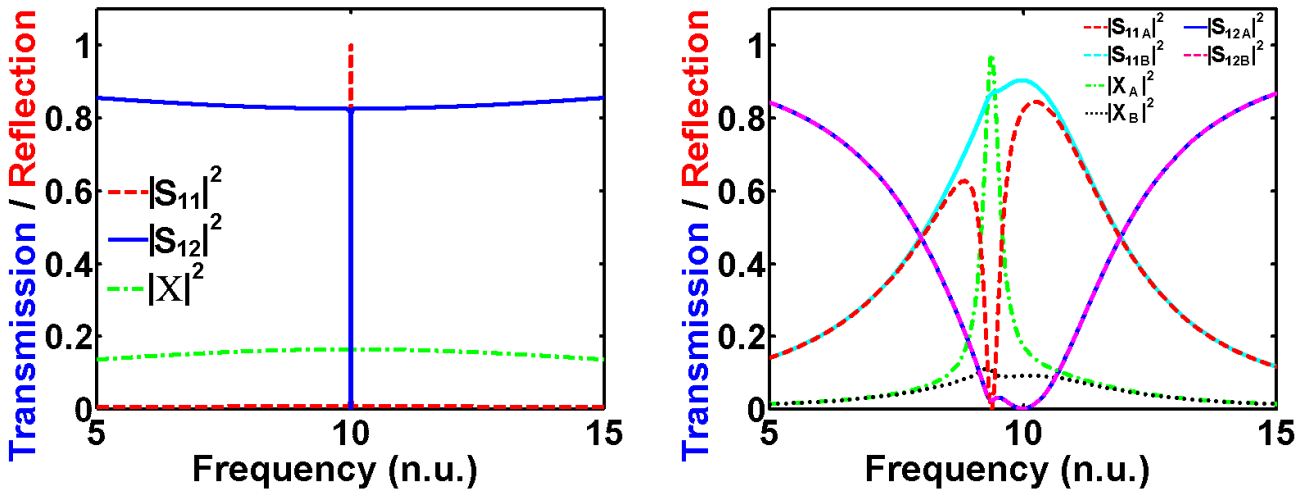

Figure 1: a) Spectral response of a single-layer metasurface composed of unit cells comprising two resonators with different absorption and radiative losses. b) Spectral response of a bilayer metasurface with the same radiative losses but different resonance frequencies and in the presence of absorption losses.

Chirality Transfer in Silicon Nanoparticles with Chiral Molecules

H. Sugimoto[1*], H. Kasai, K. Shintani, S. Ghamari, F. Vollmer, M. Fujii[1]

[1]Department of Electrical and Electronic Engineering, Graduate School of Engineering at Kobe University, Japan

Abstract: Chiral molecular sensing plays a crucial role in biomedical and pharmacological applications. However, the sensitivity of existing methods for chiral discrimination is limited by the weak interaction between light and molecules. In this study, we introduce a novel platform that enhances chiral light-matter interactions using Mie-resonant silicon nanospheres, ranging in size from 100 to 200 nm, which can be dispersed in solution.

The bioactivity of chiral molecules varies significantly between enantiomers, making highly sensitive detection techniques essential. Although circular dichroism (CD) spectroscopy can distinguish between enantiomers, detecting small amounts of chiral molecules (<μM) remains challenging due to the extremely weak interaction between chiral molecules and circularly polarized light. Recently, approaches to enhance CD signals through optical chirality amplification or chirality transfer via optical nanoantennas have been proposed.[1] Among the nanoantennas, high index dielectric nanoparticles exhibit electric and magnetic Mie resonances and provide opportunities for manipulating and enhancing the light-matter interactions. In addition, several theoretical studies have predicted significant CD enhancement using resonant nanostructures. Dielectric nanoantennas are typically fabricated using electron beam lithography on solid substrates, which limits the applicability of solution-based assembly techniques compared to their plasmonic counterparts, as commercially available gold and silver colloids are widely used.

In this work, we experimentally investigate chirality transfer in silicon nanoparticle antennas with chiral molecule-doped polymer shells, utilizing colloidal silicon nanospheres developed in our group.[2-4] We also discuss the mechanism behind the enhanced signals and the contributions of optical chirality and chirality transfer.

Colloidal suspension of perfectly spherical silicon nanoparticles dispersible in alcohol by thermal disproportionation of silicon monoxide at very high temperature (>1450°C) followed by chemical etching. We also developed monodisperse silicon nanoparticles by applying density gradient centrifugation process for the size separation.[2-4] Figure 1a shows the solution in which different sized silicon nanoparticles are dispersed. The solutions exhibit bright scattering colors depending on

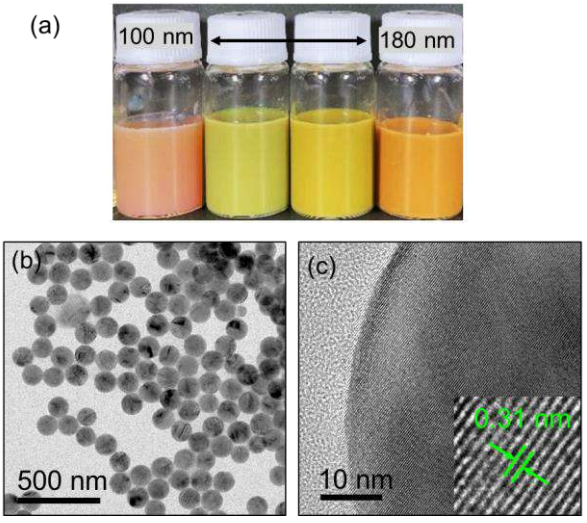

Figure 1. (a) Photo of colloidal suspension of Si nanoparticles with different average diameters. (b, c) TEM and HRTEM images of Si nanoparticles, respectively.

nanoparticles sizes. TEM image in Fig. 1b shows the monodisperse silicon nanoparticles with highly spherical shapes. In addition, HRTEM image in Figure 1c demonstrates high crystallinity of the particle.

We calculate the differential extinction spectra[5] under right- and left-handed circularly polarized light assuming a chiral medium shell with a refractive index n = 1.33 and Pasteur parameter κ = -10^{-5}–$10^{-7}i$. The upper panel compares the extinction spectra of a 150 nm silicon nanosphere with (red) and without (black) a 10 nm chiral medium shell. A slight shift in the spectrum can be observed due to the shell coating. The lower panel shows the differential extinction (ΔC_{ext}) spectra of a silicon nanosphere with a 10 nm chiral shell under right- and left-handed circularly polarized light. ΔC_{ext} shows peaks at the wavelengths of ED and MD resonances for a silicon nanosphere. It should be noted here that these signals are absent in a bare silicon nanosphere, as it is an achiral structure. These results suggest that chirality transfer occurs from the chiral shell to the Mie-resonant silicon nanosphere. In the presentation, we will also show the experimental results on silicon nanospheres with chiral molecule-doped polymer shells.

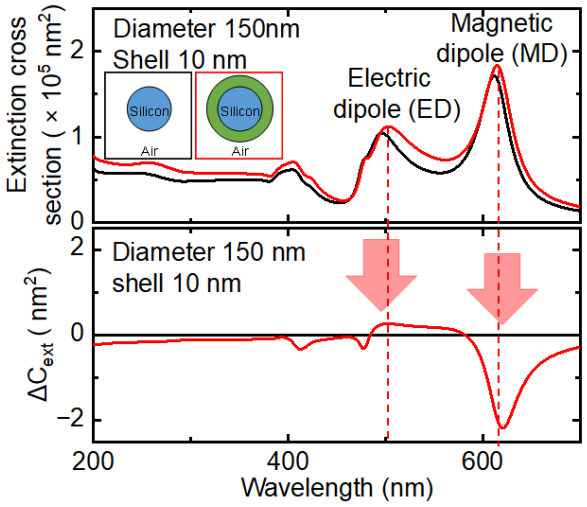

Figure 2. (Upper panel) Calculated extinction spectra of 150 nm silicon nanosphere with (red) and without (black) a 10 nm chiral medium shell (n = 1.33 and κ = -10^{-5}–$10^{-7}i$) (upper panel). (Lower panel) Calculated ΔC_{ext} spectra of 150 nm silicon nanosphere with a 10 nm chiral medium shell under right and left handed circularly polarized light.

Non-Hermitian dynamics in bosonic systems: classical and quantum realizations.

Y. N. Joglekar[1]

[1]Indiana University Indianapolis, United States
[*]corresponding author: yojoglek@iu.edu

Abstract: Open systems governed by a non-Hermitian Hamiltonian, called Parity-Time (PT) symmetric systems, have been deeply investigated over the past decade. Although most of their realizations are with waves, in recent years, these ideas have been extended to the quantum domain. With a photonic Floquet topological insulator and number-resolved phonon dynamics as examples, I will present salient properties of such systems in the classical and quantum domains respectively. (Work done in collaboration with Alexander Szameit's group (University of Rostock, Germany), Anthony Laing's group (University of Bristol, UK), and David Allcock's group (University of Oregon, US)).

PAST, PRESENT AND FUTURE OF MASS DIFFUSION METAMATERIALS

J.M Restrepo-Florez

[1]University of Florida, United States of America
[*]corresponding author: restrepoflorezj@ufl.edu

Abstract: Precise control of mass diffusion is vital in separations, reactions, and sensors. Metamaterials theory has recently advanced our understanding of mass diffusion in these systems. This talk explores how metamaterials can transform separations, outlining the current state of the art, key challenges, and promising future research directions.

Enhanced photo-excitation of spin-forbidden gray exciton in 2D materials by using spin-orbit-coupled vector vortex beams

Shun-Jen Cheng*

Department of Electrophysics, National Yang Ming Chiao Tung University, Hsinchu 300, Taiwan

*corresponding author: sjcheng@nycu.edu.tw

Abstract: We present a comprehensive theoretical investigation, implemented on the first-principles base, of the light-matter interaction between excitons in WSe2 monolayers and vector vortex beams. Through the optical spin-orbit interaction, vector vortex beams are shown to enable the photo-generation of gray excitons, a type of spin-forbidden dark exciton.

Superimposing two scalar optical vortex beams produces a vector vortex beam (VVB) in non-separable states where not only complex amplitude but also polarization are spatially structured and entangled with each other. Hence, a VVB can be encoded with entangled degrees of freedom of angular momentum (AM), both spin angular momenta (SAM) and orbital ones (OAM). In addition to the non-separability, the SAM and OAM in a VVB are intrinsically coupled by optical spin-orbit interaction (SOI), which has recently drawn a great deal of attention because of the profound underlying physics and potential photonic applications.[1] In this work, we present a comprehensive theoretical investigation, implemented on the first-principles base, of the intriguing light-matter interaction between spin-orbit-coupled VVBs and exciton complexes in transition-metal dichalcogenide monolayers (TMD-MLs) monolayers, being one of the best-promising two-dimensional (2D) materials in optoelectronics.

Theoretically, we have established the theory of the light-matter interaction between a 2D exciton and structured light carrying OAMs, i.e. a scalar vortex beam, by using the time-dependent perturbation theory.[2,3] Accordingly, we calculate the energy band structures and the microscopic wave functions of structured-light-excited exciton complexes in 2D materials by solving the Bethe Salpeter equation (BSE) established on the base of first principles.[4] We show that an incident structured OAM-light photo-generates an exciton wave packet that is formed by the coherent superposition of finite momentum exciton states and whose spatial structures are encode with the optical information of the structured light. The experimental signature of those photo-generation of finite momentum exciton states by structured OAM-light is the spectral blue shift in photo-luminescence spectroscopy that is increased with increasing the optical OAM, and was for the first time observed in Ref.[2].

Furthermore, the theory of structured-light-exciton interaction has been extended for the study of the intriguing interaction between 2D exciton and VVB, a superposition of multiple scalar vortex beams.[5] As one of the key findings, we show that, via the optical SOI, a VVB enables the photo-excitation of the one of

the spin-forbidden dark exciton doublet, i.e. gray exciton. Moreover, the spatial structure of the wave function of a VVB-generated gray exciton is imprinted by the entangled SAM and OAM encoded in the exciting VVB. Those findings unveil the indispensable role of gray excitons in the desired conversion of optical information to solid-state optoelectronic systems.

Higher-order Mie resonant metasurfaces for ultrafast all-optical light manipulation

C.U. Hail[1,2*], L. Michaeli[1], and H.A. Atwater[1]

[1]California Institute of Technology, United States
[2]University of California, Berkeley, United States
[*]corresponding author: cuhail@berkeley.edu

Abstract: We report on high-Q dielectric optical metasurfaces for ultrafast spatiotemporal light manipulation leveraging the optical Kerr effect and free-carrier effects from two-photon absorption.

Local modulations in refractive index due to ultrafast nonlinear effects present a promising route for realizing space-time-varying optical materials. However, the typically small changes in refractive index prohibit their application for spatial wavefront patterning. In this talk, we will introduce dielectric higher-order Mie resonant metasurfaces and show how these surfaces enable space-time light modulation using local ultrafast all-optical changes of the refractive index due to the optical Kerr effect and free-carrier effects. We present experimental results of strong pump self-modulation, space-time diffraction using a transient ultrafast grating, and time-dependent pump-probe measurements.

Snapshot Polarimetric Stereoscopic Imaging and On-Chip High Dynamic Range Correction System

Shuming Wang[1]

[1]Department of Physics, Nanjing University, China
[*]corresponding author: wangshuming@nju.edu.cn

Abstract: Capturing 3D objects in 2D images leads to significant information loss. While time-of-flight (ToF) and structured light techniques reconstruct 3D morphology, they require active excitation and are highly sensitive to environmental conditions. Polarization stereo-imaging passively collects reflected light, avoiding these limitations, but conventional methods rely on multiple polarizers, restricting single-shot imaging. We present a snapshot polarimetric stereoscopic imaging (SPSIM) system based on a polarimetric metalens that decouples and focuses six distinct polarizations, enabling high-resolution 3D reconstruction with a neural network-mediated algorithm (Fig. a & b). The system achieves an average extinction ratio of 25 dB and a central wavelength efficiency of 65%, surpassing conventional polarization cameras. With the ability to capture full Stokes parameters (FSPs), our approach reconstructs complete 3D textures with sub-millimeter precision, significantly enhancing surface normal recovery.

Beyond 3D imaging, high dynamic range (HDR) correction is essential for accurate visual representation under complex lighting conditions. Traditional HDR methods suffer from ghosting, computational intensity, or increased system complexity, making them impractical for compact and dynamic imaging applications. To address these challenges, we introduce an on-chip metasurface-based non-uniform transmittance array for single-exposure HDR imaging. This system achieves multi-exposure-equivalent performance while eliminating motion artifacts and temporal delays. Experimental validation (Fig. b & c) confirms its broadband response and ability to capture high-contrast scenes, preserving details in both bright and dark regions. By integrating optical and computational strategies, the system employs ultrathin metasurface films directly fabricated onto chips for on-chip light field modulation (Fig. d & e). This highly integrated solution provides a compact, high-performance HDR imaging approach, particularly suited for dynamic video applications, advancing next-generation imaging technologies.

(b) Numerical amplitude modulation of a single unit in the non-uniform transmittance metasurface and corresponding experimental measurements. (c) Imaging results under low exposure, high exposure, and HDR achieved by the metasurface-based system. (d) Imaging results of the metasurface-based system and optimization through computational processing. (e) Photographic image of the on-chip integrated fabrication, along with optical and electron microscope images.

Building complex nanophotonic device with self-assembled colloidal particles

Weihua Zhang

College of Engineering and Applied Sciences, Nanjing University, Nanjing, Jiangsu 210023, China
*corresponding author: zwh@nju.edu.cn

Abstract: Deterministic self-assembly techniques were developed for functional colloidal nanomaterials, including semiconductor, dielectric, plasmonic, and magnetic micro-/nanoparticles, with single-particle, nanometer precision. Using these techniques, novel devices such as subwavelength non-replicable QR codes and unidirectional optical antennas were demonstrated, presenting a new approach for fabricating complex nanophotonic devices.

Van Der Waals Polaritonic Crystals and Their Applications in THz Detection

Huanjun Chen*, Ximiao Wang, Shaojing Liu, Hongjia Zhu, and Shaozhi Deng

[1]State Key Laboratory of Optoelectronic Materials and Technologies, Guangdong Province Key Laboratory of Display Materials and Technologies, School of Electronics and Information Technology, Sun Yat-sen University, Guangzhou 510275, China

Abstract: Polaritons are hybrid modes formed through the coupling of the electromagnetic field with the charged collective excitations in materials [1]. They exhibit a remarkable ability to confine the electromagnetic field within or at the surface of a material, thereby significantly enhancing the interaction between electromagnetic fields and matter at the nanoscale. This unique property positions polaritons as highly advantageous for the development of nanophotonic and optoelectronic devices. Noble metals, doped semiconductors, and their nanostructures excel at supporting polaritons in the visible and near-infrared regime. However, their field confinement capabilities degrade significantly as the operational frequency shifts into the mid-infrared and terahertz region. This limitation makes them unsuitable for developing high-performance and miniaturized photonic and optoelectronic devices in the specified frequency domain. Recent studies have uncovered the remarkable capability of van der Waals (vdW) two-dimensional atomic crystals and their nanostructures to sustain diverse polaritonic modes across the mid-infrared to terahertz spectral range [2,3]. In this presentation, we will briefly review the roadmap of polaritonic van der Waals crystals. Subsequently, we will introduce our recent work on the plasmon polariton properties of graphene and its nanostructures. Following that, we will share our recent results on multiparameter THz detection using these graphene plasmonic nanostructures [4,5].

Abstract: In Weyl semimetal $(TaSe_4)_2I$, excitation of femtosecond optical pulses induces terahertz emission in the CDW state, arising from contributions of ultrafast photocurrent and various collective modes. Due to topologically non-trivial linear bands, we discover that properties of the collective modes at low temperatures can be manipulated with an ultrafast manner.

Charge density wave (CDW) is widely present in various quantum materials[1], where investigation and control of its associated collective modes have been a subject of great interest[2]. Here, the terahertz (THz) emission spectroscopy has been used to study the collective excitations in the typical quasi-one-dimensional CDW Weyl semimetal $(TaSe_4)_2I$. Upon excitation of femtosecond optical pulses, we observe broadband THz radiation including the contribution from the ultrafast photocurrent and multiple collective modes related to CDW at low temperature. We discover that properties of the collective modes can be controlled by tuning the circular polarization state of the incident light (see Figure1). Essentially, the Weyl fermions play the key role in switching the phase of collective modes. Our findings have significant implications for manipulating CDW, provide novel insights into control of charge ordering parameters in quantum materials.

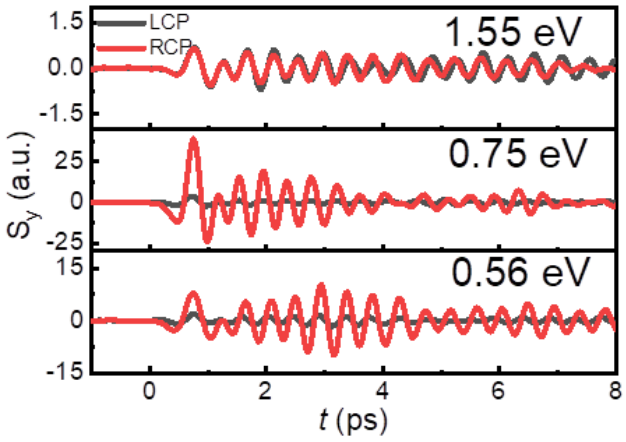

Figure1. Typical THz emission signal measured for left-handed (black) and right-handed (blue) circularly polarized pump light at 78 K with various photon energies.

Abstract: Many fields of research rely on optical trapping, whose limits are dictated by diffraction. We report the trapping of multiple cold atoms in four super-resolved traps and demonstrated the control of the reshuffling of atoms among traps. We also provide a simple and quantitative modelling of the atom dynamics.

Over the past few years, tremendous efforts have been made to realize digital and analog quantum computation using cold atoms trapped in optical tweezer arrays. This technique offers versatility in trapping geometry and atom arrangement. However, the inter-trap distance remains typically large, limiting the interaction strength between atoms and preventing tunneling. Here, we address this important limitation by creating an ensemble of four traps super-resolved in size and separation [1].

To realize our super-resolved light structures, we use an original approach consisting of a superoscillatory field [2] in combination with phase control of the traps. We benchmark the system by transferring atoms into the super-resolved traps with an efficiency close to one. In addition, by analyzing the atom-pair losses, we are able to precisely characterize the reshuffling mechanisms of the atoms among the traps. This is an important figure of merit for future quantum simulation experiments. Finally, the compact arrangement of the tweezers can be used to strongly enhance energy scales in quantum simulation and computing experiments. Thanks to its promising spatial and temporal control, super-resolution has the potential to initiate a paradigm shift in the field of atom trapping.

Optical skyrmions from metamaterials

Yijie Shen and Nilo Mata-Cervera

Nanyang Technological University, Singapore

Abstract: Optical meta-materials and the topologies of light are two emerging hot topics in the photonics community. In this article, we perspective a very emerging direction – Meta-devices for generation, manipulation and detection of diverse novel topologies of light – which will be rapidly growing interdisciplinary field across the studies in electromagnetic metamaterials and structured light. We will provide a bird's-eye view of the roadmap outlining how recent metasurface technologies enable integrated optical skyrmion generators and the future trends in meta-devices for generating more complex light topologies, which will help turning these novel structures from abstract concepts into practical applications.

1. Introduction: Many novel particle-like topologies were recently created in light [Nat. Photon. 18, 15–25 (2024)]. Generation of such topologies requires precise spatial control over phase, amplitude and polarization of light, which has been traditionally addressed with spatial light modulator setups, making it bulky and hindering applications. Metasurfaces and metamaterials [Science 376, eabi6860 (2022)] provide practical solutions for synthetizing the generation stage in a single device. Up to date, basic topological textures have been generated with metasurfaces, but the generation of higher dimensional particle-like topologies is still an intriguing direction to explore.

2. Recent advances of topological optical skyrmions: We summarize optical topologies in a zoological way. Singular points (phase, polarization singularities), then topological textures from basic cylindrical vector beams, 2D baby skyrmions, 3D and 4D knots, links, and particle-like topologies.

3. Meta-generators of topological light: Optical vortices with phase and polarization singularities is one of the main applications of meta-generators [Science368,707-708(2020), Science357,645-645(2017), Science374, eabj0039 (2021), Nanophotonics 10, no.5, 1469-1486 (2021)]. Here we focus on topologies beyond 2D (skyrmions, merons, hopfions), the emerging meta-designs for skyrmions [Nat Commun 15, 10141 (2024), J. Opt. 26 09LT01, Optica11 (11), 1588-1594 (2024), Nanophotonics (2025)] optical knots [Adv Opt Mat, 7(10), 1900263 (2019), ACS Photonics 11(10), 4380-4389 (2024)]. The next challenge is tunability, there is tunable OAM vector solution [Science 368, 760-763 (2020); Nature 612, 246–251 (2022)] and recent designs with tunable knotted fields [arXiv:2410.16756 (2024)], but how to achieve tunable control of polarization-inhomogeneous beams with topological features is still a direction to explore.

4. Perspectives of meta-detectors of topological light: We review the meta-devices for OAM sorting [Laser & Photonics Reviews, 18(9), 2400113, ACS Photonics 9(9), 3043-3051 (2022)] and meta-detectors of OAM [Science 368, 763–767 (2020)] and SAM-OAM [Nat Commun 15, 5396 (2024)] with detection of the higher-order Poincaré sphere. However, currently there are no compact meta-devices for detection of skyrmion number or other higher-order topological structures of light. We will propose the potential solutions and perspective the future trend of the meta-detectors for topologies of light.

Thermal Photonics for Advanced Energy Conversion Systems

A. Sakurai[1,2,3*]

[1] Department of Mechanical and Production Engineering, Niigata University, Japan
[2] Graduate School of Science and Technology, Niigata University, Japan
[3] Interdisciplinary Research Center for Carbon-Neutral Technologies, Niigata University, Japan
[*]corresponding author: sakurai@eng.niigata-u.ac.jp

Abstract: We investigate thermal photonics strategies for improving energy conversion efficiency. Emphasis is placed on near-field radiation, spectral control of emission, and carbon-based films. These approaches demonstrate the potential to surpass classical thermal limits, offering scalable routes to high-performance energy harvesting.

Thermal photonics offers a powerful framework for manipulating radiative and photonic heat transport to enhance energy conversion performance [1-3]. In this work, we present a set of studies focused on nanoscale control of thermal processes relevant to advanced energy systems. The first study explores near-field thermal radiation, where engineered photonic structures facilitate radiative heat transfer well beyond the blackbody limit. This enhancement is crucial for compact energy harvesting and thermal management applications under high energy density conditions. The second study examines a thermophotonic system optimized for low-grade waste heat utilization. By tailoring the spectral properties of emitters and filters, the system achieves far-field emission control that allows for efficient energy recovery even from sub-ambient sources [4]. This concept is particularly promising for applications where conventional thermodynamic cycles underperform due to temperature constraints. Lastly, we investigate carbon nanotube (CNT) films exhibiting strong anisotropic emission and wavelength-selective absorption. These films serve as robust platforms for directional radiative control, with implications for solar thermal conversion and thermally-driven photonic devices. Their unique spectral and thermal stability make them attractive candidates for scalable and tunable energy technologies.

Together, these results highlight the critical role of material design and spectral engineering in thermal photonics. The presented approaches offer practical routes to overcome classical efficiency barriers and pave the way toward next-generation sustainable energy solutions.

Abstract: Here we report the study of a quadrupole topological states in a gyromagnetic PhC, and verify its topological phase transition from the Chern insulator phase, as well as the formation of topological bound states in the continuum. This work thus expands the scope of higher-order topological physics, and integrates topologically protected propagating and localized modes in a same platform.

Polarization optics using nonlocal dielectric metasurfaces

Yu Geun Ki[1], Changhyun Lee[1], SeokJae Yoo[2] and Soo Jin Kim[1*]

[1]School of Electrical Engineering, Korea University, Seoul 02841, Republic of Korea
[2]Department of Physics, Inha University, Incheon 22212, Republic of Korea
[*]corresponding author: kimsjku@korea.ac.kr

Abstract: In this work, we exploit nonlocal resonances, including guided mode resonances (GMR), to realize ultrathin polarization optics which exhibit spin-selective responses with near-unity efficiency. We experimentally demonstrate chiroptical behavior induced by symmetry-breaking in nanostructures, facilitating precise manipulation of polarization states and effective detection of Stokes parameters at the nanoscale.

The field of nanophotonics has attracted significant technological interest over the past decade due to its potential to enable ultrathin optical components and next-generation optoelectronic devices. However, a key challenge remains in addressing the mismatch between electronic and photonic length scales: while CMOS technology has successfully scaled electronics to the nanoscale, photonic components are still predominantly limited to the microscale.

Metasurfaces—ultrathin layers composed of subwavelength nanostructures—have emerged as a promising solution to overcome these limitations and drive advances in nano-optics development. More recently, designing metasurfaces with the geometry of symmetry-breaking have enabled the effective manipulation and detection of spin states of light [1-3]. Such metasurfaces, typically defined as chiral metasurfaces, open up new opportunities in spin-selective light–matter interactions and chiroptical applications including molecular sensing, optical communications, and advanced imaging.

In this work, we explore effective light manipulation with spin-selective fashion using nonlocal dielectric metasurfaces engineered with symmetry-breaking in nanostructures. We optimize the design parameters of such nanostructures for a dynamically reconfigurable metasurface capable of controlling phase, wavefront, and polarization states of light with near unity efficiency at the nanoscale. We further reveal that the chiroptical behavior of the designed metasurface could be maximized by judiciously combining nonlocal and local resonances, such as GMR and Mie resonances.

In addition, we analyze various symmetry-breaking configurations—both in-plane and out-of-plane—to distinguish between intrinsic and extrinsic types of chiral metasurfaces. In particular, ultrathin and planar type of intrinsic chiral properties without three-dimensional structures are demonstrated by designing a metasurface with substrate induced out-of-plane symmetry breaking. It is found that the hybrid resonance mode caused by the chiral resonance interacting with the substrate breaks the out-of-plane mirror symmetry of the optical near fields and mimics the resonances which typically occur in helicity structures. The operational principles of these metasurfaces are evalusted using coupled-mode theory, which offers a robust framework for their design by relating the co-polarized and cross-polarized components of transmitted light in terms of their phase and amplitude.

In summary, the proposed work demonstrates the potential of nonlocal dielectric metasurfaces as polarization optics and effective platform for compact and nanoscaled photonic systems. By strategically integrating nanostructures with symmetry-breaking and leveraging hybrid resonances, we demonstrate versatile control over multiple optical degrees of freedom at the nanoscale including the detection of Stokes parameters

and manipulation of polarization conversions. The designing rules of polarization metasurface can be applicable to the development of tunable, multifunctional metasurfaces tailored for applications in integrated optics, chiral light detection, and next-generation polarization-based nanoscaled photonics.

Abstract: We demonstrate the first generation of spatiotemporal optical vortices (STOVs) in the extreme ultraviolet via high harmonic generation. This highly nonlinear process enables attosecond-scale spatiotemporal coupling, paving the way for novel probes of ultrafast light-matter interactions with structured light carrying high topological charge in space and time.

In recent years, the ability to tailor structured light pulses has attracted growing interest due to the emergence of novel light-matter interaction schemes. For instance, vector beams with spatially varying polarization states enable interactions where the magnetic field can dominate over the electric field [1, 2]. More recently, spatiotemporal optical vortices (STOVs)—light pulses carrying angular momentum coupled in space and time—have gained attention. Unlike conventional longitudinal optical vortices with spiral phase profiles in the transverse plane, STOVs exhibit twisted phase structures in the spatiotemporal domain. Defined by their topological charge—the number of 2πpi phase windings across space and time—STOVs have been successfully generated in the near-infrared (IR) spectrum, as well as in the visible range through perturbative harmonic generation [3,4]. However, generating STOVs in the extreme ultraviolet (EUV) or even soft x-ray range, where attosecond temporal resolution is achievable, has remained challenging due to the inefficiency of conventional optics at such high frequencies.

In this work, we build on a successful strategy that has enabled during the last decade the generation of highly coherent structured light beams in the EUV and even attosecond regime. Exploiting the nonlinear process of high-order harmonic generation (HHG) we demonstrate that STOVs can be upconverted from the near-IR into the EUV. This approach has proven highly effective in generating longitudinal high-frequency vortices [5], among other structured light beams. Recent theoretical advancements have also outlined the feasibility of producing high-frequency STOVs through HHG [6]. Notably, focused STOVs introduce additional degrees of control over the HHG process, particularly with respect to the target's position, as these vortices do not constitute propagating eigenmodes [7]. We demonstrate both theoretically and experimentally that EUV high-order harmonic STOVs can be generated through HHG [8]. Our research opens the pathway for using STOVs with controlled high topological charges in the EUV/soft x-ray spectral regime, offering unique tools to probe ultrafast electronic and magnetic dynamics near absorption edges. The spatiotemporal characterization of EUV STOVs and SSOVs is addressed, aiming to motivate the development of complete spatiotemporal characterization techniques of HHG pulses with tailored angular momentum [9-10].

Optical properties of nanoporous gold and their change upon electrochemical oxidation

Maurice Pfeiffer[1], Xinyan Wu[1], Manfred Eich[1,2], Alexander Yu. Petrov[1,2*]
[1]Institute of Optical and Electronic Materials, Hamburg University of Technology, Hamburg, Germany

Abstract: Nanoporous gold shows a strong change of color upon electrochemical oxidation. This can result from a reduced volume of plasmonic gold, dielectric coating on the gold surface or an increase of electron collision frequency. Using brute-force simulations we identify the contribution of these effects.

Nanoporous gold (npAu) is a sponge-like material obtained by dealloying. The dealloying procedure typically leads to a porous sponge-like structure with gold ligament diameter in the order of 10 nm. The thin films of npAu usually have brown appearance as radiation can enter the network structure and is strongly absorbed. This absorption has two origins: ligaments parallel to applied electric field and resonances between dangling ligaments at the surface of npAu. Upon electrochemical oxidation the npAu color changes to black which is attributed to increased absorption and transmission. Several explanations for the observed optical effect are possible:

1. Oxidation results in a smaller volume of gold in the porous structure, changing its effective dielectric constant. Also, the gap between two gold surfaces of the dangling ligaments is increasing.
2. The dielectric coating produced by oxidation changes the effective dielectric constant of npAu and increases the dielectric constant in the gap between two dangling ligaments.
3. The change of gold surface leads to the increase of the electron collision frequency, so-called Chemical Interface Damping (CID) [1]. CID changes the effective medium parameters, but also the damping of resonances at dangling ligaments.

We have implemented a 3D leveled-wave model for the structure of npAu similar to Ref. [2] and simulated its optical response. Implementing all of these free effects sequentially, we have identified that gold volume reduction and dielectric coating both define the change of color in the visible range. Whereas CID effect becomes dominant only in the IR range.

This study shows the complexity of the random plasmonic network and its response to surface oxidation. Further reduction of the ligament size can be used to increase the modulation by electrochemical oxidation and can lead to even stronger modulation of the reflection and transmission.

Abstract: Optical phase change materials (PCMs), such as Sb_2Se_3 and Sb_2S_3, have created a paradigm shift for integrated photonics. Ought to the decoupling of phase and amplitude they enable more complex functions and lower losses. This talk will discuss the development of low-loss PCMs for higher transparency and longer switching durability.

Optical response in twisted bilayer graphene

M. Sánchez Sánchez[1], J. González[2], and T. Stauber[1*]
[1]Instituto de Ciencia de Materiales de Madrid, CSIC, E-28049 Madrid, Spain
[2]Instituto de Estructura de la Materia, CSIC, E-28006 Madrid, Spain
Corresponding author: tobias.stauber@csic.es

Abstract: We report on the optical response of twisted bilayer graphene obtained from an atomistic tight-binding model. Within the Hartree-Fock approximation, the Drude response increases due to the renormalization of the Fermi velocity. We will also calculate the chiral response and the shift current related to the Berry curvature dipole.

Twisted bilayer graphene (TBG) has attracted much attention mainly due to the discovery of superconductivity [1]. Assuming the weak-coupling regime such that the one-particle band-structure of the normal and superconducting state only differs by the one-particle gap, the transverse superfluid density can be discussed by the longitudinal Drude weight that can be measured e.g. via scattering-type scanning near-field optical microscopy. Calculating the optical response of the TBG can thus complement the discussion of the electronic properties.

Here, we will investigate the optical properties of TBG employing the tight-binding model using the Slater-Koster parametrization proposed by Koshino and Moon [2]. Also lattice relaxation shall be included, but more importantly, Coulomb interaction is approximated by a self-consistent Hartree-Fock scheme [3]. By this, we are able to discuss the renormalization of the Drude weight shown in Fig. 1 for a twist-angle of 1.3°.

Apart from that, not only the charge response characterizes TBG, also the huge paramagnetic counterflow and chiral response give important insights in the electronic structure of TBG. Together with the charge response, they are defined by the following expressions:

$$D_{tot}(\mu) = \frac{1}{2A} \sum_{\mathbf{k},n} \int \mathbf{k},n|j_x|\ \mathbf{k},n\ |^2 + |\ \mathbf{k},n|j_y|\mathbf{k},n\ |^2\big)\, f_F(\epsilon_{\mathbf{k},n} \in \mu) \tag{1}$$

$$D_{mag}(\mu) = \frac{1}{2A} \sum_{\mathbf{k},n} \int \mathbf{k},n|j_x^1 \in j_x^2|\mathbf{k},n\ |^2 + |\ \mathbf{k},n|j_y^1 \in j_y^2|\mathbf{k},n\ |^2\big)\, f_F(\epsilon_{\mathbf{k},n} \in \mu) \tag{2}$$

$$D_{chi}(\mu) = \frac{1}{2A} \sum_{\mathbf{k},n} \int \mathbf{k},n|\mathbf{j}^1|\mathbf{k},n\ |\times|\ \mathbf{k},n|\mathbf{j}|\mathbf{k},n\ |^2\big)\, f_F(\epsilon_{\mathbf{k},n} \in \mu) \tag{3}$$

In the above equations, we introduced the eigenenergies $\epsilon_{\mathbf{k},n}$ and eigenstates $|\mathbf{k},n\ $ of the tight-binding Hamiltonian as well as $\mathbf{j}^\ell$, the sheet-currents of layer ℓ, and $\mathbf{j}$, the total current. Furthermore, $f_F(x) = (e^{\beta x}+1)^{-1}$ denotes the Fermi function with $\beta = (k_B T)^{-1}$.

Finally, we will also comment on non-linear response and discuss shift current. Special attention shall be placed on the quantum response due to a Berry curvature dipole, present in TBG samples with uniaxial heterostrain.

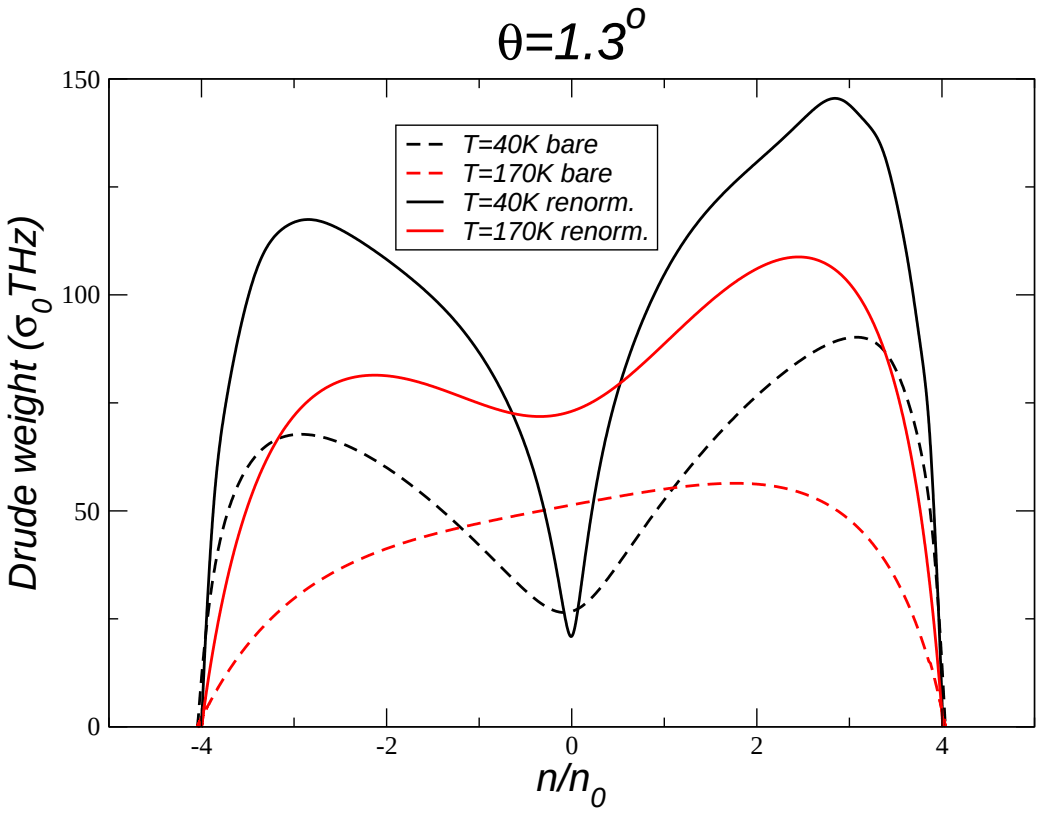

Figure 1: The Drude weight at temperatures $T = 40, 170$K as function of the carrier density n of the flat bands with n_0 being the density of one particle per moiré unit cell. The dashed lines are the bare quantities whereas the solid lines denote the renormalized Drude weights due to Coulomb interaction, in units of the conductance quantum $\sigma_0 = e^2/h$.

Abstract: We demonstrate an optical chip with which one can induce the transient metallization of dielectrics with pJ-level femtosecond laser pulses in micron-sized gaps between electrodes. Because of the ultrafast and reversible nature of the current generation process, our device paves the way toward PHz optoelectronics applications.

Ultrafast current control in dielectric media was demonstrated some 12 years ago with amplified femtosecond laser pulses [1]. By the use of few-optical-cycle pulses as short as 5 fs, one can even steer the direction of the generated current with the carrier-envelope phase of the pulse, enabling ultrafast switching applications.

Based on this phenomenon, we developed an optical chip with which we realized light-field-driven current control in homogeneous dielectric media with pJ-level laser pulses at 80 MHz repetition rate, i.e. the full repetition rate of a femtosecond laser oscillator for the first time [2]. As a first application, we used this device for building a 3D carrier-envelope phase scanner tool [3].

We will also feature very recent results on how to use dielectric-metal heterostructures to enhance CEP dependent signal levels significantly, also relevant for the strong-field nano-optics research direction [4]. In addition, our new experiments on revealing the mechanisms of the ultrafast current generation process will also be presented.

In summary, our demonstration of a robust optical-to-electrical readout of light waveforms using an engineered heterostructured material represents an important cornerstone for the development of few-cycle beam diagnostics and PHz devices.

Abstract: We provide experimental evidence that an effective radiative recombination of complete perovskite cells can be larger than 10% of the total direct recombination. The design and fabrication of nano-structures which are effective in limiting radiative recombination and raising the open circuit voltage without significantly altering sunlight absorption will be discussed.

Summary:

Single junction semiconductor non-concentrator solar cell devices can convert sunlight into electrical energy with a relatively low upper limit efficiency established by Shockley and Queisser many years ago. Different intrinsic energy loss mechanisms such as thermalization, below bandgap transmission or Boltzmann losses limit the power conversion efficiency of such photovoltaic devices to about 33 %. Overcoming thermalization or below bandgap losses has been explored following different strategies. Among them, the tandem or multiple junction approach are, probably, the most successful ones. However, Boltzmann losses, which are linked to the large mismatch between the cell light absorption and emission cones, have been largely overlooked for several different reasons which partially relate to a low external fluorescence quantum yield in the majority of the photovoltaic configurations used and the challenge to obtain cell architectures simultaneously effective in trapping photons emitted by the photovoltaic material but also in capturing sun photons.

It has been shown that an adequate nano-structuration of the solar cell architecture may lead to an upper limit conversion efficiencies slightly higher than 43%. In here, we will provide experimental measurements based on a $Cs_{0.05}FA_{0.95}PbI_3$ perovskite cell indicating that the effective radiative recombination of completed cells can be larger than 10% of the total direct recombination. We will also discuss the design and fabrication of nano-structures which are effective in limiting radiative recombination without significantly altering sun photon absorption in perovskite solar cells.

Active IR and THz light modulators based on epsilon-near zero InAs and GaSb semiconductor frequency-selective surfaces

J. Guise[1], F. Gonzalez-Posada Flores[1*], S. Blin[1] and T. Taliercio[1]

[1]Institute for Electronic and Systems, University of Montpellier, France
[*]corresponding author: fernando.gonzalez-posada-flores@umontpellier.fr

Abstract: Our research explores light-matter interaction applications, focusing on surface field-enhanced optical filters and transducers in the mid-infrared (MIR) and terahertz (THz) spectral ranges using plasmonic effects. We present thermal and optical activation of epsilon-near-zero (ENZ) materials based on epitaxial InAs and GaSb semiconductors, with emphasis on THz and IR frequency-selective surface optical devices.

The terahertz (THz) and mid-infrared (MIR) ranges are critical for the development of efficient, tunable, and integrable detection and filtering devices. Our approach leverages plasmonic light-matter interactions in heavily doped semiconductors to address these challenges. In particular, we demonstrate how semiconductor-based plasmonic epsilon-near-zero (ENZ) platforms enable high-sensitivity detection and lay the foundation for reconfigurable IR filters. These advances have significant implications for healthcare diagnostics, environmental monitoring, spectroscopic imaging, and telecommunications.

Our work focuses on enhancing plasmonic filtering and transduction mechanisms in the THz and MIR domains using semiconductor-based metal-insulator-metal (MIM) structures, in which the insulating layer is replaced by an ENZ material. The development of such structures, featuring tunable absorption and resonance behavior through surface patterning, enables frequency-selective filtering. Ultimately, our goal is to dynamically control the activation of these metasurfaces to realize IR and THz filters integrated into photodetectors or spectrometers.

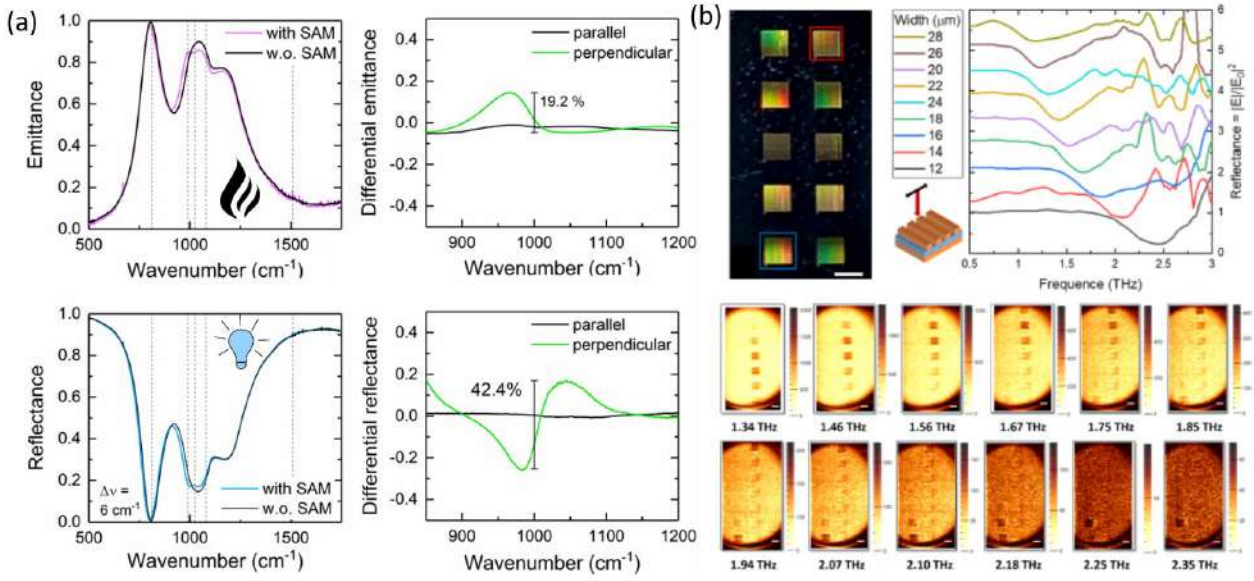

Figure 1: (a) Surface-enhanced thermal emission spectroscopy (SETES); (b) Frequency-selective THz surface measured via time-domain spectroscopy (TDS).

We adopt a systematic and modular approach, beginning with electromagnetic simulations (FDTD and RCWA) to design semiconductor-based plasmonic architectures tailored to MIR and THz operation. We present

a perfect absorber model based on a semiconductor MIM-like configuration that enables full absorption in the IR and THz ranges. This design supports surface enhanced thermal emission-based spectroscopy (SETES) and allows for the selective detection of surface-adsorbed molecules, such as self-assembled monolayers (SAMs).

The fabrication of the layered transducers and surface antennas is based on epitaxial GaSb and InAs. Precise doping allows us to target specific plasma frequencies and achieve ENZ behavior. Surface patterning is performed via e-beam lithography to create ribbon-shaped antennas that act as frequency-selective elements in both the MIR and THz regions. These platforms support scalable, on-chip THz sensing with both material and geometric tunability.

A major focus of our current work is the activation and dynamic control of metasurfaces for tunable IR and THz filters. Starting from monolayer and absorber models, we have engineered metasurfaces capable of thermal, optical, and electrical modulation. By tuning carrier density or integrating localized heaters and electrical contacts, we achieve real-time dynamic control of plasmonic resonances, enabling selective filtering on demand. This strategy opens the path toward reconfigurable IR filters directly integrated onto photodetectors, overcoming the inherent limitations of static designs.

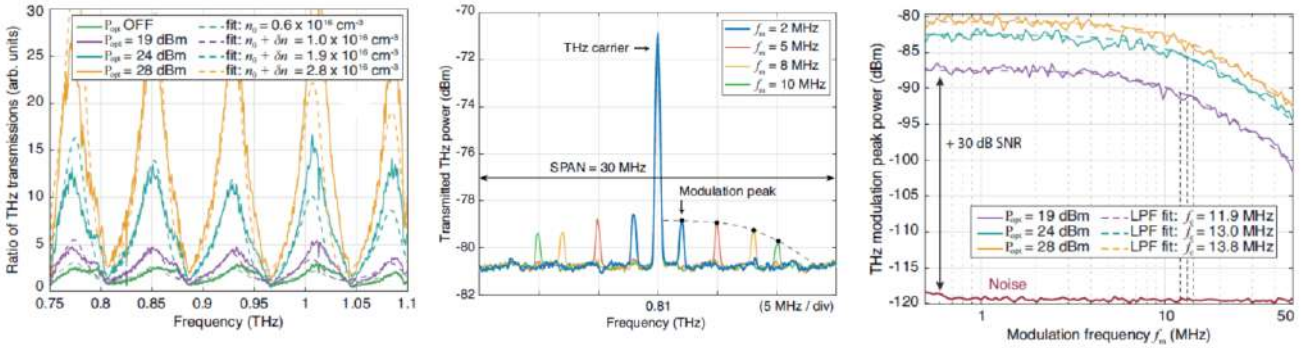

Figure 2: Optical modulation of THz signals under varying excitation power and frequencies.

Our results demonstrate that semiconductor-based plasmonics unlock new capabilities in THz sensing and dynamic IR filtering. We have established proof-of-concept platforms for surface-enhanced thermal molecular detection and tunable optical filtering in both the IR and THz domains using microstructured surfaces. Future research will focus on the development of fully integrated IR chips that combine sources, detectors, transducers, and reconfigurable metasurfaces. These systems have wide-ranging potential applications in on-chip spectroscopy, smart sensing, and telecommunications.

High-Speed Self-biased 2D InS Photodetector

S. R. Tamalampudi[1], Ghada Dushaq[1], and M. S. Rasras[1*]

[2] Electrical Engineering Program, Engineering Division, New York University Abu Dhabi, UAE
[*]corresponding author: mr5098@nyu.edu

Abstract: We demonstrate a high-speed, self-powered InSe Schottky photodetector featuring a 2.5 MHz response time at 785 nm. Through integration with a SiN platform and the application of strain modulation, we extend its detection capability to 1550 nm and attain an ultrafast response time of 4.5 ns under 974 nm excitation.

Indium selenide (InSe), a layered 2D semiconductor, has attracted considerable interest for optoelectronic applications due to its high optical absorption, direct bandgap, and tunable photoresponse across visible to near-infrared (NIR) wavelengths. InSe photodetectors have demonstrated outstanding responsivities up to ~10^5 A/W, with performance further enhanced by engineering strategies such as the use of graphene electrodes and h-BN encapsulation [1]. However, vertically illuminated InSe devices often suffer from slow response times in the millisecond-to-microsecond range, limiting their use in high-speed applications. Recent efforts have focused on self-driven photodetectors using heterojunctions (e.g., graphene/InSe/MoS_2, InSe/SnS_2) or Schottky junctions with engineered contacts to minimize interface doping [2].

Here, we report a self-powered, high-speed InSe photodetector based on an asymmetric Au-InSe-Gr/Au Schottky junction. Fabricated on a Si/SiO_2 substrate, the device exploits the work function difference between Au (~5.1 eV) and graphene (~4.7 eV), generating a built-in electric field for efficient photocarrier separation [3].

Device fabrication began on a Si/SiO_2 substrate, where Cr/Au metal contacts were first patterned via standard lithography. A multilayer graphene flake was mechanically transferred onto one of the Au pads. Following this, an exfoliated InSe flake was laminated to form an asymmetric Au-InSe-Gr/Au Schottky junction (Fig. 1a). This architecture leverages the work function disparity between gold (~5.1 eV) and graphene (~4.7 eV) to create a built-in electric field via an asymmetric Schottky barrier [3].

Electrical characterization was conducted under dark and 785 nm illumination (Fig. 1b). Even at 0 V bias, a photocurrent of 0.5 μA was observed due to the internal field effectively separating photogenerated carriers without the need for external power. Frequency response measurements under the same illumination revealed a 3-dB cutoff frequency of 2.5 MHz, equating to a response time (τ_a = 0.35/f_{3dB}) of 0.12 μs (Fig. 1c), outperforming previously reported self-driven InSe photodetectors [2].

To further enhance speed, InSe was integrated onto a silicon nitride (SiN) photonic waveguide platform. Figure 2a presents an SEM image of the integrated structure. I-V measurements across a broad spectral range (520–1550 nm) showed that waveguide-induced strain modified InSe's band structure, improving light absorption and carrier mobility (Figs. 2b–d). Speed performance significantly improved, with the 3-dB cutoff frequency rising to 77 MHz under 974 nm illumination and 5 MHz at 1310 nm (Fig. 2e) [4].

These findings emphasize the potential of combining InSe with photonic platforms for ultrafast, self-powered detection.

Abstract: We present fully 3D scalable $\chi^{(2)}$ photonic crystals with unprecedented domain sizes (>100 unit cells), overcoming previous z-direction limitations. We combine colloidal self-assembly of polystyrene opals for templating and sol-gel barium titanate chemistry for replication. These nonlinear crystals facilitate controlled second harmonic generation within a fabrication-tunable photonic bandgap.

Three-dimensional nonlinear (second-harmonic) photonic crystals can simultaneously generate different nonlinear processes such as second-harmonic generation, optical parametric amplification, or other sum- and difference-frequency processes along different photonic crystalline directions. [1] Laser-poling and laser-erasing have been utilized in materials like lithium niobate, and barium-calcium titanate. [2] With the first bottom-up fabricated 3D second-harmonic woodpile photonic crystal, we introduced the later used sol-gel chemistry in combination with soft-nanoimprint lithography. [3] However, creating large crystals in all three dimensions, mainly in the z-direction, presents a considerable challenge, primarily due to the chemical inertness of metal oxides. [4]

This study shows the first demonstration of colloidal-crystal-templating for a second-order optical material. We selectively synthesized monodisperse nanospheres with tunable unit sizes to self-assemble polystyrene opals with different band gaps (Figure 1 a-d). These serve as templates for infiltration with barium titanate sol-gel. After a calcination step, we obtained an inverse fcc network of tetragonal barium titanate (Figure 1 e,f). We fabricated samples with unprecedented sizes for single domains: >3000 unit cells in x y directions and >100 in z (Figure 1 g). The achieved optical reflectivity values are above 80 % throughout the fabrication. We can engineer the final photonic band gap over the entire optical range, matching it both to material and setup requirements (Figure 1 h).

We successfully replicated the photonic network into a second-order material and demonstrated, for the first time, a linear photonic band gap from a fully scalable three-dimensional photonic crystal made of a $\chi^{(2)}$ optical material. With our approach, we overcame previous limitations, especially stacking in the z-direction, while obtaining full tunability of the initial unit cell. With reverse engineering of the final band gap wavelength we can both avoid the materials absorption regime and match the available laser setups. This enables the experimental investigation of SHG generated within a band gap, such as inhibited spontaneous emission. [5] Configurations for probing enhanced nonlinearities at the band edges and inhibited excitation can be fabricated with the same technique. [6] In addition, we are planning to replace the colloidal fcc template with a photonically superior, larger bandgap colloidal diamond structure. [7]

Abstract: Low-loss, high-Q dielectric metasurfaces are versatile platforms to manipulate strong light-matter interaction. By using silicon metasurfaces, we are able to realize strong-coupling-induced enhancement and phase-transition in molecular J-aggregates superradiance and exciton-polariton condensation and lasing in polycrystalline perovskite films. These works establish scalable pathways for polaritonic devices compatible with silicon photonics.

Rapid, Full-wafer Fabrication of All-inorganic, High-Efficiency Metaoptics and AR Waveguides via Additive Nanoimprint Lithography

J. J. Watkins

University of Massachusetts and Myrias Optics, Inc. USA

watkins@umass.edu, watkins@myriasoptics.com

Abstract: We fabricate all-inorganic, high-efficiency, metalenses, metasurfaces, DOEs and waveguides on full-wafer platforms with cycle times of less than 5 minutes/wafer via additive nanoimprint lithography using TiO_2 nanoparticle dispersion inks for applications in the visible and near IR.

Monolithic integration for Silicon photonics

Abstract: We report recent advancements in silicon nitride monolithic integration schemes, highlighting progress in integrated broadband nonlinear structures, non-volatile photonic memories, and precise device trimming techniques. These developments underscore significant strides in the field, paving the way for enhanced photonic device functionality and integration.

Controlling and applying the loss of electromagnetic metasurface based on machine learning

Peng Fu, Yang Guo, and Changzhi Gu*

[1]Institute of Physics, Chinese Academy of Sciences, Beijing 100190, China
*corresponding author: czgu@iphy.ac.cn

Abstract: By integrating the non-Hermitian optical theory and machine learning methods, we promoted the design of metasurfaces from traditional experience-driven to data-driven, and from single function to multi-functional collaboration.

As an artificial optical material with a subwavelength structure, metasurfaces can accurately manipulate multiple degrees of freedom of electromagnetic waves at a very small scale and are widely used in cutting-edge fields such as meta-lenses, polarization control, holographic imaging and electromagnetic stealth. However, metasurfaces inevitably introduce material loss and radiation loss in practical applications, which are regarded as the main obstacles to performance degradation in traditional design concepts. In recent years, the development of non-Hermitian physics has subverted this traditional cognition and proposed a new paradigm that takes loss as a design dimension rather than a constraint, providing theoretical support for the realization of novel optical effects such as singularity point (EP)-induced unidirectional transmission, loss-induced laser recovery and transparency. At the same time, machine learning methods such as deep learning have performed well in high-dimensional space modeling and optimization, providing powerful tools for the precise design of metasurface structures under non-Hermitian conditions.

In this work, we systematically explored the modeling, design and experimental implementation of non-Hermitian metasurface systems around the two core concepts of "loss control" and "intelligent optimization". First, Starting from non-Hermitian optics, a theoretical model suitable for metasurface design is established to sort out the advantages of singular point-related topological effects in light regulation; then, A bidirectional deep learning framework is constructed to realize the design of multifunctional devices based on scattering EP, solving the difficulties of traditional methods in high Q value prediction and dimensional matching; finally, A coupled multi-layer non-Hermitian THz metasurface system is proposed, combined with machine learning optimization methods to achieve accurate construction and positioning of EP3.

This study not only promotes the practical application of non-Hermitian optical theory in metasurface device design, but also provides methodological support for the design of future intelligent photonic devices.

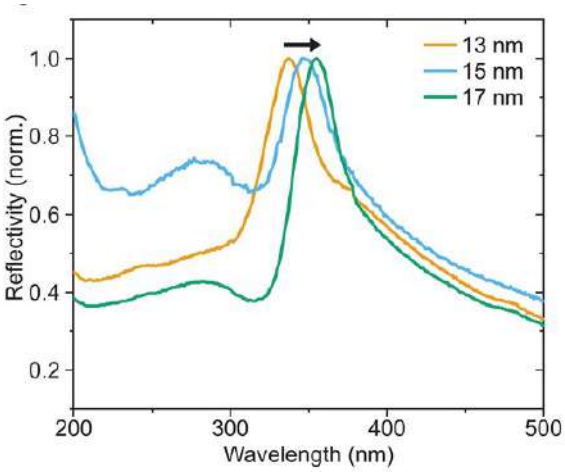
Abstract: We present a DNA-origami-assembled diamond lattice photonic crystal with 170 nm periodicity. Silicification and TiO_2 coating yield mechanically robust, high-index structures supporting UV-range photonic bandgaps. Optical measurements and simulations confirm tunable bandgap behavior. This bottom-up approach offers a scalable route toward programmable 3D photonic metamaterials with subwavelength precision.



Photonic crystals are periodic dielectric structures that manipulate light propagation via Bragg scattering, giving rise to photonic bandgaps—spectral ranges where light cannot propagate through the crystal. Among 3D photonic crystal geometries, the diamond lattice is particularly attractive for its potential to support a wide and complete photonic bandgap even at relatively low refractive index contrasts [1,2]. Despite significant theoretical interest, experimental realization of diamond lattice photonic crystals at the submicron scale has remained a challenge, especially with the degree of precision required for optical applications.

Here, we demonstrate a bottom-up approach using DNA origami to self-assemble a direct rod-connected diamond lattice with a periodicity of 170 nm. DNA origami enables the programmable folding of single-stranded DNA into rigid, well-defined nanostructures, which can be functionalized with high spatial precision [3]. In our system, we design tetrapod-shaped DNA origami monomers that mimic the tetrahedral coordination found in diamond crystals. Each monomer features four arms extending at 109.5° angles, with programmable "sticky" ends for directional binding and "fuzzy" ends to discourage non-specific aggregation. The resulting interactions enable assembly into a 3D diamond lattice with the desired cubic symmetry.

Post-assembly, the lattice is silicified to enhance mechanical stability [4] and coated with TiO_2 via atomic layer deposition (ALD) to increase refractive index contrast [5]. To characterize its optical response, we measure the reflectance spectrum using UV-Vis spectroscopy. The resulting data reveal a distinct reflection band in the ultraviolet, which red-shifts with increasing TiO_2 thickness. This observation is in agreement with photonic band simulations performed using the MIT Photonic Bands (MPB) software, which predicts a bandgap in the UV range for a diamond lattice with the measured structural parameters. The ability to tune the optical properties via ALD thickness offers additional flexibility in photonic device design. [6]

This work demonstrates the potential of DNA-origami-driven self-assembly for constructing scalable, functional 3D photonic architectures and offers a versatile platform for future metamaterial design.

Photon Manipulation with the Interface of Synthetic Temporal Photonic Lattices

Bing Wang[1*]

[1]School of Physics and Wuhan National Laboratory for Optoelectronics and, Huazhong University of Science and Technology, Wuhan 430074, China.

[*]corresponding author: wangbing@hust.edu.cn

Abstract: We experimentally constructed a synthetic dimensional temporal photonic lattice based on dual-loop coupled fiber architecture, and demonstrated its versatile applications in gauge potential modulation and nonlinear photonics. By tailoring the distribution of scalar and vector potentials, we demonstrate reconfigurable temporal interfaces enabling phenomena such as refraction, total internal reflection, and perfect imaging. We further observe a temporal Goos–Hänchen shift arising from total internal reflection, jointly governed by scalar and vector potentials. Finally, by introducing optoelectronic Kerr nonlinearity, we realize nonlinear non-Hermitian skin effects and demonstrate robust skin solitons enabled by the interplay between nonlinearity and non-Hermitian transport.

Main results:

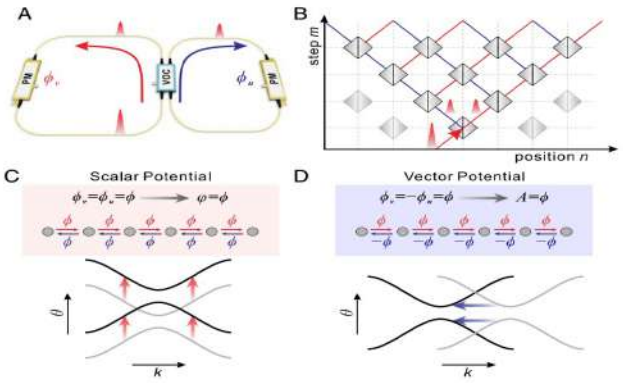

Fig. 1. A. Schematic sketch of the experimental setup used for implementing synthetic temporal lattice. **B.** Synthetic temporal lattice mapping from the pulse evolutions in A. **C,D** Effective scalar and vector potentials and their influence on the band structure.

As illustrated in Fig. 1, applying identical phase modulations to the long and short fiber loops induces an effective scalar potential in the synthetic temporal lattice, leading to a vertical shift of the Floquet band structure. In contrast, opposite phase modulations generate an effective vector potential, resulting in a horizontal displacement of the bands.

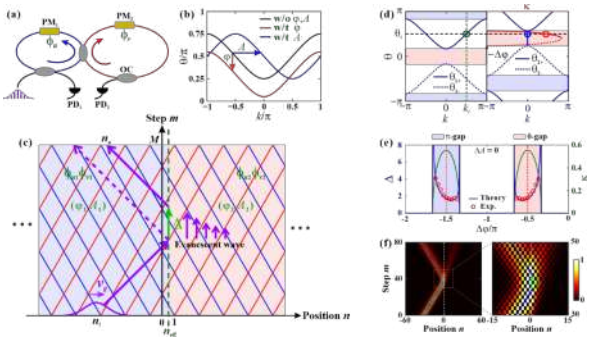

Fig. 2. (a). Schematic of two coupled fiber loops for realizing the synthetic temporal lattice. (**b)** Illustration of the effects of scalar and vector potentials: inducing vertical and horizontal shifts of the band structure, respectively. (**c)**

Diagram of a temporal heterolattice with a gauge-potential interface; the green arrow indicates the Goos–Hänchen shift along the interface due to temporal total internal reflection. (**d)** Band structure matching between the left and right regions across the interface. (**e)** Dependence of the Goos–Hänchen shift on the relative scalar potential difference. (**f)** Temporal evolution of the reflected wave packet; the green arrow marks the Goos–Hänchen shift.

We propose the construction of photonic gauge-potential heterointerfaces using synthetic temporal lattices, and experimentally confirm the existence of temporal Goos–Hänchen shifts (GHS) in discrete-time reflections. The physical connection between GHS induced by single-interface total internal reflection and by finite-width potential barriers is revealed. Moreover, we introduce an accumulation-based reflection scheme to enhance the precision for detecting small GHS values.

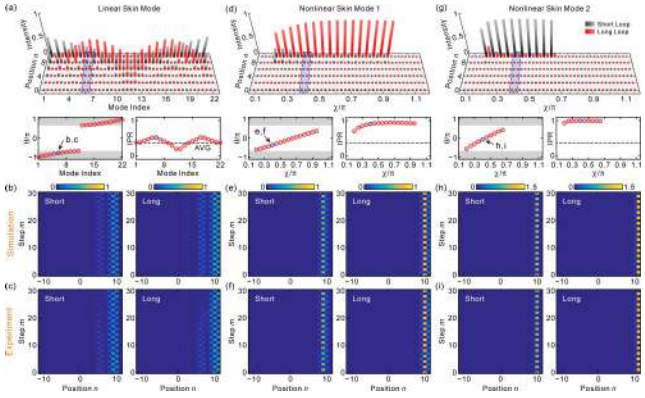

Fig. 3. (a) Mode profiles, eigenvalue spectrum, and IPR of linear skin modes. The black and red bars in mode profile subplot correspond to short and long loops, respectively. The gray zones in spectrum indicate the real parts of bulk band structure, and the circles correspond to the skin modes. The dashed line in the IPR subplot represents the IPR of the averaging intensity of all skin modes. **(b),(c)** Simulated and measured intensity evolutions of the 6th linear skin mode. **(d)** Mode profiles, eigenvalue spectrum, and IPR of nonlinear skin mode 1 versus Kerr coefficient χ. **(e),(f)** Simulated and measured intensity evolutions of nonlinear skin mode 1 for $\chi = 0.4\pi$. **(g)-(i)** correspond to the nonlinear skin mode 2.

We experimentally demonstrate the nonlinear non-Hermitian skin effect (NHSE) in a Kerr-like temporal photonic lattice, where opto-electronic feedforward provides tunable artificial nonlinearity without requiring high optical power. Kerr self-trapping enhances localization and robustness at the boundary, and can suppress NHSE transport to form stable skin solitons. Leveraging this effect, we design a nonlinear optical router with tunable output. These results hold promise for robust signal transmission and photonic routing.

Abstract: All-optical permittivity symmetry breaking leads to tailored ultrafast resonances in a Si thin film.

Photonic bound states in the continuum (BICs) are among the most versatile tools in optics and nanophotonics. Yet, as for most of the nano-optics toolkit, they require samples to be patterned at the nanoscale. In this talk we discuss an addition to this toolkit, where permittivity symmetry breaking via optical means is used for the excitation of photonic BICs in an unpatterned medium. Tailored ultrafast resonances and spectrally-selective third harmonic generation are demonstrated in an amorphous Si thin film. This method circumvents the optical bandwidth constraints imposed by sample patterning and allows a whole set of materials with small electro-optical coefficients to be exploited in light manipulation.

Flat band finetuning and its photonic applications

S. Flach[1*]

[1]Institute for Basic Science, South Korea
[*]corresponding author: sflach@ibs.re.kr

Abstract: Flat bands – single-particle energy bands – in tight-binding lattices, aka networks, have attracted attention due to the presence of macroscopic degeneracies and their sensitivity to perturbations. They support compact localized eigenstates protected by destructive interference. This makes them natural candidates for emerging exotic phases and unconventional orders. In this talk we consider the recently proposed systematic ways to construct flat band networks based on symmetries or fine-tuning [1]. We then discuss how the construction methods can be further extended, adapted or exploited in presence of perturbations, both single-particle and many-body. This strategy has lead to the discovery of non-perturbative metal-insulator transitions, fractal phases, nonlinear and quantum caging and many-body nonergodic quantum models. We discuss what implications these results may have for the design of fine-tuned nanophotonic systems including photonic crystals, nanocavities, and metasurfaces.

[*]corresponding author: sebastien.cueff@ec-lyon.fr

Abstract: We exploit low-loss phase-change materials such as Sb_2S_3 to propose and demonstrate integrated photonic devices with original programmable functionalities.

Phase change materials (PCMs) are currently revolutionizing nanophotonics by providing ways to tune and reconfigure optical functionalities without any moving parts. Building on this phenomenon, the last decade has witnessed many exciting reports of novel devices exploiting PCMs such as for example beam-steering, tunable light emission, reflection and absorption, programmable metasurfaces and reconfigurable neural networks [1-3]. A large majority of the first studies were using standard PCMs such as GeSbTe as simple binary on-off switches, in which the ON state is the amorphous phase and the OFF state the fully crystalline phase. However, PCMs present another degree of freedom for tunability: the possibility to encode multilevel non-volatile states via partial change of phase. Furthermore, recently a new class of low-loss PCMs emerged (e.g. Sb2S3 and Sb2Se3), with negligible optical absorption in the near-infrared [4,6].

In this talk, we will present recent results on the physics and properties of PCMs and on original methods to program PCMs into various multilevel states of crystallization. We will then present nanophotonic devices leveraging this multilevel programming and conclude on the perspectives for this technology.

We acknowledge fundings from the French National Research Agency (ANR) under the project MetaOnDemand (ANR-20-CE24-0013).

Near-unity absorption in semiconductor nanowire metasurfaces

Michael. E. Reimer[1*]

[1]Department of Electrical and Computer Engineering and Institute for Quantum Computing, University of Waterloo, Ontario N2L 3G1, Canada
[*]Corresponding author: mreimer@uwaterloo.ca

Abstract: Semiconductor nanowire metasurfaces can be engineered for realizing near-unity absorption efficiency to enhance the performance of photodetectors. We demonstrate ~95% absorption efficiency by controlling the nanowire geometry and spacing. This also improves the photodetector response time by significantly reducing device capacitance and controlling the spatial location of the absorption profile.

The ability to detect light with high speed and near-unity efficiency is desirable in photodetection-based applications. However, photodetectors have limited detection efficiency in the 850 nm – 1100 nm wavelength range, known as the 'valley of death'. In this talk, novel semiconductor nanowire metasurfaces will be presented that absorb light with near-unity efficiency in this 'valley of death' wavelength region. By controlling the nanowire geometry and pitch, we show enhanced absorption efficiency with an average of 94% absorptance over the wavelength range from 900-1600 nm [1]. We also designed multimode nanostructure resonators that generate Kerker interference at the target wavelength of 920 nm. For such metasurface absorbers, we demonstrate a peak absorptance of ~95%. By modifying the dimensions and pitch of the resonators, the Kerker resonance peak can be controllably shifted. We also show that our design enables spatial control of the absorption profile within the resonators, which is promising for a novel class of photodetectors with improved timing response without sacrificing detection efficiency. Finally, we will present our most recent work where we show photodetector devices with a fast time response (~100 ps) and high external quantum efficiency (> 90%), and progress in enhancing the performance of single-photon detectors with semiconductor nanowire metasurfaces.

Abstract: Topological photonics allows us to systematically handle information derived from the topology of light, such as optical spin and orbital angular momentum. In this talk, we focus on an ultra-compact and low-power-consumption optical switch by manipulating the interference effect of orbital angular momentum using topological photonics.

Topological electronic properties have attracted a great deal of attention in recent years, and there are growing expectations for the discovery of novel physical phenomena associated with topologically protected surface states and the development of devices based on such phenomena. Inspired by this, research centered on "topological photonics," in which the topology of an electronic system is traced to a photon system, has been flourishing in recent years [1-3].

Topological photonics has a particularly strong affinity with optical circuits, and is characterized by its ability to control optical signals with specific internal degrees of freedom (optical spin and orbital angular momentum) within a circuit. Optical circuits integrate various functions essential for optical communications on a single chip to achieve high processing speed and energy efficiency, but current optical circuits cannot handle even the internal degrees of freedom of photons themselves. In such a situation, if these can be controlled, it will be possible to make significant progress on various issues that are reaching their limits in the field of photonics.

Since optical switches are indispensable for ultrafast optical information processing and are also important as pass gates for optical computing, it is essential to increase speed and downsize them. However, current optical switches based on Mach-Zehnder interferometers tend to have large device sizes, and more innovative operating principles are required for future photonics-electronics convergence. In this situation, we have realized an ultra-compact and low-power-consumption optical switch by manipulating the interference effect of orbital angular momentum using topological photonics [4, 5]. Since the interference effect of orbital angular momentum occurs within the unit cell of a topological photonic crystal, it can ultimately be downsized to the size level of the unit cell. In this talk, we will mention the details.

Abstract: High-coherence visible and near-visible light is generated by combining second-harmonic generation (SHG) with self-injection locking (SIL) of a pump laser. Both SIL and SHG processes occur within high-Q Si_3N_4 microresonators. SHG is enabled by the photogalvanic effect together with all-optical poling, which induces a second-order nonlinearity in the Si_3N_4 microresonator.

Very Large-Scale Integration for Fibers (VLSI-Fi): Assembling Fiber-Embedded Photonics and Optoelectronics by Melt-Shaping Multimaterial Cores

Alexander Gumennik[1*]

[1]Indiana University Bloomington, Indiana, United States of America
[*]corresponding author: gumennik@iu.edu

Abstract: Fiber optics interconnecting the post–Moore's law Internet is likely to embed photonics with data processing capabilities. Inspired by the VLSI design of modern microprocessors, we melt-shape multimaterial fiber cores into architectures typical of integrated circuitry to realize fiber-embedded photonics. We dubbed this fabrication approach the "VLSI for Fibers."

The information medium of the 20th century was revolutionized twice: first with the invention of the integrated circuit, boosting data processing, and second with the demonstration of low-loss fibre optics, bringing data communication up to speed. Those two components lay the basis of the Internet in its current form: a global-scale network of data-processing nodes interconnected by high-throughput communication links.

Similarly, in the 21st century, we find ourselves on the verge of a transformative leap in the hardware used for data processing and distribution. With modern lithography reaching the ability to define features so minute they are only a few tens of atoms in cross-section, Moore's law – the necessity of doubling the areal density of transistors on a microprocessor every two years – has factually reached its physical limit driving the emergence of a whole plethora of alternative computation schemes. From spintronic and photonic to neuromorphic and quantum, the novel computational hardware platforms differ from one another in terms of the protocols used for data processing and even employ physically disparate forms and degrees of freedom in which the data itself is encoded.

Yet, fibre optics – the workhorse of digital communication - still awaits the transformation that would enable it to interconnect those diverse platforms into one harmonized network. The fibre of tomorrow will need to translate the data across those platforms. Integrating on-the-fly data transformation capabilities into fiber optics is likely to require combining photonic and optoelectronic devices and systems directly within the fiber itself.

At least one example of a comparable technological leap occurred in integrated microelectronics in the 1970s with the invention of the Very Large-Scale Integration (VLSI) approach to microprocessor design and fabrication. VLSI enabled a complete restructuring of the microelectronics industry, allowing one to think about microprocessors in terms of circuit design software, hiding the device physics "under the hood."

In fabricating a microprocessor designed using VLSI, the photoresist is deposited on the silicon wafer, which is then selectively exposed through photolithography. Exposed areas are then functionalized by a series of chemical and thermal treatments. This defines a single layer **2D** cross-section of the microchip. The process is repeated, layer by layer, resulting in a "pie" of connectorized layers stacked perpendicularly to the wafer surface in an additional **1D**. Ion implantation into the semiconducting substrate and annealing of dopants functionalize each device electronically, providing a **0D** structural and functional control on the level of an individual device. The result is the microprocessor's **3D** (or, rather, **2D+1D+0D**) structure.

Would it be possible to formulate a similar toolbox for architectural patterning of fibre-embedded structures? We develop such a toolbox, demonstrated in Figure 1. We call it the "VLSI for Fibers" [1] (or "VLSI-Fi"), and it combines several patterning approaches to control in-fiber multimaterial architecture in all three dimensions:

- **(2D)** In the fiber cross-sectional plane, the structure is defined by 3D printing the preform cladding, filling its voids with functional materials, such as metals and semiconductors, and scaling the cross-section geometry down by a thermal draw of the preform into a fiber.
- **(+1D)** Along the fiber axis, we pattern the initially continuous functional-material cores into periodic arrays of spheres using a material-selective spatially coherent capillary breakup, yielding self-assembly of electronic and photonic devices and structures in fibers, with tight dimensional control on multiple scales, from submicron to millimetric. We have recently discovered [2] that a typically chaotic capillary instability becomes predictable, and thus engineerable, in a wide yet well-defined range of processing regimes.
- **(+0D)** Internally to an individual active-material sphere, we control the crystallinity and electronic properties, forcing it to solidify from a melt along the externally imposed temperature profile. This will result in segregation-driven dopant redistribution and crystallinity defined by the stability of the solidification front.

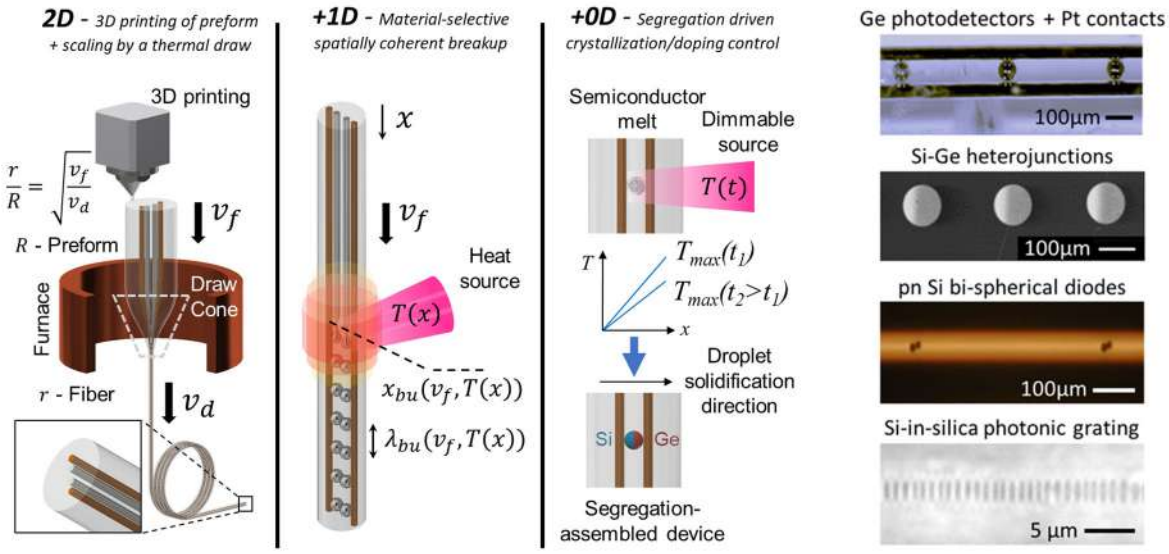

Figure 1. VLSI-Fi and the library of fiber-embedded structures realized by it [from Ref. [1]]. The manufacturing approach includes (from left to right) thermal draw of 3D printed preforms, system assembly by a spatially coherent material-selective capillary breakup (for instance, of an array of bi-spherical pn Si diodes), controlled recrystallization, and dopants redistribution (for example, of Ge mixed into Si) in an externally induced time-varying temperature gradient, due to higher solubility of the dopant in a liquid than in solid phase of the solvent material. **Notations:** R-preform radius, r-fibre radius, R/r-draw scaling factor, v_f-feed speed, v_d-draw speed, x_{bu}-breakup location, λ_{bu}-breakup period, T(t,x)-spatiotemporal temperature profile.

Abstract: Traditionally, photonic crystals are associated with the Bragg condition requiring subwavelength periods. However, over the resent years we developed direct laser written long period photonic crystals based on the Laue diffraction condition, as spatial filters. Development of such bulk structures evolving into spatial dispersion shaping for nonlinearity control.

Typically, photonic crystals (PhCs) are associated with a periodic distribution of refractive index with lattice constants on a subwavelength scale. Smart engineering allows smart light manipulation, for instance, having omnidirectional reflectors[1], switching devices[2], advanced sensors[3] etc. In terms of optical modes of operation, associated with the visible or sometimes the near-infrared range the lattice constants are achievable either by planar lithography (single or multi-layer), laser additive manufacturing, self-assembly, deposition-based methods, which in their own way provide superb resolutions, but either limit the dimensionality of the structure, the lattice geometry or are high resolution along limited dimensions (e.g. planar). However, with a shift in paradigm moving from the Bragg-like conditions (sub) to the Laue diffraction (sup-wavelength), one can achieve both transmittance and dispersion control with lower constraints in resolution and added benefit of moving in the realm of bulk processing and optical grade materials. This is important for high intensity laser applications, where optically induced damage can be an issue[4] and the technological steps to have resilient photonics are more complicated.[5] This Laue PhC concept is presented here.

The unique application that can make use of these structures is spatial filtering, mainly in laser cavities. By employing a multiphoton femtosecond direct laser wright approach interlaced phased gratings can be arranged in the bulk of an optical grade substrate (Fig. 1a). By engineering consecutive interlaced phase gratings one can produce a spatially resonant structure that has quasi-stop gaps only at preset incidence angles. If such a structure is placed inside a laser cavity it can even result in higher transverse mode suppression improving both the M^2 and Brightness output beam values per pump unit[6,7] (Fig. 1b). This led to the discovery that the principle is even applicable to gain patterns on the active media[8]. This is the simplest implementation and application of such PhCs.

However, most recently, we discovered that one can engineer the spatial dispersion curves not in terms of limited nodes, but their curvature itself[9]. This is important for a target application of counteracting the Kerr nonlinearity and suppressing destructive filamentation in cases, where one wants the propagation of high intensity beams for supercontinuum generation or other self-modulation effects (Fig. 1c). If the intensity is too high or propagation distances not controlled, one might lose the coherence of the generated beam. We demonstrate that smart engineering of the geometry allows us the manipulate the effective spatial dispersion enough to observe something alike to “antidifraction”, which is discussed in this paper in more detail.

Abstract:

How can we overcome the current challenges hindering the implementation of photonic accelerators in complex AI workloads? We explore an integrated all-optical neural architecture comprising: i) a high-speed and nonlinear photonic integrator as a neuron block, ii) an ultra-low loss photonic mesh with reconfigurable interconnections.

Artificial intelligence (AI) is reshaping modern computing, but its growing demand for data throughput and energy efficiency is pushing electronic platforms to their limits. Integrated photonics, and particularly Photonic Integrated Circuits (PICs), are promising alternatives due to their high bandwidth and low-power capabilities. However, despite demonstrating impressive performance in small-scale systems with fewer than 100 devices, fully optical AI accelerators have struggled to achieve widespread adoption due to fundamental challenges in scalability, nonlinearity implementation, and programmability. Contemporary photonic platforms remain constrained by their dependence on slow electro-optic conversions and electronic interfaces, while also lacking the flexibility needed for versatile connectivity and functionality [1]. In this work, we present a unified approach toward all-optical neuromorphic computing by combining two key building blocks: i) PHIL (Photonic-Heater-In-Lightpath) [2], which acts as a fully optical neuron unit, enabling high-speed temporal integration and reconfigurable nonlinear activation and ii) FPCA (Field-Programmable Coupler Array), which provides programmable, non-volatile interconnection between photonic neurons. By integrating both technologies, we outline a conceptual architecture where PHILs are interconnected via FPCAs, enabling cascadable and reconfigurable optical neural networks that operate without electro-optic conversion, paving the way for efficient photonic AI accelerators.

We present the first operation of an FPCA (see Fig 1a), providing programmable and reconfigurable interconnections between optical neurons. Our implementation is based on non-volatile units' cells using the low-loss phase-change material Sb_2Se_3 as the core tuning element, routing light by tuning the couplers implemented as 2×2 Mach-Zehnder interferometers. This allows compact π-phase shift in a compact footprint ($L\pi$ = 16.7 μm) with minimal insertion losses (~0.3 dB), thus enabling efficient and compact photonic meshes. We set a 4-coupler FPCA unit cell in a square mesh, achieving high extinction ratio switching (~20 dB) and programmable light routing via non-volatile states. We also demonstrate the reconfiguration of the FPCA as synapsis in a fully optical neuronal computing mimicking a functional ring resonator by selectively programming the coupling state of individual couplers, represented in Fig. 1a. Resonance wavelength tuning and coupling strength control are achieved by adjusting the PCM refractive index. Switching energy ranges from 0.15 μJ (amorphization) to ~1 mJ (crystallization), after which no static power is required.

We subsequently introduce the concept of the PHIL which performs two key neural operations: signal integration and nonlinear activation, entirely in the optical domain. Specifically, counter-propagating standing waves create high-field antinodes aligned with titanium nano-antennas in a ring resonator, enabling wavelength-selective absorption and localized thermal accumulation (see Fig 1b). This induces a controlled

thermo-optic phase shift on a low-loss probe signal. Crucially, PHIL achieves signal integration at 50 GHz over a ~130 ns thermal window, allowing the accumulation of up to 6,500 signals per wavelength, mirroring the integration function of biological neurons. Beyond integration, PHIL also enables fully photonic nonlinear activation, analogous to neuronal firing. This is achieved by exploiting the Lorentzian lineshape of the microring resonance. By tuning the probe wavelength (λ_PS) relative to the resonance peak, the thermal response from control signals (λ_cs-a and λ_cs-b) produces different nonlinear transfer characteristics. Varying the spectral position of the probe along the resonance slope leads to distinct output behaviors, ranging from quasi-linear to strongly nonlinear responses. We experimentally validate this behavior by injecting a continuous-wave control signal and measuring the transmission at different probe, confirming the tunable shape-dependent modulation.

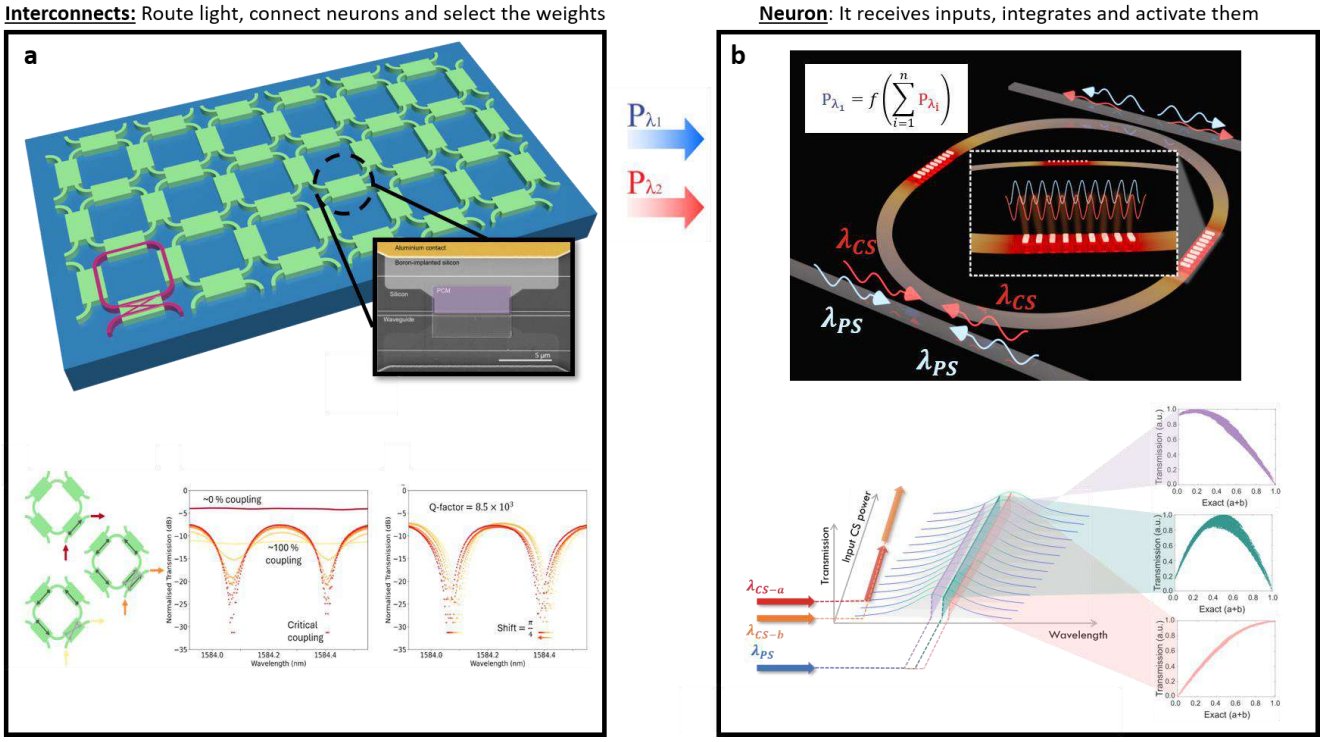

Figure 1. a) Interconnections block based on FPCA, implemented by unit cells with low-loss and non-volatile phase change material. b) Neuron block based on PHIL implementation based on standing wave activating the titaniu nano-heaters located on the top of the ring.

In summary, we present a unified neuromorphic photonic platform composed of two complementary modules, the neuron block (PHIL), with an approach that enables fully optical temporal integration and nonlinear activation functions, and the programable mesh (FPCA), with a compact, non-volatile and programmable photonic mesh. Combined, these building blocks establish a scalable, cascadable and energy-efficient architecture for AI acceleration, offering full programmability and functionality in the optical domain.

Abstract: We report on strong coupling between surface plasmons and excitons in an optically nonmetallic excitonic dye-polymer material of different thicknesses. We carried experiments of angular scans of reflectivity from silver and dye-polymer layers in a Kretshmann-Raether configuration, and we obtained the dispersive dielectric constant of the dye solutions for different dye concentrations using Lorentz model. Reflectometry theoretical experiments yielded dispersion relations of hybrid modes of propagating surface plasmons and excitons. The latter exhibit anticrossing which is the signature of strong coupling. The energy of Rabi splitting, E_{Rabi}, is sample dependent, and is in the 173-215 meV range. Strong coupling between surface plasmons and excitons is due to the field localization and enhancement as well as the sharp transition in the absorption spectrum of the excitonic material.

Interfacing the brain by photonic technologies

Abstract

A frequency response in the sub-THz regime of strained ferroelectric materials forming chiral polar ferroelectric vortex-antivortex lattices (FVL) in a meta-stable state has been observed experimentally. In this contribution, we discuss the physics of the interactions in the sub-THz regime and aim at a corresponding numerical full-wave model.

1 Introduction

Conventional bulk ferroelectric materials have been used in electronic and optical devices for decades. The recent discovery of strained ferroelectric materials forming chiral polar ferroelectric vortex-antivortex lattices (FVL) in a meta-stable state and the experimental observation of a frequency response in the sub-THz regime [1] point to the potential of such materials to be used in electronic devices operating in the sub-THz regime. However, to understand the underlaying physics and to exploit the full potential of these materials, analytical and numerical models of their electromagnetic wave interaction are required but have yet to be developed.

2 Modeling

A schematical view of a FVL is shown in Fig. 1. The structure is invariant along the z-direction and the distance between the (anti-) periodic polar vortices is d and $2d$ in the x and y direction, respectively. One prominent candidate of such a strucutre consists of alternating perovskite layers of strontium titanate (STO) and lead titanate (PTO) grown on a dysprosium scandium oxide (DSO) substrate [not shown in the figure], where d is on the order of 10 nm [1]. Based on these size parameters in conjunction with Bloch's theorem, one assumes a frequency response in the optical regime. However, although counterintuitive, the experimental observation of a frequency response in the sub-THz regime, where the wavelength is on the order of 1 mm and thus drastically exceeds the size parameters of the FVL, has been reported [1]. The reason for this is a coupling of the electromagnetic wave with the polarization vortices, as given by the Maxwell equations

$$\nabla \times \mathbf{E} = -\mu_0 \frac{\partial \mathbf{H}}{\partial t}, \qquad \text{(1a)} \qquad\qquad \nabla \times \mathbf{H} = \varepsilon_0 \frac{\partial \mathbf{E}}{\partial t} + \frac{\partial \mathbf{P}}{\partial t}, \qquad \text{(1b)}$$

where $\mathbf{E}$, $\mathbf{H}$, and $\mathbf{P}$ are the electric field, magnetic field, and polarization density, respectively, and ε_0 and μ_0 are the vacuum permittivity and permeability. It should be noted that the polarization density $\mathbf{P}$ is a superposition of dielectric polarization density $\mathbf{P}_\mathrm{d}$ and spontaneous polarization density $\mathbf{P}_\mathrm{s}$ where the former describes the dielectric response of the material (usually

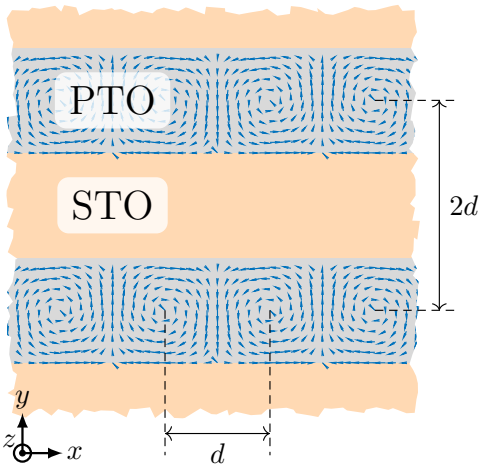

Figure 1: Cross-sectional view of a ferroelectric vortex lattice composed of alternating layers of PTO and STO. The spontaneous polarization $\mathbf{P}_\mathrm{s}$ is indicated by the arrows and evolves predominantly in the PTO material. The distance between the polar vortices is d and $2d$ in x and y direction, respectively. The structure is assumed to be invariant along the z-direction.

taken into account via a relative permittivity ε_r) and the latter refers to the vortex lattice structure. Microscopically, the spontaneous polarization density is caused by discrete dipoles, indicated by the arrows in Fig. 1. Once an electromagnetic wave interacts [cf. (1a) and (1b)] with a FVL, the dipoles' steady state is slightly perturbed yielding a restoring force towards the steady state and subsequently an oscillation. This is the case for a transversal electric (with the axis of invariance) polarized wave, when the electric field lies in the same plane as the polarisation vortices. As experimental [1] and numerical [2] observations show, the eigenfrequency of these oscillations is in the sub-THz regime explaining the frequency response in this spectral regime. Contrary, in the case of a transversal magnetic wave, the electric field is perpendicular to the polarisation vortices, and hence no first-order (linear) interaction occurs [2].

To further investigate these interactions, rigorous numerical models are required. The core of these models is the description of the dipole dynamics in the FVL based on a second-order time-dependent Landau-Ginzburg-Devonshire (LGD) equation [3] minimizing the free energy of the system

$$\alpha_\mathrm{k}\ddot{P}_i + \frac{1}{L}\dot{P}_i = -\frac{\delta F}{\delta P_i}, \tag{2}$$

where α_k and L are kinetic coefficients, index i indicates the directional components of a vector and F is the free energy functional of the system taking into account strain, depolarization, gradient energy effects and mechanical displacement.

The interaction with the electromagnetic wave in a full-wave manner is then described by solving the system of coupled differential equations (1a), (1b), and (2).

Metamaterial grating Distributed Feedback laser Spatial Coupled-mode modelling

H. Benisty[1*], Y. Liang[2], A. Ramdane[2] and A. Lupu[2]

Abstract: A metamaterial grating based on arrays of cut-wires interacts with a laser ridge to provide resonant distributed feedback. We describe the device operation by a four-modes coupled-mode model. With proper parameters, it reproduces well the electromagnetically-induced-transparency type feature of the spectrum.

The concept of resonant units is central in metamaterials. The concept was recently applied to the grating that provide the feedback, wavelength selective mechanism, in ubiquitous distributed feedback (DFB) laser diodes. Usually, the grating is dielectric, and its units are as small as $\lambda/4n$ (about 250 nm in telecom DFB laser diodes), and cannot become resonant themselves. Careful interaction with metallic system can be used to implement the concept of resonant grating units. We describe here the approach followed in the recent publication [1] to model the corresponding device.

The device principle is shown in Fig.1. The cut-wire array is the grating (typical period Λ=250 nm) that acts as a metamaterial as well. The inner gold wire is made as adjacent to the active ridge as possible, in order to provide interaction with the ridge mode. If there were only one such element, we would have a DFB with a metallic grating, which typically behaves as a modulated loss device, with in general thresholds that are degraded due to metal losses, compared to dielectric feedback (refractive index modulation thanks to various flavours of ridge etching and regrowth).

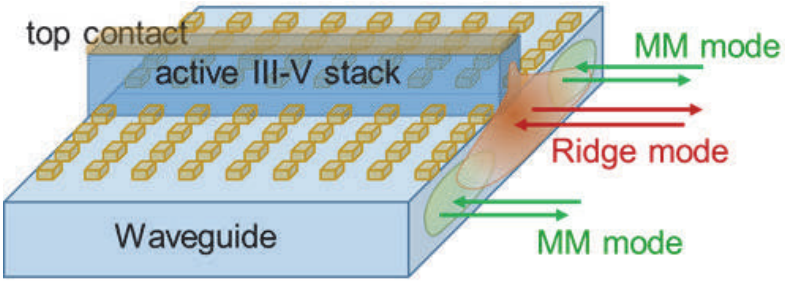

Figure 1: Scheme of a DFB laser diode with feedback provided on both sides by identical cut-wire arrays, made of gold "atoms". Each gold "atom" is a nanowire coupled to its neighbor.

By employing cut-arrays of wire, we favour a resonant behavior of the ensemble, and we get closer to the operation as a resonant metamaterial grating. However, attempts to model the cut-wires as separate resonators did not provide a good description of the observed spectra. Instead we found that the remaining dielectric guide under the cut-array should be considered as giving birth to the "MM modes" described in green in Fig.1, hence with slightly different effective indices in the ridge and for the "MM". Actually, both sides act together into a

single “supermode” of even parity. Also, the MM still has large losses, at least compared to the standard of good DFB values, but tuned in such a way that the impact is modest on the laser.

We will describe the coupled-mode theory modelling of this system. Due to the role of the grating, both modes (Ridge and MM) first interact with its counter-propagative partner. Then, we couple them together by a block matrix with two coefficients acting over the four modes. At the present stage, and for reasons that we believe to be similar to the dominance of loss over reflection in metallic DFB lasers, we do not introduce “cross-DFB” coupling with the ridge mode. Furthermore, in a Hermitian setting, we would select a rotation matrix, essentially. But here, given the various losses, we slightly modify the setting to go to a slightly non-Hermitian block matrix. As a result, we get the following dispersion relations, using five gradual sets of parameters to obtain a large modulation of the electromagnetically induced transparency (EIT) peak:

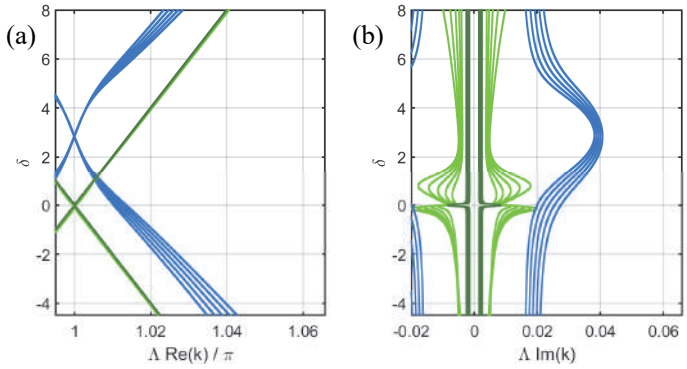

Figure 2: Dispersion relations of the system four modes given as frequency detuning δ around the Bragg frequency of the laser mode as a function of real (a) and imaginary (b) normalized wavevectors for a representative parameter span. Green are the hybridized laser modes and blue the MM modes. The dark-green line is the case of DFB only, without any MM interaction, i.e. not hybridized. It only has the small narrow dip at the Brag condition. The landscape around the Bragg peak is heavily affected by the coupling to the MM.

Essentially, the green lines of Fig.2(b) resemble closely the laser output spectra, which we analyse as an EIT feature (it is even sometimes above the background level by a couple of dB in experimental data).

We will discuss how 3D electromagnetic calculation of systems with much less periods than the actual lasers can be made to critically support (or critically question) this modelling approach.

Discretization effects in topological plasmonics

A. Neuhaus[1*], P. Dreher[1], and F.-J. Meyer zu Heringdorf[1]

Abstract: Determining the full electric field of surface plasmon polaritons (SPPs) is experimentally challenging. Therefore, experimental data often needs to be compared to numerical simulations. We use a Hankel-wavelet based simulation to address why Chern numbers, invariant in topologic plasmonic systems, are systematically smaller than the theoretical expectation.

The experimental determination of the vectorial electric fields of SPPs on the nano-femto scale has become possible in recent years by means of polarimetric photoemission electron microscopy (PEEM) [1]. This allows direct access to topological properties of these fields. Using this method, topological quasiparticles such as skyrmions [2] or merons [1] have been observed in the electric field or the spin angular momentum (SAM). The SAM is not subject to the diffraction limit and can thus exhibit deep sub-wavelength features [3]. To understand the effect of such deep sub-wavelength features on the derived topological quantities, efficient simulations are needed that include the effects of the finite resolution of the polarimetric PEEM experiment.

In a polarimetric PEEM experiment, SPPs are excited at a shaped excitation groove on a Au(111) platelet by a normally-incident pump laser pulse, as shown in Fig. 1a. To simulate the electric field of the SPPs we follow the approach by Davis et al. [4] and describe the SPPs by Hankel wavelets originating from the groove with an excitation wavelength of 800 nm. To create a meron pair topology within the SAM of the excited SPPs an Archimedean spiral groove with a gap of one SPP wavelength is illuminated with linearly polarized pump laser pulses. The simulated electric field vectors $\mathbf{E}_{\mathrm{spp}}$ in the center of the spiral are shown in Fig. 1b. The electric field vectors rotate in space with the SPP frequency due to the orbital angular momentum provided by the spiral. The magnetic field vectors $\mathbf{H}_{\mathrm{spp}}$ can be calculated from the electric field vectors using Faraday's law. Assuming time-harmonic fields with frequency ω_{spp}, the SAM can than be calculated from the electric and magnetic fields using the relation

$$\mathbf{s}(\mathbf{r},t) = \mathrm{Im}\int_{\mathcal{A}} \left(\mathbf{E}^*_{\mathrm{spp}} \times \mathbf{E}_{\mathrm{spp}} + \mu \mathbf{H}^*_{\mathrm{spp}} \times \mathbf{H}_{\mathrm{spp}}\right)/2\omega \tag{1}$$

and the result is shown in Fig. 1c. The two red-shaded SAM maxima in the center correspond to the two merons that form the meron pair. Such as skyrmions, merons are classified by their Chern number

$$C = \frac{1}{4\pi} \int_{A} \hat{\mathbf{s}} \cdot (\partial_x \hat{\mathbf{s}} \times \partial_y \hat{\mathbf{s}})\, dA, \tag{2}$$

which can be calculated from the normalized SAM vectors $\hat{\mathbf{s}} = \mathbf{s}/|\mathbf{s}|$. The integrand of eq. 2 is the Chern density, which describes the enclosed solid angle density between neighboring SAM vectors. The Chern density is shown in Fig. 1d for the simulated meron pair. Integrating the Chern density over the marked area in Fig. 1d should yield a Chern number of $C = 1 = 1/2+1/2$ given by the two individual merons within the meron pair. However, there is a true zero of the SAM field with $S_x = S_y = S_z = 0$ in between the two adjacent merons as visible in the center of Fig. 1c, that is called an amplitude vortex. As the Chern density is determined from normalized SAM vectors, the amplitude vortex acts as a point singularity. A point singularity should not contribute to the surface integral over the Chern density. In a discretized case however, such

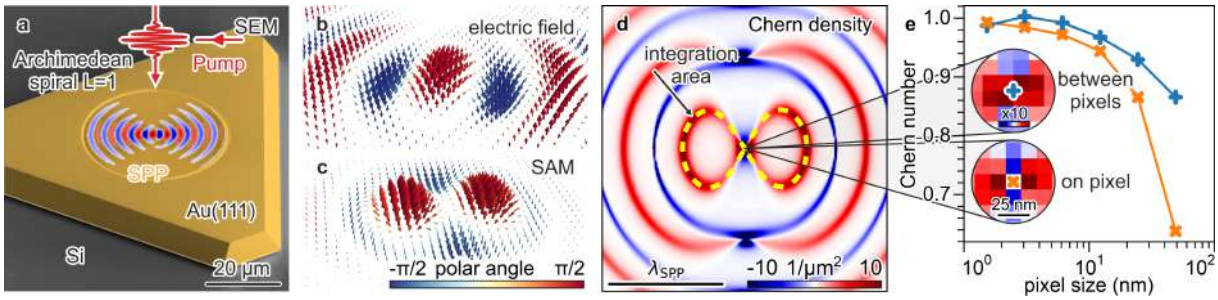

Figure 1: Excitation and analysis of a plasmonic spin meron pair. a) scanning electron microscope image of a structured Au(111) platelet excited by a linearly polarized pump laser pulse. b) simulated electric field configuration in the center of the spiral. c) simulated SAM texture in the center of the spiral. d) calculated chern density from the SAM texture. e) integrated Chern number as function of amplitude vortex position relative to pixel grid and pixel size.

point singularities are mapped onto pixels of finite size and thus can dramatically contribute to the integral. Therefore, the relative alignment of the vortex to the pixel grid and the pixel size are of great importance when analyzing SAM textures carrying point singularities. Figure 1 shows the expected Chern number for the meron pair as a function of pixel size and relative position of the amplitude vortex and the pixel grid. With decreasing pixel size, both relative alignments converge towards $C = 1$. For typical discretizations using polarimetric PEEM (approx. 10 nm) however, the Chern number is always strongly underestimated and heavily depends on the relative alignment.

The strong dependence of the numerically calculated Chern number on the pixel grid highlights the need for high resolution data and careful analysis of the topological SAM textures. The singularities occuring within the Chern density can significantly change the Chern number when analyzing experimental data. Numerical simulations of the SPPs can help to disentangle real topological features from contributions caused by the pixelation of the data itself. Generally one needs to be careful when analyzing topological SAM textures as these can contain all types of singularities in the Chern density, significantly contributing to the overall Chern number.

Terahertz metasurface for realizing high-Q chiral BICs

Xinyue Liang[1], Jian Liu[1], and Xumin Ding[1*]

[1] Advanced Microscopy and Instrumentation Research Center, School of Instrumentation Science and Engineering, Harbin Institute of Technology, Harbin 150080, China

Abstract: We propose a metal metasurface design for terahertz chiral sensing systems, leveraging symmetry-protected bound states in the continuum (BICs) to realize high Q-factor transmissive terahertz (THz) chiral response. This provides new perspectives into the creation of novel BICs in terahertz, advancing terahertz spectroscopy, polarization optics, and biochemical sensing applications.

Chiral research plays a pivotal role in analytical chemistry, pharmaceutics, and related disciplines. However, detection sensitivity has long been constrained by intrinsic physical limitations of natural materials, posing signal-to-noise ratio challenges for detection devices [1, 2]. Metasurfaces can induce strong interactions between chiral fields and chiral substances, enabling chiral effects far surpassing those of natural materials which are versatile applications [3,4]. The bound states in the continuum (BICs), characterized by theoretically infinite quality factors(Q), has opened new avenues for achieving high-Q chiral optical responses [5,6]. Here, we integrate metasurfaces with BICs physics to design a chiral BICs metasurface, achieving chiroptical responses with high-Q factors and enhanced sensitivity.

Our chiral BIC metasurface utilizes dual Z-shaped configurations (Fig. 1a) with in-plane inversion C_4 symmetry but lacking in-plane mirror symmetry to establish quasi-bound states in the continuum (q-BICs). Intrinsic planar chirality is achieved under normal incidence, demonstrating maximum circular dichroism (CD) values of 0.41 (theoretical) at 0.81 THz and 0.36 (experimental) at 0.79 THz. The q-BICs state maintains a strongly enhanced local field within structural gaps, exhibiting up to 432.0-fold enhancement (Fig. 1c).

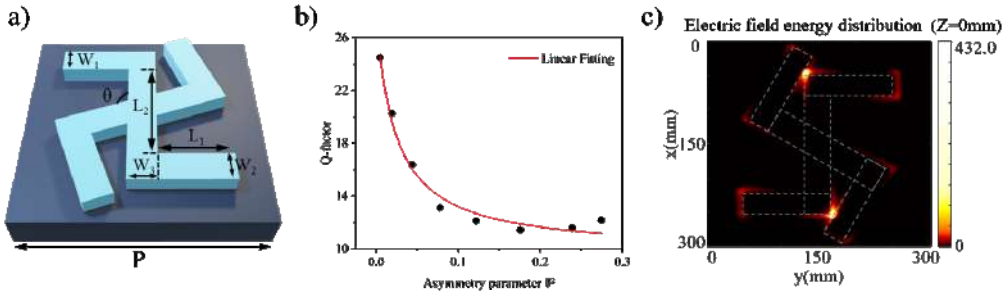

Figure 1. a) Schematic of the unit cell of a planar chiral q-BICs meta-surface formed by an aluminum dual Z-shaped configurations on a SiO_2 substrate. b) Dependence of the Q-factors of the planar chiral q-BICs mode on the relative asymmetry parameter θ^2 around the chiral q-BICs state. The curve shows a quadratic fitting. c) Electric field energy distribution of the planar chiral q-BICs meta-surface with circular eigen-polarization.

Figure 2 demonstrates the sensing performance metrics of the metasurface as a sensor. Fig. 2a illustrates that the chiral resonance peak undergoes a redshift with increasing refractive index of the analyte material, while maintaining a consistently above 0.3. The sensor sensitivity reaches S = 200.239 GHz/RIU (Fig. 2b). The

Q-factor of the resonance peak exhibits minor fluctuations around 13 with increasing refractive index (Fig. 2c), while the FOM value oscillates slightly above and below 4.5 (Fig. 2d). This highly sensitive chiral sensing system provides a viable solution for identifying chiral biomolecules with diverse refractive indices.

Abstract

We study the transport properties of honeycomb-like elastic ribbons composed of resonators and finite phononic crystals called coupled resonator phononic waveguides. Spectra for ribbons with zigzag and armchair edges were obtained for various ribbon widths. Although zigzag ribbons are gapless, armchair ribbons display a gap depending on the ribbon width.

1 Introduction

Coupled-resonator phononic metamaterials (CRPnMs), recently introduced by our group, can replicate the electronic transport properties of condensed matter systems. The study of several phenomena that are hardly or impossible to study in that area is now possible with CRPnMs. Inspired by the coupled-resonator optical waveguides [1], CRPnMs allow for the precise engineering of higher-order couplings and satisfy a phononic tight-binding model similar to that of condensed-matter physics [2, 3]. Here we study the phononic transport of coupled-resonator phononic ribbons that mimic the behavior of graphene nanoribbons. The coupled-resonator phononic ribbons are composed of resonators coupled by finite phononic crystals arranged in a honeycomb lattice as seen in Fig. 1. When a normal-mode frequency of the resonator falls within the bandgap of the finite phononic crystal the wave amplitude associated with the normal-mode frequency localize within the resonator and decay evanescelty through the finite phononic crystal. When two or more resonators are coupled, the localized modes couple to each other yielding a set of modes that satisfy a phononic version of the tight-binding model.

2 Engineering of the coupled-resonator phononic ribbons

The graphene nanoribbons are graphene strips of width w and infinite length. They can have armchair or zigzag borders. The unit cell of the coupled-resonator phononic ribbons, that mimic the graphene nanoribbons, are depicted in Figs. 1 (a) and (b); these ribbons are repeated infinitely in the vertical direction. The resonators are hexagonal plates of side L_h and thickness e and are interconnected via finite phononic crystals. The unit cell of the connectors is formed by a square plate of $L \times L \times e$ and two cuboids of $h_c \times e \times L_c/2$. The resonators are located in the vertices of a honeycomb ribbon whereas

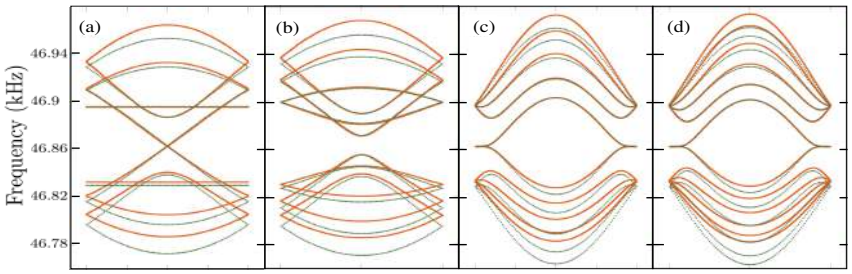

Figure 2: Band structure of the coupled-resonator phononic ribbons: (a) and (b) armchair ribbons of widths 5 and 6. (c) and (d) zigzag ribbons of widths 5 and 6. The continuous lines correspond to the finite element simulations and the continuous lines to the tight-binding model.

the finite phononic crystals connect them over the edges of the grid. The phononic crystal is designed to present a frequency bandgap between 38 kHz and 48 kHz whereas the resonant frequency of the hexagonal plate is above 40 kHz. All numerical calculations were performed using COMSOL Multiphysics.

3 Transport properties of the phononic graphene ribbons

Due to Bloch's theorem, the properties of the vibrations of the periodic (infinite) structures can be obtained by studying only a unit cell of the ribbons (See Figs. 1 (a) and (b)). The frequency spectrum will consist of bands and gaps in which vibrations can or cannot travel through the structure. In Fig. 2 the obtained band structures for the armchair –(a) and (b)– and zigzag –(c) and (d)– ribbons, are presented. As can be seen, the armchair ribbons could present a frequency bandgap, depending on the ribbon width, whereas the zigzag ribbons do not present such a bandgap and always transmit the vibrations independently of the ribbon width. Some wave amplitudes of the ribbons are given in Figs. 1 (c) and (d). In the zigzag case (c) one can observe a wave amplitude localized at the border of the ribbon. The armchair case (d) shows a wave amplitude localized in some dimers of the ribbon.

4 Conclusions

We obtained the vibration transport properties of phononic-crystal graphene ribbons. The obtained band structures show that armchair ribbons can present a frequency bandgap or a Dirac cone depending on the ribbon width, whereas zigzag ribbons do not present either a bandgap or a Dirac cone. As expected, the calculated wave amplitudes are localized on the resonators and connect through evanescent waves in the couplers.

Orienting fluorophores with the DNA origami for highly efficient plasmonic nanoantennas

Karol Kołątaj[1*], Aleksandra Adamczyk[1], Guillermo Acuna[1*]

[1] Department of Physics, University of Fribourg, Chemin du Musée 3, Fribourg CH 1700, Switzerland

Abstract: Here, we use the DNA origami technique to assemble an optical antenna and position a single fluorophore at the antenna gap with controlled, parallel and perpendicular orientation. We study the coupling for both conditions revealing a 5-fold higher fluorescence intensity when the emitter is aligned with the antenna's main axis.

For more than a decade, the DNA origami technique has been one of the most successful strategies in nanofabrication. Initially, due to its high addressability and specificity, DNA origami was extensively used as a nanometric platform to accommodate nanoparticles, biomolecules, and small molecules with nanometer precision. Moreover, DNA origami structures can be easily modified to arrange a predefined number of entities with stoichiometric control. Finally, just recently, the orientation of covalently bound molecules has been achieved by stretching the fluorophores incorporated into DNA origami structures.[1] Specifically, the orientation of a dye molecule can be varied from almost parallel to almost perpendicular relative to the dsDNA by linking the fluorophores to both sides with ssDNA while leaving some unpaired bases in the scaffold, as shown in Figure 1a.

Here, we present applications of this orientation scheme to produce highly efficient plasmonic systems. The investigated photonic nanoantennas were composed of two gold nanoparticles with a single fluorophore at the hotspot, oriented either parallel or perpendicular to the dimer's main axis (see Figure 1b).[2] We observed a remarkable 250-fold fluorescence enhancement when the dye was oriented along this axis - five times higher than the other orientation. Interestingly, despite orienting the dyes along the DNA origami structures, the performance of the nanoantennas remained rather inhomogeneous, with high signal dispersion. Therefore, we further investigated the dispersion of fluorescence enhancement for both configurations using superspherical NPs, comparing the distributions of enhancement factors to realistic simulations. We concluded that the dispersion of results arises from variations in molecular orientations and gap sizes.

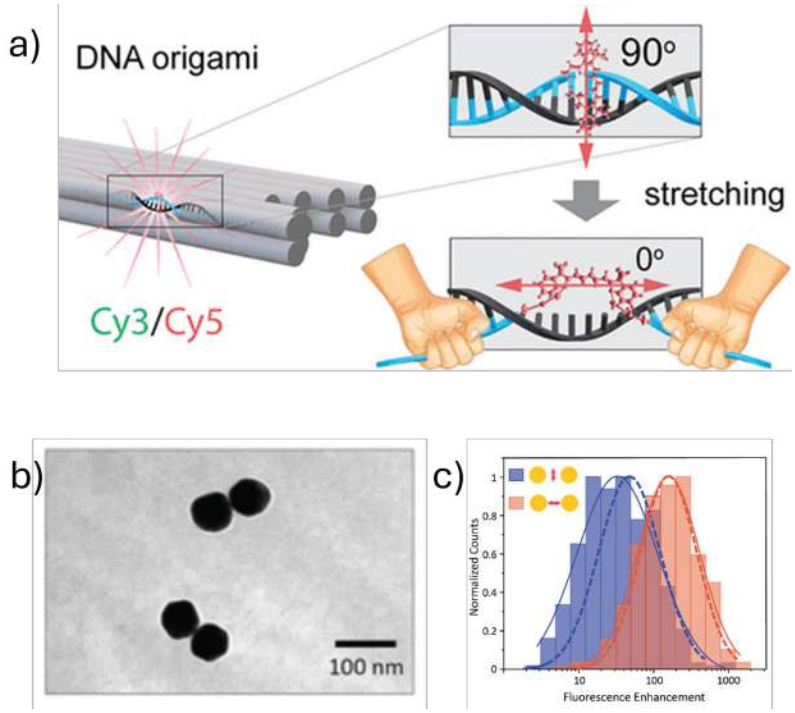

Figure 1. (a) Orienting fluorophores by applying a stretching force in the DNA origami structures (b) TEM image of the obtained optical nanoantennas (c) Fluorescence enhancement of the dye with a different relative orientation in the nanostructures.

Abstract: We demonstrate recently developed approaches for creating photonic structures and materials by mechanical machining and printing methods. The printable nanophotonic structures fabricable by imprinting and printing of metallic ink, the mechanically inscribed microtrenches with solution-processable metallic wires embedded therein, and the direct machining of metallic micrograting will be mainly presented.

We present several novel methodologies for facile, scalable, and cost-effective manufacturing of photonic structures and materials particularly by utilizing mechanical machining, printing, and imprinting techniques. First, we describe a rapid and simple method to create photonic Ag nanostructures through direct mechanical patterning – either imprinting or printing – of ionic Ag ink coating by using a soft elastomer patterning mold [1]. Then, we demonstrate the facile fabrication of metal wire-embedded microtrenches interconnected with semiconducting nanowires via continuous mechanical machining of micrograting trenches, mechanical embedding of solution-processable metal wires therein, and hydrothermal nanowire growth thereto [2]. Last, we demonstrate the highly scalable precision machining of metal micrograting structures by continuous mechanical scribing of the sawtooth-patterned cemented carbide edge tool over a metal workpiece [3]. We also discuss the excellent scalability, high productivity, and broad applicability of these methods along with their specific applications into the practical fabrication of diverse photonic materials and devices including but not limited to color filters, light sensors, and diffractive optical elements.

Linear logic operations in a quasi-digital system

R. G. MacDonald[1], A. Yakovlev[2], and V. Pacheco-Peña[1*]

[1] School of Mathematics, Statistics and Physics, Newcastle University, Newcastle Upon Tyne, NE1 7RU, United Kingdom

[2] School of Engineering, Newcastle University, Newcastle Upon Tyne, NE1 7RU, United Kingdom

Abstract: Electromagnetic (EM) wave-based quasi-digital logic operations are realized by carefully controlling the superposition of incident signals in a network of waveguides. Information is encoded into the wave characteristics of the incident signals (amplitude, phase or both). The encoding scheme is carefully selected to maximize the distinguishability of the operations.

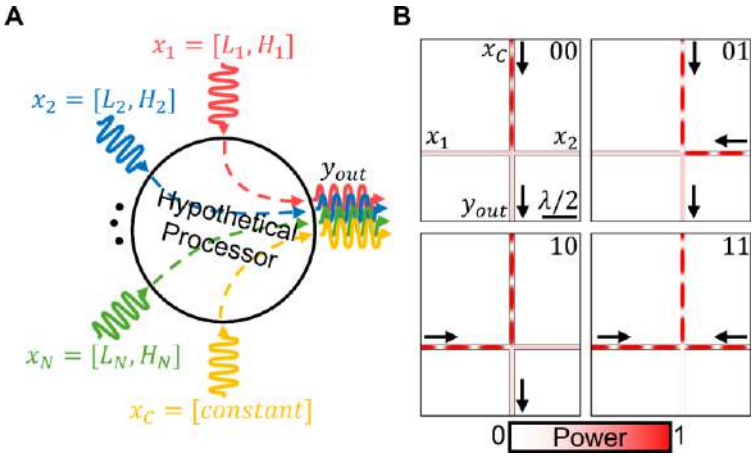

Figure 1. A. Schematic representation of a hypothetical quasi-digital processor based on the superposition of EM waves. **B.**, **C.** Numerical simulation results for the power distribution of a quasi-digital linear NAND operation.

Electromagnetic (EM) wave-based computing is an emerging paradigm which aims to harness the potential of waves[1] (high speed as an example). EM wave-based structures have been used in various computing tasks such as differentiation[2–4], integration[5], solving differential equations[6,7] and decision-making processes[8–11]. Conventional digital (or quasi-digital) computing operations including elementary logic operations have also been demonstrated[12–17]. Within this domain, a distinction exists between techniques exploiting structures with non-linearities[12–14] and those using a purely linear system. Using purely linear structures poses a challenge as output signals cannot be independently controlled[18]. This means there are a wide range of potential output signals, as opposed to a typically two-level system. Hence the adoption of the term, quasi-digital. Our work is focused on this challenge. In this work we will discuss the design of a linear system which can be used to produce distinguishable high and low output signals. i.e. where the contrast ratio $C_R = |20\log_{10}(Th_H/Th_L)|$ is maximized (Th_H and Th_L are the threshold values of the high and low output classification regions).

As will be presented in the conference, to address this, the information is encoded into the wave characteristics of input EM signals x_a (amplitude, phase or both), where $a = [1,2,\dots,N]$ is the input bit being represented. These signals, x_a, adopt one of two distinct values, L_a or H_a when a is low or high, respectively. Quasi-digital operations are then realized by carefully selecting these values such that the superposition of signals at the output y_{out}, resembles the desired logic operation, while maximizing C_R. This scenario is depicted in Fig. 1A. As an example, numerical simulation results (obtained using CST Studio Suite®) of a quasi-digital linear

NAND operation are presented in Fig. 1B, respectively. As it can be seen, the high output signal is clearly distinguishable from the low output signals indicating the linear structure is indeed emulating the NAND operation. During the conference, the core principles used to design quasi-digital logic gates will be presented along with further examples including the remaining elementary operations, many-to-one operations (*N*-input AND) and many-to-many operations (adders).

Abstract

Two-dimensional (2D) photonic crystals (PhC) are fabricated from opal slabs coated with an a-Si:C:H emitting layer. The optical response of the emitting 2D PhC's near Γ-point of the Brillouin zone have been studied. A significant increase in the luminescence intensity in the visible spectral range has been demonstrated in the synthesized structures.

1 Introduction

2D PhC's are currently as considered one of the most promising dielectric media for achieving enhance light emission by increasing the probability of radiative recombination, described by the Purcell factor [1]. In this work, we studied the possibility of increasing the photoluminescence (PL) intensity of an a-Si:C:H emitting layer, resulted from interaction with the modes of a 2D PhC fabricated on the basis of an opal slab. Such interaction can be realized if the a-Si:C:H emission is located above the photonic band gap, where various radiative modes of the photonic crystal can exist within the light cone [2]. The spectral position of the PL contour can be easily varied by changing the content of carbon in the a-Si:C:H film. The full width at the half-maximum (FWHM) of the PL contour of a-Si:C:H reaches a value of 0.6-0.7 eV.

2 Results

The samples of the opal slabs being studied include opal films [2-3 monolayers (ML) of a-SiO_2 spheres of diameter 520 nm with a spread in diameter smaller than 3] grown on fused silica substrates. The a-Si_{1-x}:C_x:H layer with a thickness of 250 nm was deposited on opal film by the plasma-enhanced chemical vapor deposition (PECVD) technique in a capacitive reactor at various relative flows of silane (SiH_4) and methane (CH_4). The optical thickness of the layers was monitored in-situ by the laser beam interference pattern. Carbon content in the film is x = 0.58, which corresponds to PL peak at 1.7 eV and refractive index n = 2.2 [3].

Angle-resolved optical spectra were measured using a Fourier imaging spectroscopy technique. For PL measurements, a 405 nm laser diode illuminates the sample by the from the backside. The spectral resolution of the setup is 0.17 nm, whereas the angular resolution is not less than 0.4° [4]. Theoretical analysis of the optical response of the structure included numerical calculations of the structure's eigenmodes and angle-resolved spectra performed by a Fourier modal method in the scattering matrix form.

The experimental and theoretical angle-resolved PL spectra are presented in Fig. 2(a, b) Due to a broad PL band in the range of 500–1000 nm, the PL spectra contain many peaks resulted from interaction processes of the a-Si:C:H emitting clusters with PhC modes near Γ-point of

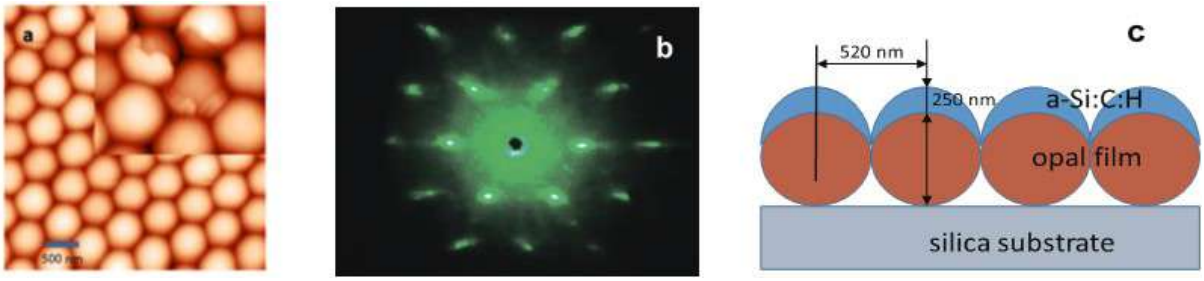

Figure 1: AFM image of the a-Si:C:H/opal slab (a). Insert: a fragment of the structure where the aSi:C:H film is partially absent and SiO2 spheres are exposed. Laser diffraction pattern of an a-Si:C:H/opal slab (b). Schematic view of the structure used in scattering matrix method calculations. Only one monolayer of SiO2 spheres is shown for simplicity (c).

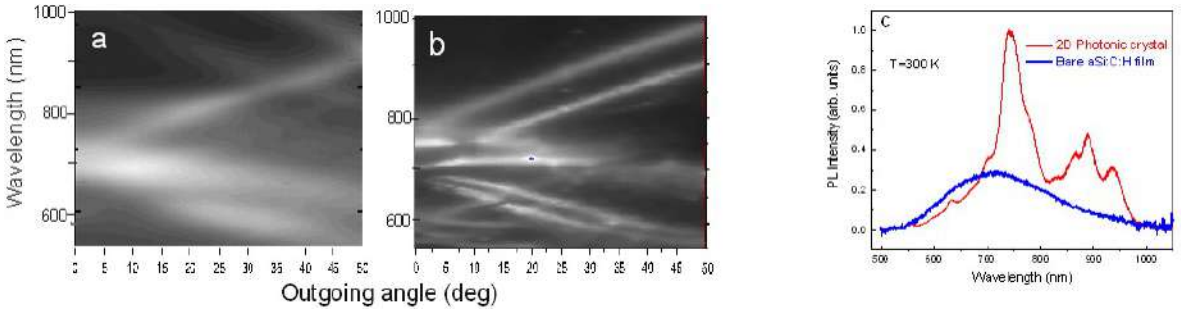

Figure 2: Experimental (a) and theoretical (b) angle-resolved photoluminescence spectra measured in p-polarization. Comparison of PL spectrum of the PhC with PL spectrum of the a-Si:C:H bare film (c).

the Brillouin zone. Figure 2c shows PL spectra from PhC slab coated with a-Si:C:H layer (a) and bare a-Si:C:H film (b) measured near Γ-point of the Brillouin zone. It is seen remarkable increasing PL intensity from PhC slab.

Finally, we have studied the angle-resolved PL spectra of 2D opal coated with a thin luminescent a-Si:C:H film. Since the measurements were carried out near the Γ-point of the Brillouin zone of the PhC, it can be assumed that the observed PL lines of different widths correspond to the interaction of the radiation of a-Si:C:H nanoclusters with PhC modes of different nature. The calculations of the PhC band diagram showed that in such structures it is possible to observe radiative modes located inside the light cone and characterized by a small group velocity, which appear in the PL spectra in the form of relatively broad, intense lines.

Hybrid Nanomaterials and Metastructures for Photonics, Sensing and Energy

Rhodium Nanospheres for Expanding Plasmonic Applications with UV and Visible Light

V. Amendola[1]

[1] Department of Chemical Sciences, University of Padova, Padova

[*]vincenzo.amendola@unipd.it

Abstract: Rhodium nanospheres synthesized via laser ablation in liquid address the UV plasmonic gap left by gold and silver and can be easily functionalized with thiols. The spherical morphology enables UV-visible optical sensing and benchmarking with classical electrodynamic models. Rh stability at high temperature and against acids outperforms Au and Ag.

Plasmonics has penetrated fields ranging from energy conversion to catalysis, biomedical analysis, nanomedicine, light management, and quantum phenomena. However, gold and silver nanostructures do not support plasmons in the ultraviolet (UV) region, while other UV-plasmonic compounds are not chemically stable and cannot be coated with functional molecules. Rh, on the other hand, has favorable characteristics for UV plasmonics, but its high cohesive energy leads to anisotropic nanocrystals with red-shifted plasmon resonance when their size exceeds 7–10 nm, which is the critical threshold for optimal performance.

To address this issue, in this study[1] we show the synthesis of Rh nanospheres (20–45 nm) via laser ablation in liquid (LAL). Unlike chemical routes, LAL avoids the formation of anisotropic shapes, preserving the spherical morphology critical for the plasmonic optical properties. The rapid cooling of Rh vapors in LAL prevents reshaping, and, while excess Rh oxide is formed, it is recoverable, promoting sustainability.

These nanospheres exhibit plasmonic behaviors modeled using classical electrodynamics, achieving a close match with experimental data. The extinction spectra, predicted via the Mie model, align Rh NPs with Ag and Au in terms of performance but uniquely extend functionality to UV ranges. In particular, Rh nanospheres display extinction cross-sections comparable to Ag and Au. While Rh's plasmonic quality factor is lower in the visible range due to interband transitions, it excels in the UV spectrum. Larger nanospheres exhibit pronounced red shifts (73 nm) in their LSP compared to Ag (24 nm) and Au (7 nm), indicating stronger size-dependent retardation effects. Moreover, Rh demonstrates balanced scattering and absorption cross-sections, making it suitable for near-field and nanolensing phenomena.

Joining the easy surface chemistry with thiolated molecules to the optical properties, functionalized Rh NPs detected toxic ions in aqueous solutions. Besides, the Rh NPs showcased stability in harsh environments (e.g., aqua regia, high temperatures) surpassing Au and Ag counterparts.

Rh nanospheres were evaluated also for surface-Enhanced Raman Spectroscopy (SERS) applications with UV and visible light, achieving calculated enhancement factors (G_{SERS}) up to 10^7 at 350 nm excitation. Numerical simulations confirmed optimal enhancement in dimers with 40 nm NPs at short wavelengths.

Although the LAL synthesis can still be optimized in terms of yield and size control, the versatility of Rh nanospheres for diverse applications emerged clearly, as well as the potential of the laser synthetic method for achieving this category of plasmonic tools.

Rhodium nanospheres bridge the gap in UV plasmonics, combining superior stability with optical performance comparable to traditional plasmonic metals. Their scalability, sustainability, and unique attributes herald innovative solutions across UV-visible plasmonic applications, including UV-visible nanosensing, catalysis, chiroplasmonics, and photodegradation of organic compounds.

Multiplexed, label-free biosensing with plasmonic nanoparticles

S. Kastner, A. Heewig, F. Seier, A. Csaki*, and W. Fritzsche[2]

Leibniz Institute of Photonic Technology (IPHT), Germany

Abstract: A biosensing platform using gold nanoparticle sensors immobilized in an array of spots is described, allowing after biofunctionalization to detect the respective target analyte molecules in a multiplexed assay. For detection, the shift in localized surface plasmon resonance (LSRP) peak due to the change in refractive index is utilized.

A biosensing platform based on the localized surface plasmon resonance (LSPR) principle has been developed: Gold nanoparticles (80 nm diameter) are thereby used as sensor: any change in refractive index around the particles induces a change in resonance frequency, which is monitored using UV/VIS imaging spectrometry. By modification of the nanoparticles with highly specific receptors molecules (such as DNA, proteins or aptamers), a molecular specificity can be achieved for the respective target molecules. In the case of DNA targets, a single-stranded (ss) DNA molecule with a sequence complementary to the target DNA is utilized, for detection of proteins and small molecules either antibodies or aptamers. The principle was demonstrated for both DNA [1,2] as well as protein detection [3]. Compared to fluorescence array formats, the chosen principle does not require labels, resulting in a more streamlined assay, and reducing time as well as costs. The platform is capable of multiplex sensing, by using an array of immobilized nanoparticle spots all incubated simultaneously in a flow chamber with the analyte solution, which can (by utilizing different receptors) detect the presence of multiple target molecules simultaneously in one assay [4,5]. Therefore, a gold nanoparticle solution is spotted by a piezoelectric tool in an array pattern with dimensions of about 300 µm spot diameter and similar scales of spot-to-spot distance. Biofunctionalization is by subsequently spotting thiolated molecules, which bind via a sulfur-gold bond to the sensor surface.

For readout of the LSPR peak shift, a spectroscopic monitoring of all spots is needed. Instead of a scanning approach (where the spots are subsequentially measured by a spectrometer) with the required mechanical movement of beam and/or sample, imaging spectrometry is utilized. This allows for a quasi-simultaneous spectroscopic readout of all spots (all pixels of the viewing field). Different approaches with spectrally filtered light have been compared: One method is using liquid crystal tunable filter (LCTF), which is quite flexible (the resolution of the reconstructed spectrum can be chosen, but higher resolution results in longer measurement times) but still complex and requiring costly equipment; the other one uses just a series of LEDs of different wavelength to reconstruct a spectrum [6], allowing for a very simple and cost-efficient detection.

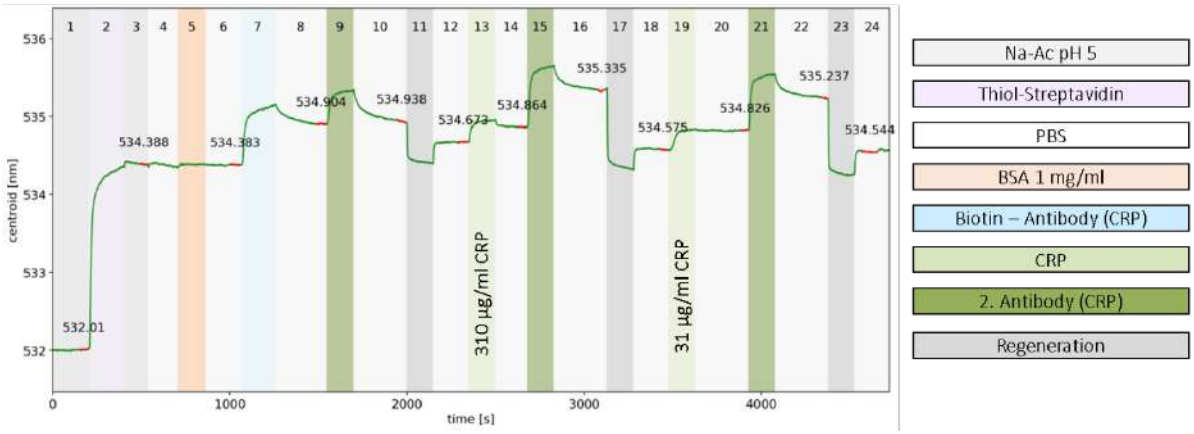

Figure 1. Sensogramm (LSPR peak wavelength centroid plotted over time) of the various steps (including sensor functionalization and control experiments) of a CRP protein detection assay. Different colors mean different (buffer/analyte) solutions. (From [3])

Plasmonic Nanostructures on Paper Lateral Flow Assays for Point-of-Care Testing

Nianqiang Wu[1*]

[1]Department of Chemical Engineering, University of Massachusetts Amherst, Amherst, MA 01003-9303, USA
[*]corresponding author: nianqiangwu@umass.edu

Abstract: This talk will introduce three types of plasmonic probes used in paper lateral flow assays. It will show how to utilize plasmonic nanostructures to amplify fluorescence and surface-enhanced Raman scattering signals. It will also demonstrate our effort to incorporate plasmonic nanostructure into paper lateral flow assays.

Plasmonic nanostructures exhibit color to human eyes due to surface plasmonic resonance (SPR) in the visible-light spectral range. As a result, plasmonic gold nanoparticles can serve as colorimetric probes,[1,2] which are extensively used in paper lateral flow strips (PLFS). However, such colorimetric PLFS suffer low sensitivity and poor resistance to interference in complex human fluidic samples, especially blood samples. In contrast, near-infrared (NIR) fluorescence and surface-enhanced Raman scattering (SERS) probes exhibit much higher signal-to-noise ration and much better interference resistance, but the sensitivity is still insufficient.[1,2] Therefore, we strived to couple plasmon with fluorescence or SERS to amplify signal. We also gained insight into the mechanisms of plasmonic enhancement of fluorescence or SERS. We optimized the structure of plasmonic nanostructure, and the overall architecture of optical probes based on the plasmonic enhancement mechanisms. We integrated the plasmonic fluorescence probes and SERS probes into PLFS, which show high sensitivity and good resistance to interference.[3,2] These plasmon-enhanced PLFS have been used to detect acute diseases such as traumatic brain injury, COVID-19, and HIV at point-of-care settings, such as home, schools, clinics and emergency departments. These efforts have paved new avenues for point-of-care testing.

Colloidal Synthesis of Chiral Plasmonic Nanocomposites via Circularly Polarized Light Irradiation

K. Saito[1*], Y. Nemoto[2], and Y. Ishikawa[1]

[1]National Institute of Advanced Industrial Science and Technology (AIST), Japan

Abstract: The synthesis of chiral plasmonic nanoparticles using circularly polarized light as a chiral source has attracted attention because it does not require any chiral molecules. In this presentation, we will report a novel method for colloidal synthesis of chiral plasmonic nanocomposites including AuNR@MnOx.

[Introduction] Nanoparticles of gold and silver with chiral shapes are called chiral plasmonic nanoparticles, and are expected to be applied to chiral sensing, asymmetric catalysis, etc. The synthesis method of chiral plasmonic nanoparticles using circularly polarized light as a chiral source has the advantage that it does not require chiral molecules [1]. For mass synthesis, it is desirable to synthesize chiral plasmonic nanoparticles in a state dispersed in solution, but the nanoparticles must be fixed on a solid substrate during the synthesis process, which has been a major challenge. We have succeeded in synthesizing rod-shaped chiral plasmonic nanoparticles that exhibit circular dichroism for the first time by driving a photochemical reaction that precipitates silver on the surface of gold nanorods (AuNRs) dispersed in solution with circularly polarized light [2]. At present, it is not clear how the chiral growth behavior changes depending on reaction conditions such as temperature. In addition, there have been no reports of the preparation of chiral plasmonic nanocomposites using materials other than gold and silver [3]. In this study, we investigated the effect of reaction temperature on chiral growth under circularly polarized light irradiation. Furthermore, we also succeeded in preparing chiral plasmonic nanocomposite by photo-induced deposition of manganese oxide on AuNRs.

[Experiment] AuNRs covered with silver (AuNR@Ag) were synthesized by irradiating left- or right-handed circularly polarized light (CPL) from a red LED (λ ~ 630 nm) on a dispersion of AuNRs containingcitrate and silver ion (**Figure 1**). CPL irradiation experiments at reaction temperatures of 5°C, 35°C, and 65°C were carried out using a water bath. We also tried to synthesize chiral AuNR@MnOx by adding permanganate reagent in the reaction solution. The synthesized nanoparticles were observed with a scanning electron microscope (SEM). The absorbance and circular dichroism (CD) of the dispersion were measured by using UV-vis and CD spectrometer. Because the CD signals depends on the absorbance of the dispersions, we calculated the g_{CD}-factors using the following equation (1) to compare between different samples:

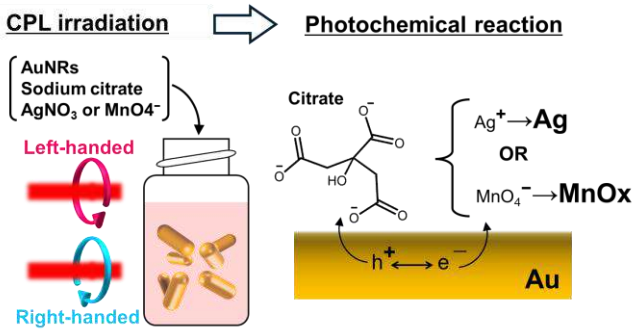

Figure 1. Schematic illustration of photodeposition of Ag or MnOx on AuNRs driven by CPL irradiation.

$$g_{CD} = \frac{4\pi \log_{10} e}{180} \frac{\text{CD Intensity (deg)}}{\text{Absorbance}} \quad (1)$$

[Results and Discussion] The absorbance peak wavelength of the AuNRs dispersion shifted to shorter wavelengths due to the silver deposition by circularly polarized light irradiation (**Figure 2a, c, e**). The peak wavelength shifted depending on the reaction temperature, and the absorbance at a wavelength of 400 nm increased. While silver deposition was accelerated at higher temperatures, the reaction was also driven at lower temperatures. As shown in Figure 2b, d, and f, CD signals were observed at all reaction temperatures. However, the CD spectra clearly changed depending on the reaction temperature. Interestingly, Interestingly, the g_{CD} values were larger at 35°C than at other temperatures. Temperature-driven silver deposition should not contribute to chiral growth. Therefore, we expected that a lower reaction temperature would be favorable for chiral growth, but the results were different from our expectation. When the reaction rate is too slow, silver deposition on AuNRs may be uniform. It was indicated that the rate of silver deposition can affect chiral growth behavior under CPL irradiation.

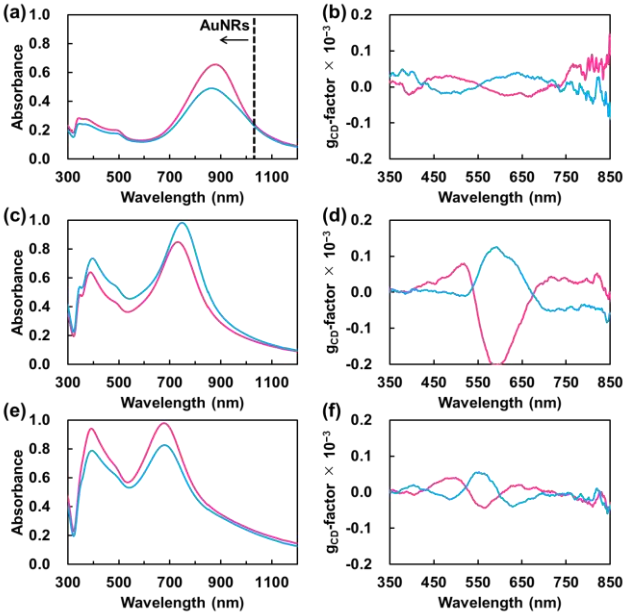

Figure 2. Absorbance and CD spectra of the AuNRs irradiated with LCP (pink) or RCP (blue) light at reaction temperatures of (a,b) 5°C, (c,d) 35°C, and (e,f) 65°C.

Figure 3a shows the absorbance spectra after CPL irradiation on colloidal AuNRs with permanganate. Unlike the case of silver deposition, the absorbance peaks were red-shifted. This result indicates that the refractive index around the AuNRs increased due to the deposition of MnOx. Indeed, several needle-like structures were observed around the AuNRs in the SEM image (Figure 3b). As shown in Figure 3c, the CD spectra clearly showed peaks and dips according to the handedness of the CPL. Although the composition and morphology of MnOx need to be investigated in detail in the future, we have succeeded in colloidal synthesis of chiral plasmonic nanocomposites of AuNRs and metal oxides via CPL irradiation for the first time. Because MnOx is useful as a catalyst, this study may contribute to the development of asymmetric catalysts.

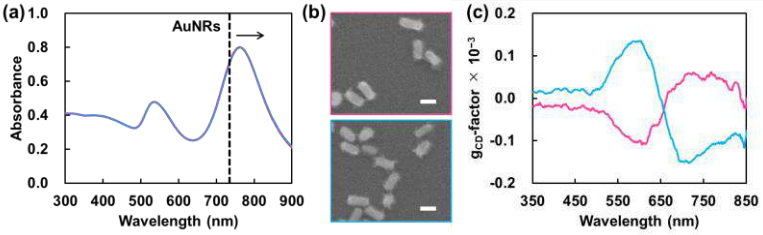

Figure 3. (a) Absorbance amd (c) CD spectra of the AuNRs with permanganate irradiated with LCP (pink) or RCP (blue) light (b) SEM images of the samples synthesized by LCP or RCP light.

Abstract: An external magnetic field forces the oscillation of superparamagnetic iron oxide nanorods, which cease to rotate above a frequency related to the local viscosity. The blinking of the scattered light is analyzed at high frequencies by heterodyne holography, and 3D rod superlocalization provides high resolution viscosity imaging.

In microfluidics and biology, many processes are driven or affected by viscosity. Mechanonsensing is indeed an essential signal pathway in the regulation of cell growth, proliferation or apoptosis, and this field of studies is now reaching out to other fields, including materials science and chemistry (e.g. polymers, soft and complex matter), clinical research (mechanical properties are crucial to cancer cells) and physics. Several methods can measure this parameter globally, but very few can provide high resolution viscosity images.

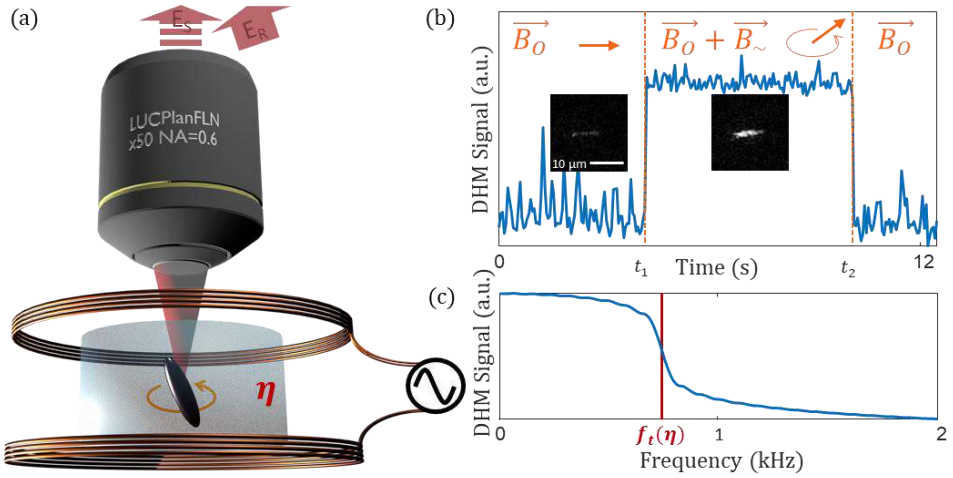

Figure 1 : a) Principle of the measurement. b) Holographic images (insets) and holographic intensity at the rotation frequency with a magnetic field turned off and on. c) Frequency dependence of the holographic signal. The cutoff frequency provides a measurement of the viscosity η.

To measure and understand the role of intracellular mechanical properties, we propose to use sub-micrometer magnetic rods to perform high resolution viscosity imaging. An external magnetic field forces the oscillation of superparamagnetic iron oxide nanorods (Fig. 1a). Under linearly polarized illumination, the rotation of these highly anisotropic optical scatterers induces a blinking which is analyzed by heterodyne holography (Fig. 1b). Rods can follow the slow rotation of an external magnetic field, but stop oscillating beyond a cutoff frequency due to the viscosity of the liquid (Fig. 1c). The local viscosity is therefore deduced from a spectral analysis of the rotation dynamics.

We have shown that 3D superlocalization with holography allows nm-range precision of nanoparticles as small as 30 nm, and that stochastic movements of the particle can be used to explore the environment and obtain a dense 3D super-resolved map. When using stochastic probes, however, Brownian diffusion affects the locality of the measurement. Optimizing the locality of viscosity measurements demands smaller probes but also shorter lateral diffusion lengths and measurement times. Indeed, during the measurement time τ_{acq}, Brownian probes travel stochastically over $\sqrt{D\tau_{acq}}$ (where D is the viscosity-dependent diffusion coefficient).

A calibration performed in model media (glycerol-water mixtures with variable concentrations) allows to validate the quantitative measurement of viscosity. We will show viscosity images obtained in various media and contexts, and show that holographic detection can reduce τ_{acq}, allowing to probe a volume of (0.5 μm^3). This time can be pushed further by increasing the magnetic field, frequency, and optical intensity. Coupled to 3D superlocalization by holography, this provides ultralocal (0.5 μm^3) viscosity measurements, paving the way for high resolution intracellular viscosity measurements.

Chiral photogrowth on plasmonic nanostructures under circularly polarized light

L. V. Besteiro[1*]

[1]CINBIO, University of Vigo, Campus Universitario de Vigo, Lagoas Marcosende, 36310 Vigo, Spain

[*]corresponding author: lucas.v.besteiro@uvigo.es

Abstract: With adequate conditions, achiral plasmonic structures under circularly polarized light can develop chiral shapes by photocatalytically imprinting on them the reduced symmetry of the local fields. Experimental realizations of this strategy can exploit different energy-transfer mechanisms. We will discuss the fundamentals of such light-to-matter chirality transfer and recent experimental demonstrations.

Plasmonic nanostructures offer strong resonant responses in the UV-to-IR spectral range, which has led to their use in many optical and energy-related applications. Plasmonic photocatalysis stands as a prominent example of the latter, with plasmonic nanostructures serving as nanoscale antennas funneling radiant energy into their local environment. This talk will cover a particular subset of plasmonic photocatalytic setups with two defining characteristics: (i) the light-driven process modifies the geometry of the plasmonic nanoparticle or the optical properties of its immediate environment, and (ii) does so preserving local asymmetries induced by impinging circularly polarized light (CPL). This creates chiral features in initially achiral shapes, hence transferring chirality from light to the nanostructures, and contrasting with common strategies yielding chiral plasmonic systems, where chirality is seeded from molecules or introduced through top-down fabrication methods. The presentation will cover theoretical considerations underpinning light-to-matter chirality transfer in plasmonics,[1] a discussion about the physical energy-transfer mechanisms driving this phenomenon,[2,3] as well an overview of experimental work going from pioneering examples[4,5] to recent progress.[6,7]

Abstract: We present the synthesis and characterization of Au-decorated Si core-shells as candidate meta-atoms. We found a damped magnetic dipole (MD) for smaller Si cores (100 – 130 nm) and an enhanced MD for larger cores (150 – 200 nm). Continuous plasmonic shells of ~12 nm are needed to significantly improve forward scattering.

Subwavelength-sized Si particles interact strongly with visible (vis) and near-infrared (NIR) light to produce strong electric and magnetic resonances. These can combine to produce interesting optical effects, such as pure forward scattering. A requirement for this to occur efficiently is that the electric dipole (ED) and magnetic dipole (MD) modes must be of similar amplitude and phase. At wavelengths where this occurs, the particles act analogously to the forward-propagating point sources of light used in Huygens' constructions. This directional scattered light has a range of potential applications in the creation of metamaterials.

We have investigated dielectric@metal core-shell architectures comprised of both resonant cores and resonant shells as candidate particles in which the spectral overlap of the electric and magnetic dipoles might be controlled to create strong directional scattering. There are currently two reports of the synthesis and characterization of Au shells around Si cores, both thicker than desirable. [1,2] Chaâbani *et al*. presented Si@Au particles, with non-uniform shells composed of Au particle diameters between 10 and 25 nm, which presented enhanced electric field and Fano-resonances due to the coupling of the Mie modes of the Si core and the localized surface plasmon resonance (LSPR) of the Au shell. [1] Sugimoto *et al.* similarly presented Si@Au particles with a rough ~25 nm Au shell. [2] In both of these reports of Si@Au core-shell particles, the experimental data could not be accurately fit by simulations due to non-spherical cores and inhomogeneous shells. Ultrathin and homogeneous coatings have not yet been achieved around spherical Si particles.

In this study, we present a two-step aqueous approach to prepare Si@Au core-shell particles with controllable shell thickness below 10 nm. The Au nanoparticle (AuNP) density around the Si particles can be increased by performing a second functionalization/deposition step. We studied the electromagnetic response of the particles using single-particle scatter spectroscopy and electron energy loss spectroscopy (EELS). Our results were

compared with reference Si spheres and SiO_2@Au core-shell particles, to allow us to establish the contribution from the Au decoration to the optical response of the hybrid particles. To further elucidate the nature of the electromagnetic response of the particles, these observations were supported by T-matrix simulations which replicated our experimental findings, and showed the importance of controlling the shell/core dimensions and the need for a continuous shell to maximize forward scattering. We found that continuous plasmonic shells of ~12 nm thickness are needed to significantly improve forward scattering intensity.

Abstract

Chiral molecules exhibit optical activity, helicity-dependent interactions with circularly polarized light, a key for rapidly characterizing biological and pharmaceutical molecules via spectroscopy. However, the intrinsic weakness of optical activity restricts its applications. In contrast, our study introduces an innovative chirally sensitive spectroscopic phenomenon that liberates itself from reliance on weak optical activity. This novel approach capitalizes on the substantial chirally sensitive birefringent response, monitored through the linear dichroism of complexes formed between charged biomolecules electrostatically coupled to enantiomorphic pairs of silicon nanostructures. Termed "meta-diastereomers," these complexes are symmetry-inequivalent diastereomers with differing birefringent properties, enabling biomolecule chirality detection. This effect is nine orders of magnitude larger than the optical active response of proteins in conventional measurements, allowing the detection of femtomole quantities. Serving as an electromagnetic analogue to the chemical strategy of leveraging diastereomers' different properties for stereostructure determination, this phenomenon is specifically applicable to charged chiral biomacromolecules and insensitive to non-charged chiral/achiral environments. It presents an ideal candidate for biosensing technologies, with charge sensitivity offering a novel discrimination mechanism to minimize off-target detection and ensure ultrasensitivity.

Chiro-optical microscopy of plasmonic materials and chiral near-field interaction with molecules and materials

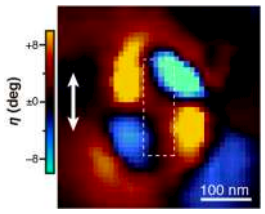
Abstract: We demonstrate here microscopic and nanoscopic imaging of chiral optical fields with far-field CD microscopy, near-field polarimetry, and chiro-photoinduced force microscopy for plasmonic materials, and near-field chiral plasmon-matter interaction phenomena.

Chirality is a broad concept that characterizes structures in wide hierarchy of materials and systems. It is of fundamental importance to investigate geometrical structures of chiro-optical responses in nanomaterials, to design chiral features and functions of the nanomaterials. We developed novel optical activity imaging methods with a few of optical measurement methods, which allow us to visualize local structures of optical activity in nanomaterials. The methods were applied to observe and control chiral plasmonic fields for gold nanostructures. We found very different characteristic features of local chiro-optical effects as compared with macroscopic chiro-optical spectroscopic characteristics. The local chiral fields that interact with molecules and materials in the peripheries of the nanomaterials provide characteristic chiro-optical properties the molecules.

For chiro-optical imaging beyond the diffraction limit, we developed a near-field polarimetry microscope using aperture-type optical fiber probe and a chiro-photoinduced force microscope. In the former one, the sample is illuminated with a linearly polarized optical near-field through the probe, and the forward scattered field in the far-field is analyzed for its ellipticity (η, corresponding to CD) and polarization rotation. Figure 1 shows a near-field ellipticity image of a gold nanorectangle.[1] In this image, the ellipticity of the scattered optical field from the sample upon near-field linearly polarized excitation parallel to the long axis of the rectangle was mapped as a function of the position of the excitation. The results suggest that strongly twisted plasmonic local fields are generated in the vicinities of metal nanostructures.



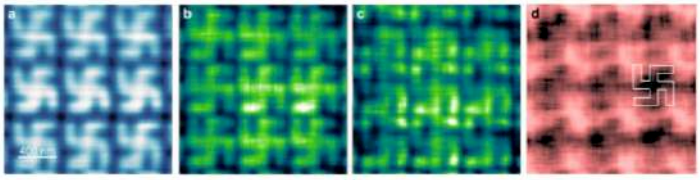


Figure 1. Near-field η image (at 800 nm) of a gold nanorod.[1]

Figure 2. (From left to right) AFM image, photoinduced force images under right- and left-circularly polarized light at 785 nm, and the differential image between the two photoinduced force images. The unit cell size is 540 nm.[2]

In the chiro-photoinduced force microscope, the local chiro-optical effect is detected through optical force measurements with an atomic force microscope. By detecting difference between the force under left- and right-handed circularly polarized illumination with the photoinduced force microscopy, we can visualize the chiral optical fields on the sample under irradiation of light. We developed an experimental system for nanoscopic observation of chiro-optical force and imaging of chiral optical fields on the samples, based on photo-induced force microscope. The photoinduced force images under illumination of left- and right-circularly polarized light were recorded, and the chiro-optical image was obtained as the difference between the two. As the test sample, we fabricated left- and right-handed gold gammadion structure arrays by

electron-beam lithography method. The result of chiro-optical image of the sample is demonstrated in Fig. 2.[2] We succeeded in visualizing nanoscale chiral optical fields in the vicinity of the nanostructures. It is seen that the local chiro-optical effect is prominent at the corners of each gammadion.

The strong local chiro-optical activity associated with the chiral plasmons indicates existence of highly chiral local fields, which may induce strong chiral near-field interaction between the plasmons and the materials in the vicinity of the nanostructures. We can thus expect near-field interaction between dye molecules and chiral plasmons, which yields highly circularly polarized luminescence from the dye coexisting with the chiral plasmonic material. In fact, we found that the luminescence from achiral dye molecules combined with chiral plasmonic nanostructure was highly circularly polarized (dissymmetry factor $g > 0.1$) as compared with luminescence from dyes with chiral molecular structures ($g \approx 10^{-3}$-10^{-2}).[3] Furthermore, the generation of circularly polarized two-photon-induced photoluminescence (TPI-PL) from chiral gold helicoid nanoparticles was demonstrated. Measurements of TPI-PL show that it has a strong dissymmetry factor of ≈0.7 for a single chiral Au nanoparticle (Fig. 3).[4] A theoretical simulation study showed that a local chiral electromagnetic field confined to the chiral gap structures contributes to the high degree of circular polarization.

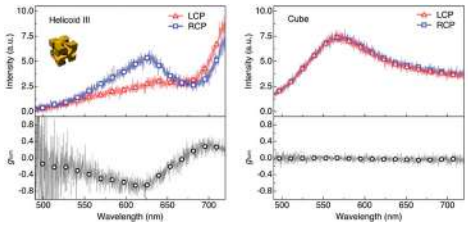

Figure 3. TPI-PL intensity and *g*-factor spectra for chiral helicoid (left) and cubic (right) gold nanoparticles.[4]

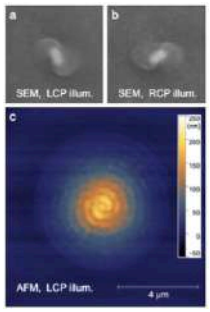

Figure 4. (a,b) SEM images of photopolymerized structure formed around the cuboid nanoparticle under the (a) LCP and (b) RCP illumination. (c) AFM image of chiral double spiral structure.[6]

When an achiral nanostructure is illuminated by circularly polarized light, chiral optical field distribution is induced, which has a potential to create materials with chiral assymmetry through photochemical reactions. This idea was reported to be achieved with metal nanocuboid, on which photoproduct was deposited at two of diagonal apexes.[5] The result was attributed to the plasmonic mode structure induced on the cuboid when excited by circularly polarized light. We report experimental results that an additional mechanism of chiral field generation due to interaction between the symmetric nanoparticle and circularly polarized light provides a further complex spiral structure of the photoproduct (Fig. 4).[6]

Abstract: We demonstrate enantioselective photocleavage exceeding circularly polarized light using chiral plasmonic shurikens with mesoporous gold. Optimized chiral near-fields enhance interactions for spectroscopy and catalysis, achieving 2–3× higher R/S-metalaxyl photolysis rates and >25% enantiomeric excess, marking the first proof of chiral plasmonic catalysis via superchiral fields.

Interactions between light and molecules present a foundation for the development of optical and spectroscopic technologies, where the modulation and control of molecular chirality is critical [1–4]. Although light is a promising stimulus for the management of enantiomers, the scale mismatch between the wavelength of light and the molecular wavefunction prevents effective interactions between molecules and the chirality of applied light [5]. Light-matter interactions involving plasmonic excitation at nanomaterials allows redirection of energy from nonradiative decay pathways for purposes of molecular transformation[6,7]. Despite the active development of chiral self-assembled nanomaterials for plasmon catalysis[8], for example, involving Au and TiO_2 NPs on chiral SiO_2 nanoribbons[9], dumbbell-like chiral Au NRs[10,11], or gold-gap-silver nanostructures with cysteine[12], the direct enantiospecific transformation of molecules has not been demonstrated. These structures exhibit catalytic activity in chemical reactions not involving chirality, including water splitting, dye degradation and reduction.

With the aim to generate evidence for chiral plasmonic catalysis, we have used a chiral plasmonic system with excitation using linearly polarized light (LPL) for interactions either with individual enantiomers or a racemic mixture of a photo-cleavable molecular entity. More specifically, we have used arrays of chiral shuriken indentations, which exhibit extraordinarily homogeneous chiroptical properties over large areas[13,14]. The chiral shurikens of our array also show high sensitivity to local interactions with chiral molecules[15–17]. The superchiral field generated by shuriken shaped nanostructures is a promising candidate for the enhancement of light-matter interactions for chiral catalysis. In this work, the superchiral plasmonic field in the resulting mesoporous chiral shuriken metafilms (MCSMs) shows enhanced surface area with increased interactions between chiral molecules and the excited superchiral near-field for enantiospecific recognition and enantioselective photocleavage of the fungicide R/S-metalaxyl.

We have adapted this strategy for preparation of a chiral metamaterial by using micelle-assisted deposition of porous gold on sub-micron-sized shurikens arranged in a square lattice (Fig. 1a). For electrodeposition, shuriken arrays were placed in a solution of polyethylene oxide block polystyrene (PEO-*b*-PS) micelles and $HAuCl_4$ prior to electrochemical reduction (0-250 seconds) leading to the further formation of mesoporous Au structures (Fig. 1a). The optimization of deposition via morphological changes (Fig. 1b), optical rotation measurements, enhancement factor in surface-enhanced Raman spectroscopy using R/S-metalaxyl revealed 150 seconds as optimal deposition time for the strongest chiral response.

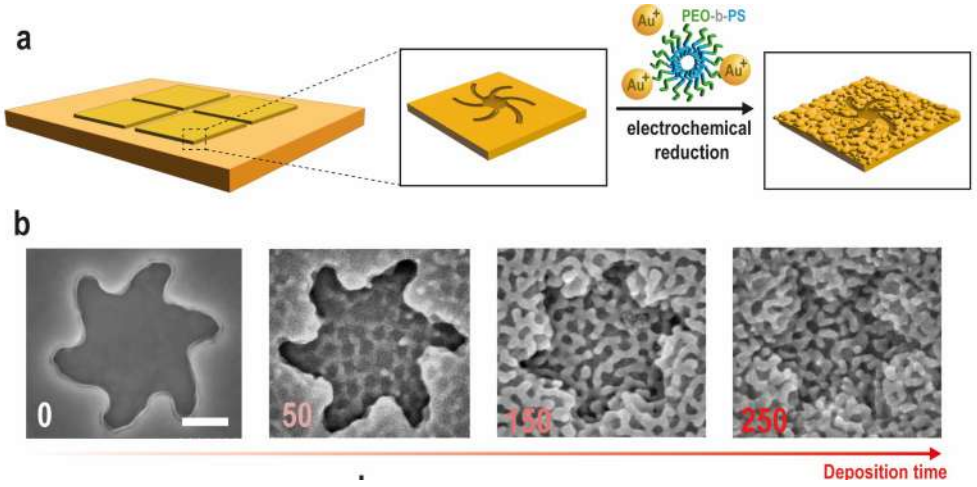

Figure 1. Synthesis and characteristics of shuriken arrays. **a**, Shuriken array (0.5 × 0.5 cm^2) is coated by electrodeposition using PSS-*b*-PEO block copolymer micelles and $HAuCl_4$ precursor to create MCSM. **b**, SEM images of MCSMs (scale bar – 150 nm) with increasing deposition time (time in s given bottom left

Subsequently, optimized mesoporous shurikens were tested to compare photocleavage efficacy towards R- and S-metalaxyl. Progress of photocleavage was monitored by precalibrated HPLC measurement using a chiral column over 48 h. We found that in the case where the enantiomer and MCSMs handedness is matched (R-metalxyl and RH, or S-metalaxyl and LH), photocleavage proceeded 2–3 times more rapidly than in case of the unmatched combinations (Fig. 2a, b). Similar differences in chiral plasmonic activity have been reported for Au and TiO_2 NPs on chiral SiO_2 nanoribbons during RhB degradation[9] and gold-gap-silver nanostructures with cysteine in nitrophenol reduction[12].

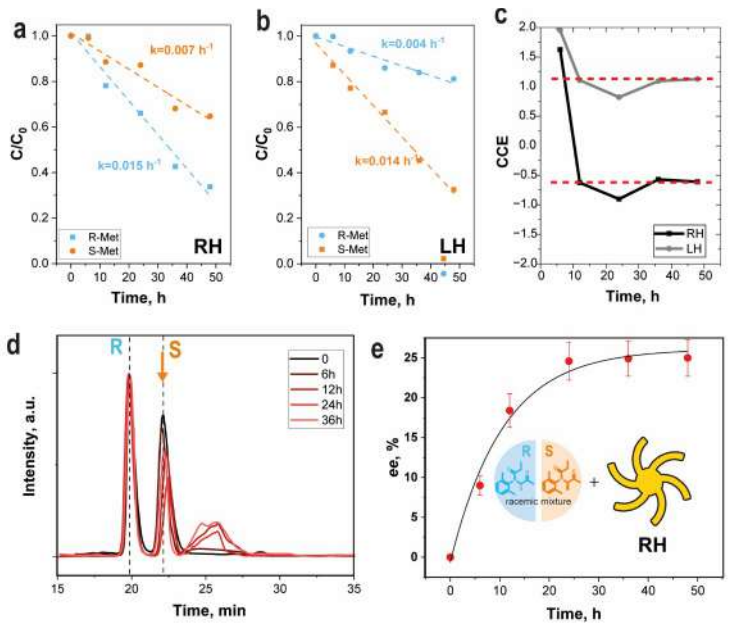

Figure 2. Plasmonic performance of MCSMs. **a**, RH and **b**, LH MCSMs for photocleavage of the individual enantiomers of R and S-metalaxyl (10^{-4} M). **c**, Related chiral catalytic efficiency (CCE). **d**, HPLC chromatograms 6, 12, 24, and 36 h after illumination with 780 nm LPL. **e**, Evaluation of enantiomeric excess obtained by exposure of racemic metalaxyl mixture.

Enantioselective transformations must also be demonstrated on a racemic mixture (Fig. 2d,e) where competing reactivity might take place, and is one of the most challenging tasks. The action of enantioselectivity during reaction leads to an emergence of *ee*, which is a measure of the ratio of one enantiomer over the other (Fig. 2e). We tested RH/LH-MCSMs under similar experimental conditions using a racemic mixture instead of pure enantiomers. The occurrence of chiral photocleavage was evaluated using *ee* as a standard descriptor for chiral catalysis. In the case of both RH and LH-MCSMs, *ee* ≈26 % was achieved.

Herein, we report enhanced light-matter interactions between R/S-metalaxyl, as a chiral subject molecule, and porous metamaterials affording enantioselective cleavage. This is made possible through the generation of a superchiral near-field achieved by the modification of shurikens with a plasmonic mesoporous Au layer. In contrast to previously published CPL-guided plasmonic activity of achiral molecules, the enantioselectivity in a racemic mixture reached >25 % based on coincidence of molecule chirality and MCSM handedness under excitation by LPL. Our work will enable new research directions in chiral systems. First, further refinement of chiral nanostructures by tuning of size, shape, and distribution of mesopores to maximize the chiral near-field effects could lead to even greater enantioselectivity generating larger enantiomeric excesses. Second, the versatility of focused superchiral plasmonic fields as an enantioselectivity source could be studied by broadening the range of target molecules especially high value targets in pharmaceuticals, agrochemicals, and materials science.

Photocatalytic hydrogen evolution with plasmonic and photonic nanomaterials

A. Naldoni[1]

[1]Department of Chemistry and NIS Centre, University of Turin, 10125 Turin, Italy
[*]corresponding author: alberto.naldoni@unito.it

Abstract: Plasmonic and photonic nanomaterials have emerged as promising platforms for transducing solar into chemical energy. In this contribution, I will present our research on hydrogen evolution driven by plasmonic and photonic photocatalysts. These catalysts leverage heat, hot electrons, or nanoscale coupling effects to drive chemical reactions relevant to energy applications.

The commitment to achieving a net-zero-emission society by 2050 necessitates the decarbonization of industry, a sector responsible for nearly 40% of global greenhouse gas emissions. Since most industrial processes involve chemicals (e.g., hydrogen, ammonia, plastics, and solvents), developing alternatives to heat and fossil fuels for driving chemical production is crucial for the future of energy and industry. Plasmonic and photonic nanomaterials have emerged as promising platforms for enabling solar energy conversion and storage in value-added molecules. Their enhanced light-matter interaction and unique non-equilibrium, non-linear effects are opening new avenues in photocatalysis. In this contribution, I will present our recent findings on clean hydrogen evolution driven by plasmonic and photonic photocatalysts. These catalysts leverage heat, hot electrons, or nanoscale coupling effects to drive chemical reactions relevant to energy applications.

From Symmetry to Chirality: Near-Field Optical Activity in Achiral Gold Nanoparticles

Abstract: Chirality plays a crucial role in light-matter interactions, with traditional research focusing on chiral structures interacting with chiral light. This study reveals that achiral gold nanotriangles with C3v symmetry can exhibit chiral near-field distributions when excited by linearly polarized light. This emergent chirality arises from the anisotropic near-field response of the plasmonic structure. By employing near-field-assisted two-photon polymerization, we further translate these optical near-field distributions into chiral-symmetric plasmonic structures, enabling direct visualization and structural manifestation of near-field chirality. We systematically investigate the wavelength-dependent behavior of these chiral optical fields under both resonant and off-resonant conditions.

Chirality plays a fundamental role in light-matter interactions, traditionally associated with the interplay between chiral structures and circularly polarized light. However, recent research has demonstrated that achiral plasmonic nanostructures can also exhibit chiral optical responses when excited by linearly polarized light.[1, 2] In this study, we demonstrate that achiral gold nanotriangles (NTs) with C_{3v} symmetry can exhibit chiral near-field distributions under linearly polarized excitation. Using near-field-assisted two-photon polymerization (NF-TPP), we translate these optical near-field patterns into chiral plasmonic polymerized structures, allowing direct visualization of near-field chirality. The SEM image of a pristine NT (Figure a) and its modified structure after 780 nm polarized irradiation (Figure b) highlight polarization-dependent polymerization effects. Additionally, AFM difference mapping (Figure c) and simulated field dissymmetry maps (Figure d) reveal asymmetry in the plasmonic response.

To quantify this emergent chirality, we compute the chirality density enhancement factor (C_{enh}), defined as the local chirality density normalized to free-space circularly polarized light. Figures e and f illustrate the spatial distribution of C_{enh} under LH (45°) and RH (-45°) polarization, showing sign reversal at key structural points. Our results indicate that plasmonic chirality arises from the anisotropic near-field response, where the incident electric field aligns differently with the nanotriangle's edges and corners, leading to local chirality inversion. Furthermore, by varying wavelengths and polarization, we investigate resonant and off-resonant chiral responses, confirming that plasmon-induced chirality is highly tunable.

These findings provide a new approach to engineering chiral plasmonic structures without the need for

inherently chiral materials. The ability to control and visualize near-field chirality using polarization and plasmonic polymerization offers potential applications in chiral light manipulation, optical sensing, and nanophotonic device fabrication. This study highlights the significance of anisotropic plasmonic interactions in shaping and controlling chiral optical

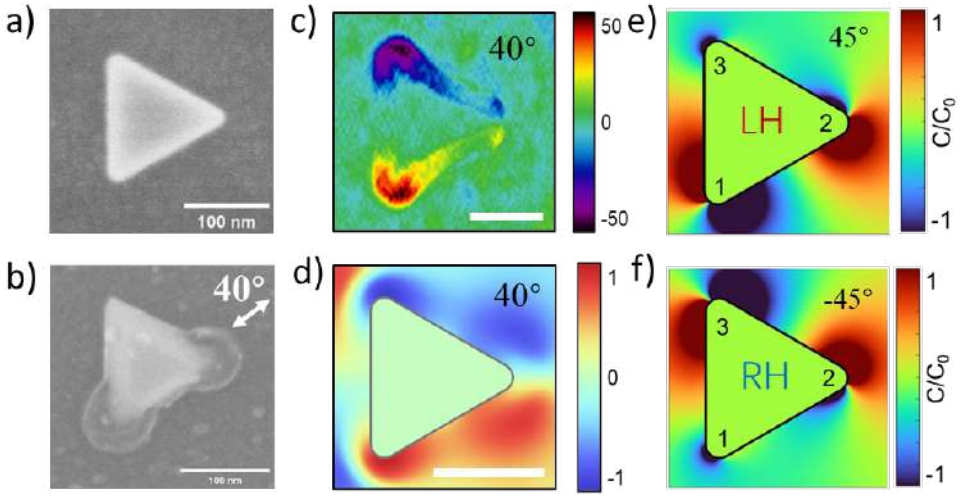

Figure a) SEM image of single gold nanoprism. b) SEM image of single gold nanoprism after irradiation with linearly polarized optical light at 780 nm. c) AFM difference map derived from the LH (40°) AFM map and RH (-40°) AFM map. d) Field dissymmetry map obtained from simulation calculations. e) Spatial distribution of chirality density across the triangular nanostructure under excitation at 45° and f) −45° polarization angles.

Abstract: A general approach to prepare 3D metasurfaces by stacking metasurface layers will be proposed. Bilayer metasurfaces prepared by nanoantenna stickers on another nanoantenna are exhibited as preliminary examples.

Three-dimensional (3D) metasurfaces allow light manipulation with a higher degree of freedom in comparison to 2D counterparts, but it is generally a challenge to fabricate them. Here we propose a concise and reproduceable way of constructing such 3D metasurfaces by stacking 2D metasurface layers. For this we utilize nanoantenna stickers, which is the nanoparticle array embedded in the flexible polymer[1,2]. They are self-adhesive to any clean surfaces to work as nanoantenna. As preliminary examples, we show bilayer systems by combining nanoantenna sticker and the nanoantenna on the substrate [Fig. 1]. By placing light emitters in between, we can tune the photoluminescence from the emitter modulated by both top and bottom metasurfaces[3]. Another example is the induced chirality from twist or moiré metasufaces[4]. We believe these works will lead to future construction of multiple-layered metasurfaces, like a pancake, with multiple functionalities.

Abstract: A mechanical resonance is a very specific way of energy absorption. The question of whether human living cells exhibit mechanical resonances has remained unresolved for more than 70 years. In this work, we have finally proved the existence of these resonances exploring the frequency response of a nanomechanical resonator.

The cell, the basic unit of life, is an extremely complex structure whose behavior is governed by numerous biochemical processes constantly occurring within it. All these processes give the cell its identity and provide it with certain properties as a complex mechanical structure. Diseases alter these processes, which in turn affect the mechanical properties of cells. Therefore, the mechanical properties of cells can be considered an excellent indicator of disease or cellular malfunction[1,2]. One of the main parameters that might be considered as a mechanical fingerprint of a structure is its resonance frequency. Moreover, a mechanical resonance constitutes a highly specific way of energy absorption, meaning that a structure will not absorb energy if the signal from the source is not close to its resonance frequency. This has motivated the search for mechanical resonances of human cells in their natural environment for more than 70 years[3]. However, due to the high dissipation in such an environment, this question has remained unresolved all these years. In this work, we have finally demonstrated the existence of these resonances using nanometric-thickness cantilevers[4]. The cell is placed near the free end of the cantilever, and the frequency response is measured by searching for anomalies in the cantilever's flexural and torsional spectra (Figure 1).

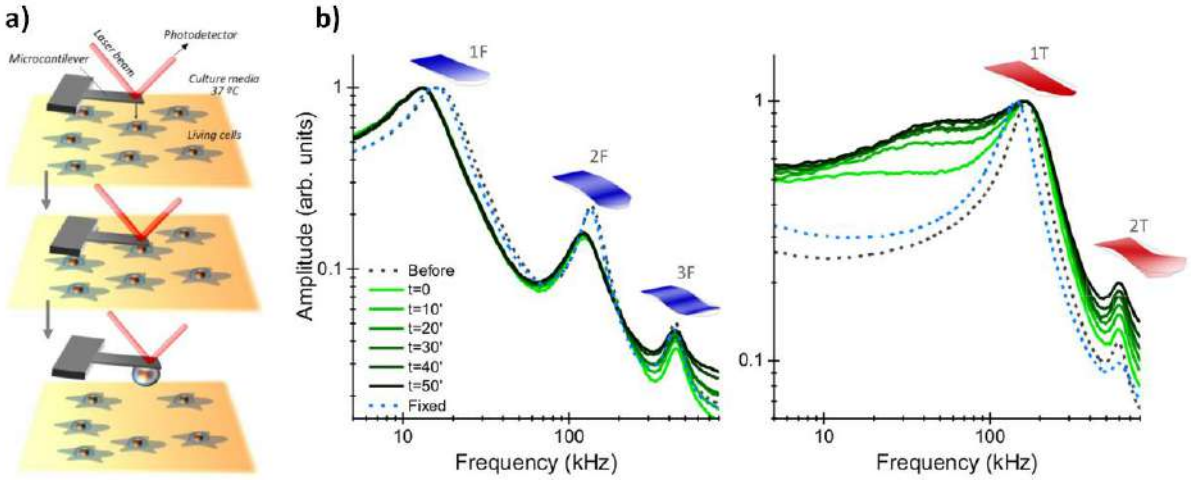

Figure 1. a) Schematic depiction of the process of capturing the cell with the cantilever resonator and b) flexural and torsional spectra measured before and after the cell attachment for different times.

Both spectra are monitored in real time using the optical laser beam deflection technique. With this method, we have found clear evidence of coupling between the mechanical resonances of the cantilever and those of the cell itself. Finally, through a theoretical model that explains the experimental observations, we have been able to extract valuable real-time information about the cell, such as its resonance frequency, intrinsic dissipation, elasticity modulus, and contact area with the cantilever surface (Figure 2).

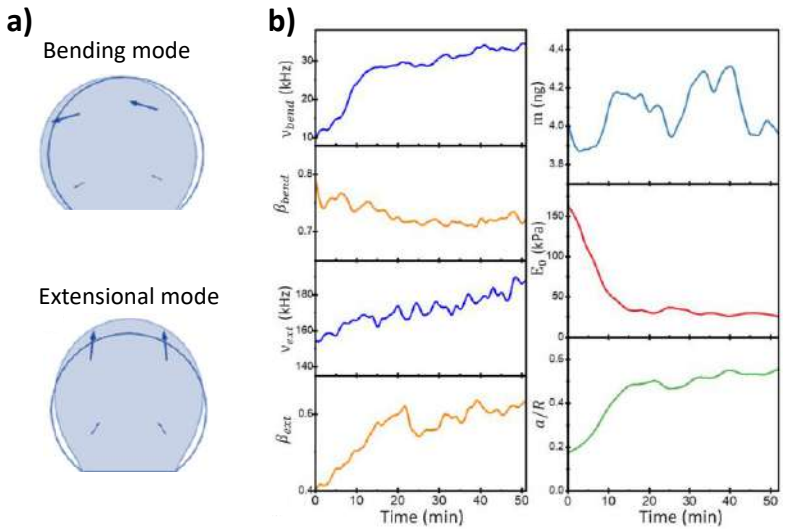

Figure 2. a) Schematic of the bending and extensional vibration modes of the cell and b) different mechanical properties of the cell as a function of time: resonance frequencies and power-law exponent of bending and extensional modes, total mass, Young's modulus and relative radius of contact.

This discovery paves the way for new techniques to study and measure the mechanical properties of human cells in their natural environment, as well as new therapies for diseases such as cancer.

Organic optoelectronic devices and biofunctionalized nanoplasmonic gratings: integration into miniaturized optical biosensors

M. Bolognesi[1*], M. Prosa[1], and S. Toffanin[1]

[1] *Institute of Nanostructured Materials (ISMN) – National Research Council (CNR), Via P. Gobetti 101, Bologna 40129, Italy*

Abstract: We present the design approaches, characterization and demonstration of miniaturized optical biosensors relying on the combination of: i) miniaturized and monolithically integrated organic light-emitting diodes or transistors, and organic photodiodes as the optical transduction elements; ii) antibody-based immunoassays as recognition elements; iii) nanoplasmonic gratings for surface plasmon resonance (SPR) sensing.

Optical sensors demonstrate the largest potential for Lab-on-a-chip (LOC) systems to perform sensitive, quantitative, and fast sensing for food quality and safety monitoring, but also for environmental monitoring or healthcare. Among all options, biosensors based on optical plasmonic sensing schemes combine high sensitivity with label-free detection. However, most of them still have not yet been miniaturized in LOC devices for sensing or analysis in situ of real samples.[1]

We present here the chemical, physical and engineering design approaches,[2] the full characterization, and the detection performance of miniaturized optical SPR sensors and biosensors, that enable quantitative detection of analytes of interest from different food chain production systems. The sensors rely on the combination of: i) miniaturized, monolithically integrated, and cost-effective optical transduction elements based on organic optoelectronic devices, such as organic light-emitting diodes and transistors,[3] and organic photodiodes; ii) direct and competitive immunoassay-based bio-recognition elements; iii) nanostructured plasmonic gratings for SPR based detection.

Quantitative or semi-quantitative analyte-specific detection is demonstrated for different targets, each one representing a different class of analytes: a high molecular weight protein (lactoferrin) is detected at a sensitivity as low as 9 ug/mL;[4] an antiparasitic small molecule (albendazole) is detected at the ppb level; a heavy metal (Cadmium) is detected at the ppb level.

The presented work opens the way for the universal application of optical plasmonic biosensors in LOC devices, for on-site food analysis, environmental or health monitoring, among others.

This work has received funding from the European Union's Horizon Europe research and innovation programme under grant agreement 101157922 (E-SPFdigit) and from the PNRR MUR Project ECS_00000033_ECOSISTER within the FARM project.

Abstract: In the realm of chirality, the helicity of photons, akin to the spins of electrons, holds promise for encoding information swiftly through the polarization of light in both classical and quantum computing. However, the development of a chiral single photon source remains a significant challenge due to the degeneracy of magnetic sublevels in achiral emitters. Here, we demonstrate the achievement of chiral single-photon sources made by a DNA templated trimer antenna (Figure 1) with C2v symmetry group, excited by an asymmetrically positioned achiral emitter without vector beam excitation. In this 2D configuration without inherent structural chirality, the antenna still exhibits chiral emission with a high degree of circular polarization (DCP), attributed to the presence of excited rotating orthogonal electric dipoles inside the structure.

Experimental femtosecond pulse trains for time-modulation metamaterials in the terahertz spectral band

W. P. Wardley[1], C. M. Hooper[1], I. R. Hooper[1], S. A. R. Horsley[1], E. Hendry[1]

[*]corresponding author: w.wardley@exeter.ac.uk

Abstract: Time-modulated metamaterials are investigated using femtosecond pulses for modulation of THz absorption in graphene-based materials. To do this, we describe a new multi-cavity optic which generates pulse-trains from a single femtosecond pulse. We demonstrate the use of this tool for temporal diffraction experiments, including temporal double-slit experiments and constant-amplitude pulse-trains.

Time-modulated metamaterials offer a mostly unexplored route to elaboration and innovation within the field of metamaterials. Traditionally, metamaterial design has, for the most part, been based on repeating structural units in space. However, there is nothing preventing metamaterials using variation in time instead. For instance, a temporally periodic variation of material properties (such as by high energy laser excitation) in an otherwise spatially homogenous medium can equally be used to form novel and otherwise unobtainable properties when the magnitude of the modulation is large enough.

One such means of modulation is based on generating frequency shifts via temporal diffraction effects that are larger than the resonant frequency of a system, allowing experimental demonstration of negative frequencies and the ramifications of interference between them and positive frequencies. In many spectral regimes this is challenging to achieve due to the large frequencies and modulation speeds required, but for terahertz (THz) based systems it is not only achievable via excitation with optical frequencies, but can take advantage of the need for ultrafast laser light for optical rectification for the generation of terahertz radiation, meaning that a femtosecond laser is a key part of many THz systems already. Therefore, simply adding another beamsplitter and beam-path to reroute enough energy to include an additional pump-probe scan can produce a route to the coherent and high-frequency modulation of THz interactions required for the generation of negative frequencies in THz-active materials.

To investigate this time-varying behaviour, a system is required where the modulation behaviour is both rapid and large in extent. For the THz regime, graphene and similar materials make excellent candidates due to their significant change in THz transmissivity, due to the large change in the permittivity when charge carriers are photoexcited.

In particular, we focus on an experimental scheme based around our design of an optic to produce pulse trains of femtosecond laser light of near-constant amplitude to rapidly modulate resonances in the terahertz spectral region, demonstrated by pump-probe measurements of graphene-based materials. These include double-pulse experiments, analogous to Young's double slit experiment, and multiple pulse experiments that offer a route to amplification of terahertz radiation. The double-slit interference measurements show strong evidence for interference between positive and negative frequencies, a key indication of the presence of negative frequencies in our system and a useful tool for investigating time-varying phenomena. In addition to the experimental results, simulations showing the possible extent of negative frequency effects are presented alongside future plans for experimental demonstrations of more novel and exotic temporally modulated effects. This will include discussion of the route to designing and producing the means to generate pulse trains and the technical problems therein, the analysis of the THz measurements from a range of

graphene-based systems and routes to applications based on the results generated.

Abstract: A plasmonic device with a complex design has been developed. The nanocomposite, consisting of an ultra-thin aluminum oxide matrix with tiny embedded silver nanoparticles and a gold film, is fabricated in a single reactor using dual laser ablation. It enables sub-attomolar cancer markers detection, offering promise for early disease diagnosis.

This communication presents the development of a specific highly sensitive plasmonic device for rapid and early-stage disease diagnosis. Surface plasmons are collective oscillations of free electrons waves that exist at the interface between a thin metallic layer, and a dielectric environment. Surface Plasmon Resonance (SPR) is generated when a *p*-polarized incident light interacts with these oscillating electrons under specific conditions, leading to a resonance effect. This unique property of thin metallic films is highly sensitive to changes in the surrounding environment, and can be particularly useful for sensing applications to detect biological molecules in fields of medical diagnosis, biochemical research, and environmental monitoring. Even if plasmonic sensors provide label-free and real-time detection, most classical SPR-based sensors (angle or intensity-interrogating devices) often exhibit limited sensitivity regarding cancer markers, hormones or antibiotic detection. To overcome this issue, the development of a specific sensing setup based on lateral position shift, known as Goos-Hänchen (GH) effect, together with a highly-sensitive plasmonic material was achieved.

SPR occurs when attenuated total reflection (ATR) conditions are met, typically using a prism in Kretschmann configuration. At the resonant angle, the phase of the reflected p-polarized wave undergoes a drastic change due to its coupling with surface plasmons, while the *s*-polarized wave remains unaffected and serves as the incident point reference. This phase variation leads to a giant differential GH shift, where the lateral displacement of the reflected wave is significantly enhanced for the *p*-polarized component. The magnitude of this shift is directly linked to the derivative of the reflection phase change and can be expressed as,

$$\Delta GH = -\frac{\lambda}{2\pi n}\left(\frac{\partial\Phi_p - \partial\Phi_s}{\partial\theta}\right) \quad (1)$$

where λ and n are the wavelength of incident light and the refractive index of the prism respectively, θ is the incident angle and Φ is the phase shift of reflection [1].

Gold (Au) and silver (Ag) are well known for their excellent plasmonic properties in the visible range, mostly due to their high conduction electron density and low energy losses. Gold has been more used for its stability, chemical inertness and biocompatibility, while silver suffers from oxidation and toxicity against living entities, even if it has better plasmonic capabilities. The ability to reach high sensitivities by the association of Au and Ag in a single device was demonstrated by simulations based on Transfer Matrix Method coupled with Maxwell-Garnett theory. The nanocomposite material is made of an ultra-thin (12 nm) aluminum oxide (Al_2O_3) matrix, with embedded 2.3 nm sized Ag nanoparticles (NPs). The characteristic of this layer is to support localized SPR, with

electromagnetic field amplification in the vicinity of the NPs. An upper 48 nm gold film is finishing the architecture. The combination of localized SPR in NPs with propagating SPR in the Au layer provides high resonance performances, highlighted by the simulations of attenuated total reflectance spectrum that describes reflected intensity as a function of incident angle of light on the sample surface. For this architecture, calculations of the minimum reflectivity in water at $\lambda = 785$ nm, was estimated to 10^{-6}, while standard 50 nm gold film was estimated at 0.07, considering the normalized power of the reflected wave.

The fabrication of this challenged complex architecture is achieved using a specific reactor developed by our group [2], which combines pulsed laser deposition (PLD) coupled with a free cluster generator. PLD allows the deposition of films with nanometer-scale controlled thicknesses, with high quality in terms of density and crystallinity. The associated free cluster generator leads to controlled NPs synthesis, with a diameter chosen in the range 1-10 nm and a quasi-monodisperse size distribution. This coupled setup enables the synthesis of the nanocomposite thin film architecture presented in Figure 1, showing dense films free from porosity and well-defined contamination-free interfaces, respecting the desired ultra-low thicknesses for each layer.

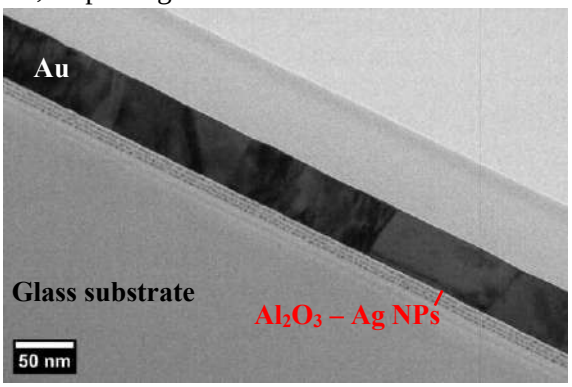

Figure 1 - High-resolution Transmission Electron Microscope cross-section image presenting the architecture of the nanocomposite: Ag-NPs in aluminum oxide covered by Au thin film on glass substrate, 50000× magnification.

The GH shift measurements are performed at $\lambda = 785$ nm with a specialized setup that allows direct changes of the biological environment in contact with the sensor. The ratio between GH shift and refractive index unit (RIU) indicating the sensitivity of the material for our nanocomposite achieved of 3.3×10^{-8} nm.RIU^{-1}. Significant GH shift of 10 µm to 1 aM concentration for a specific cancer marker, namely Tumor Necrosis factor-α was obtained. To the best of our knowledge, this represents the highest detection level ever reached [1]. Furthermore, those sensors are biocompatible and do not require any functionalization before detection tests, making them easier to use compared to other platforms. Given these detection capabilities, our materials have excellent potentials as biosensors for the ultra-early-stage detection of cancers.

Topological Thermal Emitters

Said Ergoktas

Department of Physics, University of Bath, UK
mse38@bath.ac.uk

Abstract: The ability to control thermal emission has scientific and technological importance and profound implications for thermal management. We introduce a new concept that offers unconventional manipulation of thermal emission by controlling the reflection topology of a surface, achieving the near unit emissivity at the boundary of two topologically distinct surfaces.

Controlling the thermal emission by conventional methods have been limited by the spatial resolution of the engineered material structures and materials' absorption in the infrared regime. In this work, we implement a new route to control light emission from thermal sources based on the concept of topology. We used a lossy optical cavity with one mirror being a thin metal film to tailor the thermal emission at well defined frequency. Precise tuning of the thin metal layer enables a continuous transition from trivial to non-trivial reflection topology, leading to topologically protected zero reflection at a critical thickness. Transition regions from sub critical to super critical domains support topological states that exhibit localized near unit emissivity. Our experimental results illustrate that topological concept would enable new tools for infrared optics and thermal management.

Abstract: We present a DNA-functionalized whispering gallery mode microlaser for DNA hybridization detection via spectral shifts. Gold nanoparticles enhance sensitivity without secondary labelling, and we introduce a hairpin-based system as a dual-purpose sensor and controlled release mechanism for potential drug delivery. This novel platform advances sequence-specific detection and in vivo applications.

(Photo-)catalytic activity of sub-5nm gold nanoparticles limited by Coulomb repulsion

M. Garai[1] and T.A. Klar[1*]

[1]Institute of Applied Physics, Johannes Kepler University Linz, 4040 Linz, Austria
[*]corresponding author: thomas.klar@jku.at

Abstract: Gold nanoparticles can serve as (photo-)catalytic agents promoting reductions. Frequently, it is assumed that the smaller the particles, the better they serve as catalysts. However, when storage of electrons takes place between the oxidative and reductive half-reactions, Coulomb blockade hampers the activity for nanoparticles with diameters ≤ 4 nm.

Noble metal nanoparticles can act as redox catalysts in reactions including water splitting, nitrogen fixation, or CO_2 reduction.[1] In case their diameter falls below about 10 nm, literature is split between, on the one hand, reports of ever-increasing catalytic activity with decreasing diameter[2-4] or, on the other hand, reports about an optimal diameter of about 5 nm, below which the catalytic activity decreases rapidly.[5, 6] In our study, we use the model reduction of ferricyanide to ferrocyanide[7] catalyzed by gold nanoparticles of diameters between 2 and 13 nm and determine the reduction rates and the activation energies to demonstrate that it actually depends on the oxidative counter reaction whether the decrease of the diameter below 5 nm leads to an increased or a decreased catalytic activity.

If no intermediate charge storage takes place on the nanoparticles, the catalytic activity increases monotonically roughly with the inverse of the diameter, down to 2 nm. If, however, the strong reductant triethanolamine (TEOA)[8] is present, the nanoparticles act as an intermediate storages of electrons, so called nano-cathodes. [2, 7, 9] We now find that such electron storage is compromised by Coulomb repulsion.[10, 11] This leads to an optimal diameter of 4-5 nm. In our study,[11] exactly the same batches of gold nanoparticles and the same model reduction were used, so that the parameter space for the different size dependencies of the catalytic activity is restricted to the differences in oxidative counter-reactions. Besides, the two qualitatively distinct dependencies of the catalytic activity on diminishing particle diameter are independent form the use of the gold nanoparticles as catalyst in the dark or as photocatalysts. Although illumination increases the overall catalytic activity, there is still an optimal diameter of about 4 nm if intermediate cathodic charging takes place, while the activity monotonously increases with shrinking diameter if no such intermediate charging takes place.

The fact that the Coulomb repulsion is detrimental rather than helpful (as sometimes assumed)[3] when using sub–5 nm AuNPs should have even more impact in case of multi-electron redox-reactions catalyzed by AuNPs. We also note that the Coulomb blockade is symmetric in adding or removing electrons from a gold nanoparticle. Therefore, in an alternative scenario where an oxidant is used to positively charge gold nanoparticles in order to render them oxidative agents, the problem that the Coulomb repulsion compromises the (positive) charging of the AuNP will equally hold.

Collective behavior of a plasmonic particle array with a chiral arrangement under modal coupling regime

T. Oshikiri[1*]
[1]Institute of Multidisciplinary Research for Advanced Materials, Tohoku University, Sendai, Miyagi 980-8577, Japan
[*]corresponding author: tomoya.oshikiri.c1@tohoku.ac.jp

Abstract: We fabricated a cluster of isotropic gold nanodisks with a chiral arrangement on the Fabry–Pérot (FP) nanocavities of TiO_2/Au film. We demonstrate that collective mode formation under modal coupling regime between localized surface plasmon resonances with a chiral arrangement and Fabry–Pérot (FP) nanocavity modes can induce chiroptical responses.

Introduction

Chiral systems, that are noncongruent with their mirror images, have attracted much attention due to their unique properties and applications. Generally, the interactions between circularly polarized light (CPL) and chiral molecules are not strong because of the size difference between the light wavelength and the molecule[1, 2]. Localized surface plasmon resonances (LSPRs), which is the collective oscillation of surface electrons in metal nanostructures, harvest incident light and enhance local electric fields in the near field. The interaction of incident light with chiral metal nanostructures induces helical near fields around these structures[3, 4]. Additionally, metal nanostructures irradiated with light possessing angular momentum, such as CPL and optical vortices, show asymmetric near field distributions[5-7]. The configuration and arrangement of plasmonic particles also play important roles in determining their chiroptical response[8, 9]. This study aimed to induce chiroptical responses in a cluster of isotropic plasmonic particles with a chiral arrangement based on collective mode formation under modal coupling between the LSPRs and FP nanocavity modes.[10] We designed a cluster of isotropic Au nanodisks (Au-NDs) with a chiral arrangement (Au nanowindmill, Au-NW) on an FP nanocavity. We evaluated the contribution of modal coupling to the chiroptical responses by comparing the spectral properties of the identical cluster in the presence and absence of the FP nanocavity.

Experimental

Au NWs were fabricated on a substrate by electron beam exposure and lift-off techniques. The substrates were fabricated by coating with the titanium oxide (TiO_2) onto indium-thin oxide (ITO)-coated SiO_2 (ITO/SiO_2) and coating TiO_2 onto Au-coated SiO_2 (Au/SiO_2). We deposited TiO_2 thin films having thickness of 60 nm using an atomic layer deposition equipment at 300°C. The morphologies of the nanostructures were observed using field-emission scanning electron microscopy. The transmission and reflection spectral properties were investigated at room temperature using a W-halogen lamp as an irradiation source, a microscope with an objective lens (40×/NA0.75), a spectrometer, and a charge-coupled device camera detector electronically cooled to -80°C. Left- or right- CPL (LCPL or RCPL) was generated by a linear polarizer module, half-wave module, and quarter-wave module with a retardance of $0.25\pm0.03\pi$. T

Results and Discussion

We designed Au-NWs, as shown in Figures 1. Au-NW was a cluster of Au-NDs with a two-dimensional chiral arrangement bearing three-fold or five-fold rotational symmetry on TiO_2/Au (Au-NWs on TiO_2/Au). TiO_2/Au works as an FP nanocavity whose resonant wavelength was approximately 700 nm. The FP nanocavity couples with multiple plasmonic particle modes. In this situation, the interparticle interaction between plasmonic particles is also enhanced through the FP nanocavity as reported[11]. Consequently, the formation of collective mode and corresponding near-field can be expected based on the

arrangement of the cluster of Au-NDs under modal coupling conditions. Au-NWs in the absence FP nanocavities were also fabricated on TiO_2-coated ITO/SiO_2 under the same conditions as the control samples (Au-NWs on TiO_2).

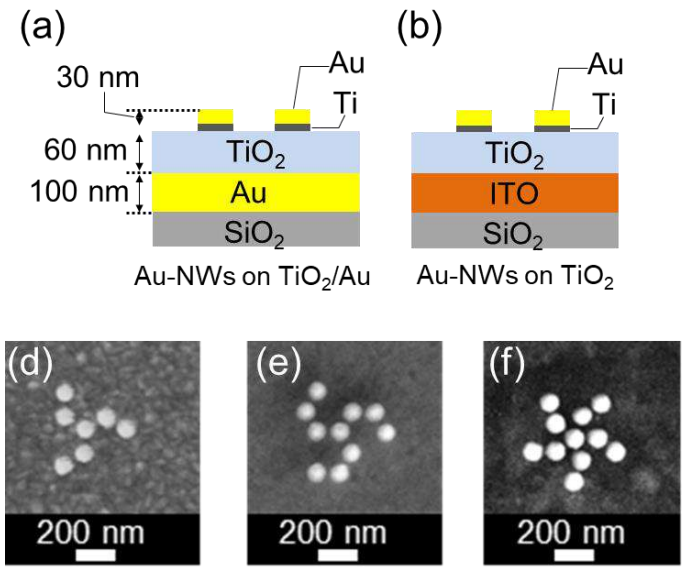

Figure 1. (a,b) Cross-sectional view of Au-NWs on TiO_2/Au (a) and TiO_2 (b). (c-e) FE-SEM images of Au-NWs on TiO_2/Au with different geometries. Scale bars indicate 200 nm.

We measured the differential absorption spectra of the LCPL and RCPL irradiations. The differential absorption spectrum of TiO_2/Au did not show a significant signal, indicating that the FP nanocavity alone did not exhibit a chiroptical response. In contrast, the differential absorption spectra of the Au-NWs on the TiO_2/Au-film show clear negative signals. These results suggest that the modal coupling between the LSPR and FP nanocavity modes induces chiroptical responses in Au-NWs having a chiral arrangement.

Photocatalysis and Local Growth Driven by Plasmonic Hot Electrons

E. Y. Santiago[1*]

[1]CINBIO, Universidade de Vigo, Spain

Abstract: This study explains a phenomenon intrinsic to plasmonic nanomaterials: the efficient generation of hot carriers on their surface that drive secondary processes, such as photocatalysis. This can lead to a photogrowth process that constructs nanostructures with a controlled and asymmetric optical response that depends on the incident light polarization.

Summary

The study of plasmonic nanomaterials is a fundamental part of modern nanoscience and nanotechnology. These systems exhibit strong and tunable absorption and scattering of electromagnetic radiation due to their strong localized surface plasmon resonances (LSPRs) excited by light, dependent on the nanostructure shape and composition. A phenomenon intrinsic to plasmonic nanomaterials that currently elicit great research interest is the efficient generation of hot carriers[1], which are electrons and holes that can leave the metal due to their large kinetic energies and drive secondary processes such as photocatalysis. By taking advantage of non-uniform distribution of these excited carriers on the metal surface, we can create an asymmetrical optical response by building nanostructures in a controlled manner through a photogrowth process[2].

This occurs when electromagnetic radiation is absorbed and the LSPRs relax. Depending on the geometry, size, material and surrounding medium of the nanoparticle, hot carriers are generated on its surface. They can then drive surface chemistry, which in adequate conditions can lead to a nonlinear and inhomogeneous photogrowth process. Such photogrowth can be exploited in combination with sources of light to break the symmetry of an initially symmetric nanoparticle. This study explains our deepened understanding of the light-matter interaction through plasmonics, which allows us to explore new avenues to develop a fine control over nanoparticle morphology. This is done through theoretical and computational methodologies to explain the response of nanoparticles under light of different polarizations.

Abstract: We discuss the fabrication and the exploitation of hybrid systems composed by plasmonic optical resonators coupled with 2D materials. We provide examples of TMDC transfer onto plasmonic nanostructures and of nanofabrication of plasmonic systems on top of TMDC layers. Different applications are discussed.

Semiconducting transition metal dichalcogenides (TMDCs), such as MoS_2 and WS_2, have emerged as promising candidates for next-generation optoelectronic devices, owing to their remarkable electronic and optical properties. They exhibit room-temperature excitonic effects and, when thinned down to a three-atom-thick monolayer, exhibit direct-gap semiconducting band structure, making them an excellent playground for exploiting light-matter interaction at the nanoscale.

By coupling a TMDC monolayer with metallic nanostructures exhibiting localized surface plasmon resonances (LSPR) it becomes possible to realize hybrid photonic systems for fundamental studies and novel applications. Within this framework, the excitons of the TMDC and the LSPR are viewed as optical resonators whose spatial coupling and spectral overlap can be freely tuned by engineering their nanoscale characteristics. Additionally, hybrid TMDC/plasmonic systems can be exploited as novel platforms to investigate the heat dynamics at the nanoscale, exploiting the thermoplasmonic effect of the plasmonic counterparts for locally generating heat, and the temperature dependence of the PL energy to act as a nano-thermometer.

Realizing these hybrid structures is by all means a complex task, that typically combines nanolithography approaches to deterministically fabricate the plasmonic counterpart with delicate growth-and-transfer methods to introduce the TMDC in the system. The issue with the realization of these systems is that the direct fabrication of plasmonic structures onto TMDCs with energetic particles (electrons, ions) is prone to damage these materials, whereas the transfer of TMDCs onto fabricated structures tends to be a non-deterministic process. In this contribution, we report results from two different approaches. In the former case, we achieve a deterministic transfer of TMDC layers onto existing plasmonic resonators, while in the latter, we succeed in fabricating plasmonic nanostructures onto monolayer 2D materials.

The common denominator of both approaches is the achievement of large-area TMDC-monolayer flakes, that allow to have large spatial extensions for transfer or fabrication. In detail, we exploited gold-assisted exfoliation as a reliable technique for peeling off large-area TMDC monolayers from bulk crystals. The strong affinity between gold and chalcogens overcomes the van der Waals interlayer attraction, thus peeling off the outermost layer from the bulk TMDC, and allowing in some cases to transfer such a layer onto another substrate [1]. We recently demonstrated a large-scale exfoliation-and-transfer procedure based on the technique proposed by Liu et al. [2], and refined by Petrini et al. [3], where Au films are adopted to exfoliate large-area monolayer TMDCs. Subsequent treatments then allow the deterministic transfer of large-area monolayer TMDCs onto virtually any substrate, yielding high-quality flakes with minimal defects and large lateral dimensions, while requiring limited experimental effort and using common consumables.

Using samples produced on PDMS substrates, we demonstrate the possibility of systematically transferring the produced samples onto a desired target with micrometer control of the sample positioning. Examples of MoS_2 transfer onto previously-fabricated plasmonic nanostructures are reported and discussed, including nanosystems for measuring the thermoplasmonics heating of metallic nanodisks.

For the latter approach, we exploit thermal scanning-probe lithography (t-SPL) as a viable alternative to electron-beam lithography or focused-ion-beam etching to directly write plasmonic nanostructures onto previously-fabricated large-scale exfoliated 2D materials [1,2]. t-SPL works similarly to an atomic force microscope (AFM) with a heating tip; the desired pattern is written on a thermosensitive resist while acquiring a topological image of the sample. After gold deposition and resist lift-off, we are left with gold nanostructures over our TMDC. We demonstrated the appeal of this technique, fabricating regular, evenly spaced, 15 nm-thick plasmonic nanodisks (NDs) on square lattices onto monolayer- and bilayer-thick regions of TMDCs. We show that delicate photonic functionalities, such as TMDC photoluminescence, are preserved after the fabrication [4].

Statistical Evaluation and Dipole Determination by Polarimetric Spectroscopy Yielding the Orientation of Gold Nanorods

P. C. Simo[1*], A. Mildner[1], D. P. Kern[1], M. Zbytovska[1], and M. Fleischer[1]

Abstract: Within just four measurements the presented technique acquires the azimuthal orientation of gold nanorods of various aspect ratios. An analytical dipole model in tandem with dark-field spectroscopy enables the extraction of phase shift information to determine the azimuthal orientations.

The polarization and spatial orientation of a plasmonic emitter, such as a gold nanorod (AuNR), are required for the investigation of optically active hybrid compounds through applications such as chiroptical spectroscopy in the pharmaceutical and biomedical research fields [1]. Similarly, quality control of meta-atom constituents of metasurfaces would benefit from a reliable non-contaminating method that determines an accurate azimuthal orientation to pass a set error margin. Simple structures like AuNRs are known to exhibit a longitudinal resonance (LR) mode that naturally coincides with their azimuthal orientation, and can be extracted by conventional excitation polarization sweep measurements [2]. Advanced optical setups that benefit from image analysis with deep-learning algorithms allow pioneering high-throughput single-shot techniques [3,4]. Nevertheless, the orientation prediction is limited to AuNR aspect ratios (ARs) of under 1.6 and reaches standard deviations of below 5°.

In this work, we present an alternative all-spectroscopic method that yields angular information of single AuNRs within four measurements [5]. A regular dark-field spectroscopy setup, two polarizing filters, and a cross-shaped aperture realize this technique with an accuracy of ±2.4° for a range of ARs. An analytical dipole model is applied to coherently fit the measurements obtained by varying the planar orientation of the analyzing filter [6]. The additional elements, such as a piezo-electric rotational mount for the positioning of the analyzing polarizer filter, offer enhanced automation possibilities.

With a fixed excitation angle $\Phi = 45°$ and randomly varying analyzer angles (here $\Theta = [9°, 106°, 155°]$), one can use the model to fit the data coherently and extract γ_{fit} (Figure 1a)). Compared to γ_{fit}, the SEM-extracted angle γ_{SEM} shows a standard deviation of only ±2.4° for a set of multiple AuNRs of diverse ARs [5]. An SEM micrograph with the drawn-in γ_{fit} and γ_{SEM} can be seen in Figure 1b) and shows good concordance. This approach proves to be reliable and has a low sensitivity to AR. To statistically evaluate the choice of the analyzer angles used for the coherent fitting, a range of discretized analyzer angles Θ from 0° to 180° in 15° steps were used, and the results for any three-angle combination were compared (Figure 1c)). Nearly all fitted azimuthal orientation angles γ_{fit} are within one standard deviation of the real physical orientation γ_{SEM} throughout the possible combinations of three analyzer angles.

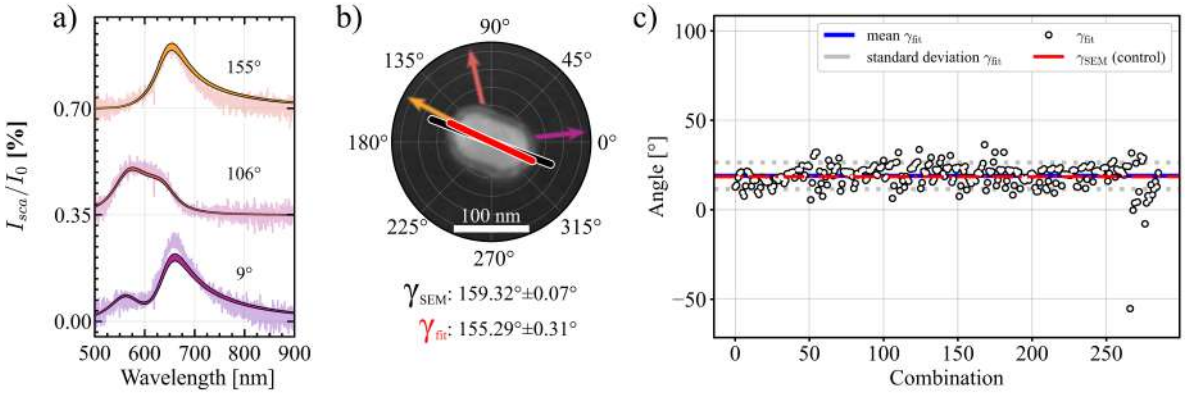

Figure 1: **a)** Polarimetric spectra at a fixed polarization angle Φ and three separate random analyzer angles Θ. The corresponding fitting curves of the analytical model are overlayed with the data. **b)** SEM micrograph of particle which exhibited the spectra shown in b), overlayed with the physical (black) and fitted (red) orientation. **c)** Statistical evaluation of the fitted angle γ_{fit} for all 286 possible combinations. The obtained angle γ_{fit} for the respective combination is shown versus the physical orientation γ_{SEM} of an arbitrary AuNR. Graphs a) and b) taken from [5] with permission.

Abstract: Characterizing the chirality of nanostructure at the single-particle level is essential for understanding the relationship between morphology and chirality. Here, we present our recent development of a single-particle chiral optical microscope, which enables high-precision and high-throughput characterization of chiral nanostructures.

Engineering the chirality of the plasmonic nanostructures is crucial for various applications, including biosensing, chiral catalysis, and chiral separation. As the chirality of the nanostructures is regulated by their morphologies, understanding the relationship between morphology and chirality remains very challenging. Conventional circular dichroism spectroscopy, which measures the average chiral signal from a sample with a heterogeneous geometry distribution, often fails to provide this insight. Therefore, quantifying the chirality of a single nanostructure is important to overcome this limitation.

To address this challenge, several single-particle techniques have been developed to measure the chirality of plasmonic nanostructures. Dark-field scattering (DFS) microscopy is widely used because of its ease of implementation and the ability to acquire circular differential scattering (CDS) spectra, which quantify the chirality of plasmonic nanostructures. While DFS microscopy has demonstrated success in characterizing single-particle chirality, it is often prone to false CDS signals, introducing uncertainties in chiral characterization.

In this presentation, we introduce a novel DFS microscope designed to measure CDS spectra of single plasmonic nanostructures with high accuracy and throughput. We pinpoint the source of artifact CDS signals, attributing them to linear dichroism and the imperfect retardance of polarization optics. Moreover, we have developed a robust method to identify and completely eliminate these artifact signals, ensuring reliable chiral characterization.

Photoluminescence-based polarization conversion in quantum rods aggregate-containing hybrid polymer system

Y. Okazaki[1*], Y. Kawahara[1], S. Kimura[1], H. Shimizu[1], K. Hachiya[1], and T. Sagawa[1]

Abstract: We fabricated various hybrid linearly polarized luminescent films containing different aggregation states of quantum rods in dilute condition. In this presentation, we discuss about the correlation between aggregation states of QRs and polarization converting properties.

Polarization converting materials have attracted attention because of its intrinsic property to utilize incoming light energy effectively. In particular, photoluminescence (PL)-based polarization converting materials have advantage including spectral conversion function, and material formability. For the fabrication of PL-based polarization converting materials, several approaches such as donor-molecule/acceptor-polymer composite system[1] and quantum-dot/quantum-rod system[2] have been reported. However, little is known about the correlation between aggregation formation of luminogens in dilute system and resulting polarization converting property. We recently found that CdSe/CdS core/shell quantum rods (QR) form nano to micrometric aggregates in polymer media in a diluted condition, resulting clear polarization conversion phenomenon based on excitation energy transfer. In this study, we investigate the effect of aggregation forms of QRs in polymer media on the polarization conversion.

QR was synthesized by hot-injection method based on the previous report[3]. The obtained QR/toluene solution showed yellow-colored emission under 365 nm UV light irradiation. Transmission electron microscope (TEM) observation of the dried sample showed a clear rod-like structure with over 90 nm average length and 5.0 nm average width. The width (5.0 nm) is smaller enough than the exciton size of CdSe (10.6-10.8 nm) calculated from the previously reported exciton Bohr radius (5.3-5.4 nm)[4-5], indicating that the obtained QR can show linearly polarized luminescence (LPL). Photoluminescence excitation (PLE) spectra of the QR/toluene solution showed clear PL peak shift by changing the excitation wavelength. Time resolved PL spectral measurements of the QR/toluene solution showed no significant peak shift by time. These results indicate that QRs are well dispersed in the liquid toluene media. Next, the QR/toluene solution was mixed with polymer/toluene solutions, and the mixtures were casted on the substrate to obtain QR/polymer films. The QR/polymer films were uniaxially stretched to obtained $LPL_{QR/polymer}$ films. We first selected poly(ethylene-*co*-vinyl acetate) (EVA) as a media polymer. In contrast to the solution system, PLE spectra of $LPL_{QR/EVA}$ film showed no significant excitation wavelength dependence on PL peak. In addition, PL peak shift was observed in time resolved PL spectral measurements. These results evident that the excitation energy transfer occurred in the $LPL_{QR/EVA}$ film system, indicating aggregation formation of QRs in the EVA media. Aggregation of QRs can also be formed in the liquid media by adding a bad solvent for QRs. When a certain volume of ethanol (EtOH) was added into the QR/toluene solution, no significant excitation wavelength dependence in PLE spectra was confirmed. Using this approach, we fabricated various hybrid LPL films containing different aggregation states of QRs. In this presentation, we will discuss about the correlation between aggregation states of QRs and polarization

converting properties.

Meta-Atoms Based on Self-Assembly of Gold Nanoparticle on Polymer Microspheres

H. Yabu[1*]

[1]Advanced Institute for Materials Research (WPI-AIMR), Tohoku University, Japan
[*]corresponding author: hiroshi.yabu.d5@tohoku.ac.jp

Abstract: Fabrication of gold nanoparticle decorated polymer microspheres and their applications as sensors and metamaterials will be shown.

Particles that accumulate noble metal nanoparticles on the surface of dielectric particles can become 'meta-atoms', the building blocks of metamaterials that utilize plasmon absorption with independent of incident angle of light. Efforts have been made to realize such meta-atoms by electroless plating of silver on the surface of dielectric particles like silica or polymer microspheres, or by adsorbing noble metal nanoparticles such as gold. However, challenges existed in controlling nanoparticle size, as well as their arrangement and density.

We have reported a method for fabricating polymer microspheres with nanostructures mixing various types of polymers, using the Self-ORganized Precipitation (SORP) method, which involves adding a poor solvent to a polymer solution and removing the good solvent by evaporation to obtain a dispersion of polymer microspheres. We have applied the method to fabricate metal nanoparticles-polymer composite particles for various applications (Figure 1). When polystyrene (PS) and amino-terminated polybutadiene (PB-NH2) were mixed and fabricated using the SORP method, core-shell type microspheres were obtained[1], with positively charged PS as the core and PB-NH2 as the shell[2]. Subsequently, by mixing a dispersion of uniformly sized gold nanoparticles, composite microspheres were obtained, where the gold nanoparticles were densely arranged on the surface due to electrostatic interactions.

The resulting composite microspheres have been demonstrated to be applicable as dispersed surface-enhanced Raman scattering (SERS) substrates[3] for analyzing adsorbed molecules, as meta-atoms in the visible to near-infrared region[4], and as probes for antigen-antibody reactions with high optical density[5].

Hot-electron dynamics and speciality optical fibres for quantum applications

Kristina R. Rusimova[1]
[1]Department of Physics, University of Bath, BA2 7AY, UK
Email - K.R.Rusimova@bath.ac.uk

I will discuss two experimental systems – the first uses a scanning tunnelling microscope (STM) to capture the ultrafast dynamics of hot electrons that are relevant to energy applications [1]; the second integrates atomic vapors within speciality optical fibres for quantum technologies [2].

1. STM induced hot-electron dynamics. Hot electrons are central to the operation of important electronic devices like transistors and solar cells. However, accessing and understanding their dynamics is challenging (with only a few experimental techniques capable of such a measurement so far) due to their ultrashort lifetimes (~100s of fs) and corresponding nanometre transport length scales. The tip of a scanning tunnelling microscope is a local tunable source of hot electrons and can be used to excite and manipulate matter right down to the single chemical bond limit. Recently, molecular nanoprobe experiments, where the target molecule is a few nanometres away from the STM tip, have come in the spotlight as viable tool for studying the dynamics of hot electrons in real space. In molecular nanoprobe experiments, charge injected from the STM tip is transported across the surface causing the apparent-simultaneous manipulation of hundreds of molecules with a single pulse of charge carriers. The manipulation process is in effect parallelised and completely decoupled from the STM tip.

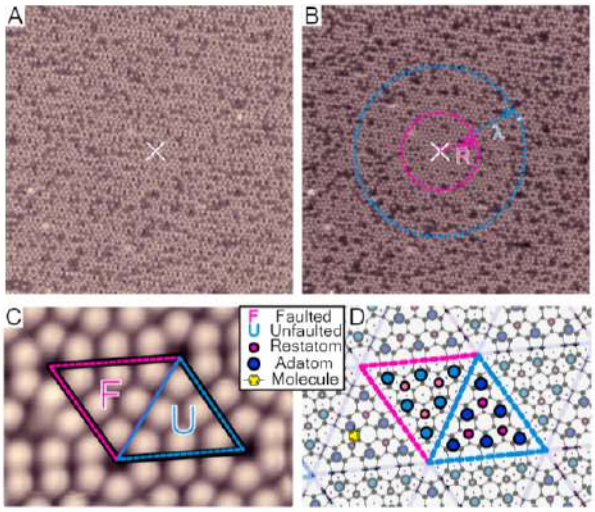

Figure 1 A,B Nonlocal manipulation of toluene molecules on Si(111)-7x7. C,D STM image and corresponding schematic of the Si(111)-7x7 surface reconstruction.

Here we quantitatively link the voltage dependence of the nonlocal manipulation probability to the integrated local density of surface states of the Si(111)–7×7 surface. Our results further corroborate the previously proposed ballistic-diffusive transport model.[3] We show that the measured increase in the probability of nonlocal manipulation with injection bias voltage is not due to an energy dependence of the molecular manipulation process. Instead, it is caused by an increase in the fraction of the tunnelling current that is captured by the surface state mediating nonlocal manipulation. This result is an important breakthrough in the understanding of hot electron dynamics and should allow us to tailor the energy band structures of catalytic systems.

2. Speciality optical fibres for quantum technologies. Alkali metal vapors enable access to single electron systems, suitable for demonstrating fundamental light-matter interactions and promising for quantum logic operations, storage and sensing. However, challenges remain in achieving low-loss, high bandwidth storage and multiplexing that is required for quantum schemes. Moreover, demonstrations of optical quantum memories and switches which address these challenges have been predominantly done with bulk optical components, which require free space alignment and result in high losses when integrated with optical fibres. One way of mitigating loss resulting from the coupling between free space and optical fibres is by integrating the atomic vapours directly inside the core of a hollow-core optical fibre. Here, we demonstrate a low-loss, fibre-integrated cell which once filled with an atomic vapour, can be used to realise an in-fibre quantum memory. We also discuss progress towards filling optical fibres with warm alkali vapours and ensuring high vapour density while at the same time preventing decoherence of the atomic states upon collisions with the walls of the fibres. One way of achieving this condition is

by using plasmonic nanoparticles to convert light into localized thermal energy and to achieve optical depths in warm vapors, corresponding to a ~16 times increase in vapor pressure in less than 20 ms, with possible reload times much shorter than an hour. Our results enable robust and compact light-matter devices, such as efficient quantum memories and photon-photon logic gates, in which strong optical nonlinearities are crucial.

Experimental measurement of nanoscale circular dichroism in plasmonic chiral structures using electron beams

Abstract: Measuring and understanding optical polarization at the nanometer scale is usually a complex problem. Here, we present recent nanometer-scale measurements using cathodoluminescence, demonstrating highly localized circular dichroism in canonical 3D plasmonic chiral objects. The relationship between local dichroism and global chirality is discussed.

Measuring and understanding unpolarized optical properties at the nanometer scale is now commonplace with various spectroscopy techniques. However, addressing optical polarization at this scale remains a much more challenging problem.

In this presentation, we will present recent results on nanometer-scale circular dichroism in canonical 3D chiral objects and their interpretation. More specifically, these results concern a series of nanoscale, circularly polarized cathodoluminescence (CL) experiments performed in a scanning transmission electron microscope on plasmonic Born-Kuhn systems (BKS, see Figure 1, left).

Using a novel detection scheme, we demonstrated a highly localized and strongly circularly dichroic signal (Figure 1, center), which can be reproduced by simulations (Figure 1, right). While this strong dichroic signal could have been naively interpreted as a signature of the well-known large chirality of BKS, a systematic experimental and simulation analysis as a function of the BKS geometrical parameters reveals a surprisingly small effect of this chirality in the emergence of strong local circular dichroism.

A theoretical analysis, ongoing at the time of writing, will be discussed during the presentation to explain this unexpected observation.

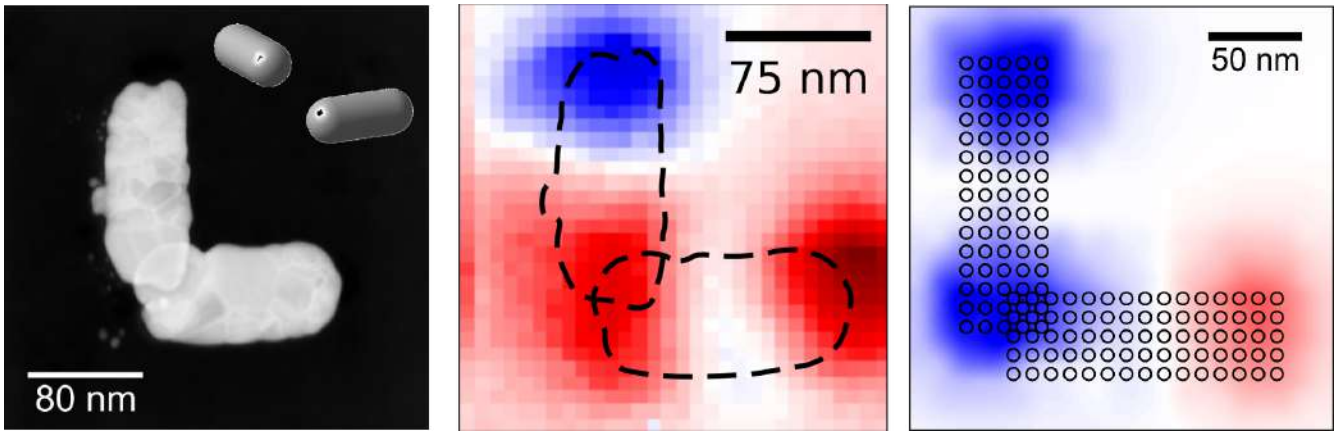

Figure 1: Circular dichroic measurement of a plasmonic BKS structure by spatially resolved cathodoluminescence in a STEM. Left: High angle annular dark field image of a BKS with a schematic of the BKS structure in the inset. Middle: Experimental and Right: simulated circular dichroic cathodoluminescence maps filtered at ~ 1.38 eV.

Abstract: Based on the assembly of Au@protein nanoparticles, we enhance and modulate plasmon-coupled circular dichroism (PCCD) by in-situ stretching of biomolecules between plasmonic nanoparticles, achieving a 1.18-degree circular dichroism and 0.2 dissymmetry factor. Unlike hotspot-based methods, our approach enables reversible PCCD switching over 100+ cycles with significant amplitude changes.

Traditional plasmon-coupled circular dichroism (PCCD) suffers from inherently weak signals due to the size mismatch between chiral molecules and achiral nanoparticles[1,2]. Consequently, researchers have long attempted to enhance PCCD via the creation of strong plasmonic hotspots; however, such approaches have yielded limited improvements, and PCCD intensity still remains far below that of structural circular dichroism (CD)[3-6]. In our work, we shift the focus from engineering plasmonic hotspots to investigating the conformation of chiral molecules. By applying a simple yet effective strategy—namely, the in-situ stretching of biomolecules anchored to plasmonic nanoparticles—we achieve a substantial enhancement of PCCD, with a circular dichroism of 1.18 degree and a dissymmetry factor of 0.2. This lever-effect not only amplifies the PCCD signal to levels comparable to structural CD but also introduces a reversible switching capability over more than 100 cycles. Our approach harnesses dynamic modulation of asymmetric electrostatic fields, enabling real-time tunable chiroptical activity through various stimuli such as pH, light, electric fields, and temperature.

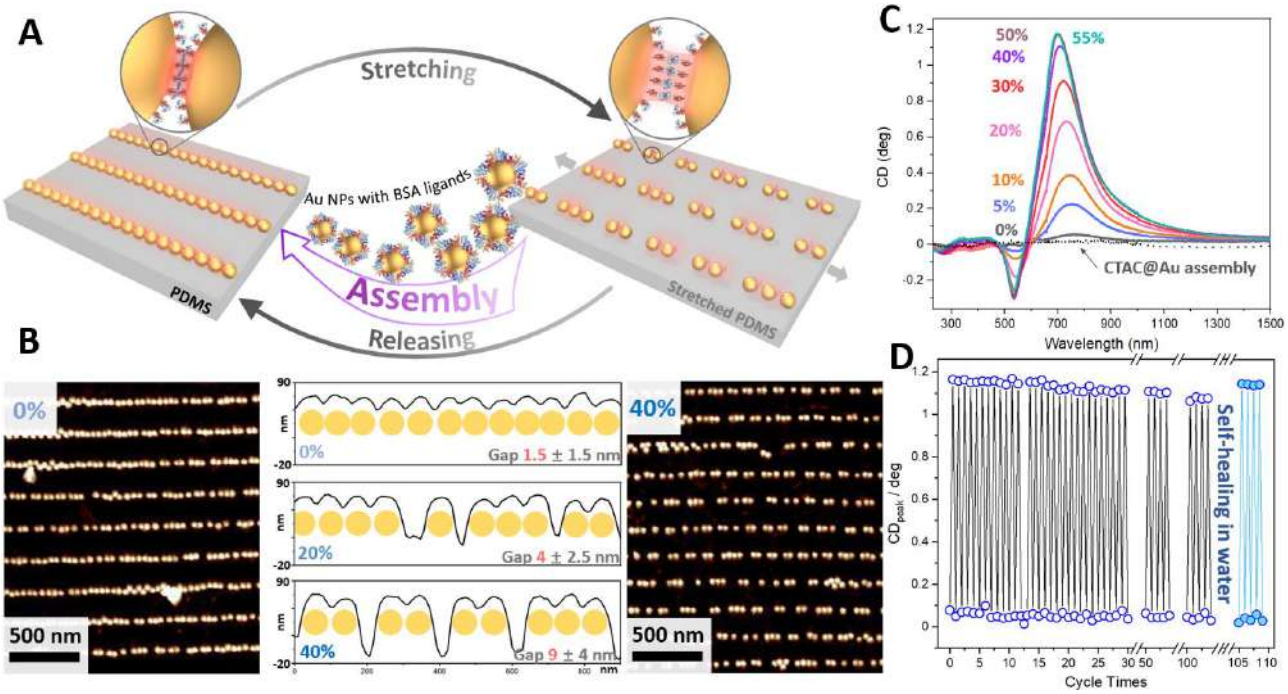

Figure 1. Novel 1D chiral assembly of Au nanoparticles coated with BSA protein, which can be stretched due to the elastic PDMS substrate (A). During stretching the distance between nanoparticles increased gradually (B), triggering sharply increased CD signals (C) together with super cyclic stability (D).

Surface Plasmon Enhanced Photocatalysis

D. Ma[1]

[1]Institut national de la recherche scientifique (INRS), Canada

[*]corresponding author: dongling.ma@inrs.ca

Abstract: Plasmonic nanostructures can enhance photon harvesting of semiconductor materials via hot carrier injection, near-field effects and/or enhanced scattering, which has significant implications for the realization of cost-effective high-performance solar utilization technologies. In this talk, I will overview some of our recent progress on the development of plasmonic nanostructures for photocatalysis.

With unique surface plasmon resonance properties and high potential for many important applications, plasmonic nanostructures are attracting more and more attention in the past decades. In addition to consistent research interest in realizing precise control over their structure (such as size, shape, aspect ratio and uniformity), plasmon enhanced photocatalysis represent a highly promising and important research area. In this context, I will present some of our development in plasmonic nanostructures, such as Cu nanoparticles, CuS nanocrytstals and Ag nanoparticles as well as their contributions to solar fuel production and photocatalytic degradation of pollutants [1-4].

One example is about Ag nanoparticle (NP)-enhanced metal-organic matrix (MOM) with interface-engineering for efficient photocatalytic hydrogen evolution. We developed a facile one-step approach to construct a hybrid structure of in situ synthesized plasmonic AgNPs and Ag-porphyrin MOM, denoted as Ag–AgMOMs. The in-situ growth strategy enables the AgNPs and AgMOM to share the Ag atoms at the interface, which appears essential for an intimate interface between the two compounds (Fig. 1a). A“clean” metal-MOM interface with few surfactants is demonstrated by surface-enhanced Raman spectroscopy (SERS) and related control experiments. The lack of surfactants (polyvinylpyrrolidone, PVP) at the inner NP/MOM interface allows the ef cient interfacial charge transfer, while PVP on the outer surface of Ag–AgMOMs imparts the excellent dispersibility and stability of the latter in aqueous solution. Electron energy loss spectroscopy (EELS) spectra and mapping offer the observation of the plasmonic effect of AgNPs on the AgMOM. The plasmonic AgNPs signicantly enhance the photocatalytic hydrogen evolution of the AgMOM, reaching high values of 1025 and 3153 μmol h−1 g−1 under visible-light and full-spectrum light irradiation, respectively. These values are comparable with those of the state-of-the-art metal-organic-based photocatalytic systems. The underlying charge transfer from the plasmonic AgNPs to AgMOM, exciton- plasmon coupling and associated dynamics under light irradiation are further revealed by in-situ X-ray photoelectron spectroscopy (XPS) and ultrafast transient absorption (TA) spectroscopy. This work may guide the design of plasmonic nanoparticles coupled with organic semiconductors for effective electronic and energy communication.

In another case, we achieved efficient hot hole collection via interfacing plasmonic CuS nanoplatelets with a suitable p-type semiconductor for the first time [2]. The approach we applied was to rationally select a semiconductor (herein, BiOCl) such that it has a suitable band structure to prevent the hole loss from CuS in the dark, while allowing the hot hole injection from the plasmon-excited CuS under illumination. The resultant, efficient hot hole injection was then verified by our systematic measurements along with theoretical modelling. We showed that the transversal mode dominates the hot hole generation and has a greater contribution to photocatalysis than the longitudinal mode. We then elaborated on an optimal CuS/BiOCl composite configuration allowing for efficient hot hole collection in near-infrared photocatalysis. This work demonstrates

the feasibility of harvesting hot holes from plasmonic semiconductors and opens a new route for the rational design of broadband and cost-effective plasmonic photo catalysts.

Sensing 3D Electromagnetic Landscapes with Enhanced Quantum Light-Matter Interaction at the Single-Molecule and Nanometer Resolution

R. M. Córdova-Castro[1,2]

Abstract: We apply single molecule super-resolved measurements to observe the fine details of quantum light-matter interaction at the nanoscale, simultaneously mapping the position of the emitters and its spontaneous emission decay rate modified by the enhanced density of photonic states in unique engineered material platforms.

Understanding how to control the spontaneous emission of light, which determines how likely, how quickly, and where an excited emitter will release a photon, is a necessary part for exploiting the quantum behavior of light for new or advancing existing quantum technologies. The rate at which an emitter can convert its excited-state energy into a photon increases as more photon states are available to radiate into, which is quantified by the local density of states (LDOS) and the Purcell factor. The efficiency with which a single quantum emitter can generate photons in a prescribed optical mode depends on a number of factors: efficiency of excitation (absorption cross-section of the system), the quantum yield of emitted fluorescence and overall collection efficiency. Coupling single emitters to nanostructures that support very small mode volumes can enhance and control the interaction. By acceleration of the spontaneous emission process diminishing the probability of other vibrational transitions, the number of photons per second can significantly increase achieving a bright single photon source with a well-defined two-level system transition decay rate, yielding quantum light behavior at room temperature. When light illuminates a nanostructure, the electromagnetic field is concentrated extremely close to the nanoparticle by resonant optical modes. Quantum emitter's spontaneous emission will dramatically depend on its position near these modes. This makes the single-photon emission rate a precise measure of location, far more accurate than the optical resolution from the same photon. We present three system with engineered LDOS enhancement; GaP nanodimers, 3D hollow plasmonic nanocones and hyperbolic nanorod metamaterial, the engineered materials can drastically modify the photon emission rate of single molecules observed at the nanometer scale. We compared numerical calculations of Purcell factors with the detected enhancements, finding accuracy in the variation of the nanoposition along the 3D fields inside the material. These properties make it an exceptionally sensitive platform for molecular sensing applications and variations of small vectorial fields detections.

Far-Field Single-Molecule Super Localization Microscopy (SMLM) allows the detection of single- emitter position and emission rate modification without disrupting the local environment with metallic probes. The single-photon emission lifetime is measured by a single-photon avalanche diode connected to a time correlating single photon counter (TCSPC) with picoseconds resolution, and correlated with SMLM to image the Purcell factor enhancement below the diffraction limit. Single-molecule nanophotonics is an emerging sub-field with many possibilities to explore new phenomena at the super resolution level of light-matter interaction. Opening up solutions for applications in technologies limited by the resolution, the efficiency of emission of single

photons, the detection of small changes of small fields, the sensing for early diagnostics for low density detections, and many more.

We show that molecular quantum emitters hold promise to play a key role in sensing at the super-resolution level with nanoscale resolution when interaction with nanostructures that supports a high local density of photonic states, with ultra-high enhancement of the spontaneous emission lifetime till picoseconds with extremely position dependence at the nanoscale level. While bringing the possibility of controlling fast single-photons sources on demand at room temperature, the extreme variation of decay rate with the position and dipolar moment, enabled by the metamaterials, creates substantial nanoscale variations in the density of photonic states throughout the structure. These properties provide an exceptionally sensitive platform for applications in molecular sensing and detection of small vectorial fields variations, suggesting potential applications in developing quantum nanophononics technologies.

Abstract:
The rapid advancement of nanophotonics and integrated optics is driving the transition toward reconfigurable and adaptive photonic systems capable of operating at the speed of light [1-2]. My talk will overview recent breakthroughs in reconfigurable integrated photonics, focusing on the development of dynamically tunable optical components that enable ultra-fast signal processing, optical memory storage, and quantum photonic applications[3-6]. I will introduce novel material platforms with high optical nonlinearity and phase-change properties, facilitating real-time reconfigurability in compact photonic circuits. Special emphasis will be placed on the integration of photochromic materials, metasurfaces, and Fabry-Pérot resonators to achieve adaptive optical functionality. Additionally, the role of AI-driven optimization for self-learning photonic systems will be discussed, paving the way for autonomous, high-performance optical computing and secure quantum communications. These advancements hold significant promise for applications in next-generation telecommunication networks, quantum information processing, and energy-efficient data centers [1].

Bilkent University UNAM, Department of Electrical and Electronics Engineering, Department of Physics, Institute of Materials Science and Nanotechnology, Ankara, Turkey

hvdemir@ntu.edu.sg, volkan@bilkent.edu.tr

Colloidal semiconductor nanocrystals enable enriched color conversion essential to superior lighting and displays. These colloids span different types and heterostructures of semiconductors from colloidal quantum dots to wells. In this talk, we will focus on atomically flat, tightly confined, quasi-2-dimensional quantum wells for use in lighting and displays [1-14].

Also, we will present a powerful, large-area, orientation-controlled self-assembly technique for orienting these quantum wells either all face down or all edge up and demonstrate three-dimensional constructs of their oriented self-assemblies with monolayer precision [8,9].

Among their extraordinary features important to applications in lighting and displays, we will show record high efficiency from their colloidal LEDs [10,11] and record high gain coefficients and record low lasing thresholds from their colloidal laser media [1,12,13] using a variety of their heterostructures [2-6,10] and/or oriented assemblies [8,9,11]. We will finally discuss our recent work for the use of colloidal quantum wells intimately integrated into metasurfaces to make a new class of colloidal meta-devices [14].

From hairy particles to particle-based metamaterials

Andreas Fery

Institut für Polymerforschung Dresden e.V. and Technical University Dresden, Germany

Metallic nanoparticles offer a number of interesting optical and electronic effects. A prominent example is the localized surface plasmon resonance (LSPR), which is due to resonance excitations of the particle's free electron cloud vibrations by light. Consequently plasmonic nanoparticles provide excellent opportunities for controlling electromagnetic near-fields at optical frequencies, which has led to a wide range of applications in various fields such as surface-enhanced spectroscopy, light harvesting, or photonics.

While much of the research has been devoted to understanding nanoparticle synthesis and tailoring their LSPR at the single-particle level, novel perspectives arise from combining plasmonic nanoparticles with a functional polymeric shell which does not only allow controlling inter-particle distances but as well tailor transport / electronic couping. [1,2,3]

Increasing the level of complexity, the ordering of particles at different length scales opens another powerful routes to optical and electronic functionality due to novel collective plasmonic excitations arising from plasmonic coupling effects. We focus on achieving such ordered particle arrays through self-assembly approaches. Colloidal self-assembly can indeed yield well-defined colloidal clusters and surface arrays [4] in which coupling effects can be controlled. In particular, large-scale assemblies are possible in combination with biomimetic surface patterning like controlled wrinkling. We discuss the underlying physicochemical principles of the structure formation process and the resulting plasmonic coupling effects including chiroplasmonic metamaterial effects [5, 6]. Finally, we present perspectives on how these assembly principles can be relevant for developing circular economy approaches for advanced materials.

Due to their potential use in a wide range of applications such as nanophotonics, light harvesting, sensing, photothermal therapies, nanocrystals (NCs) exhibiting localized surface plasmon resonance (LSPR) have induced a strong research activity. Highly doped semiconductors NCs have recently gained a significant attention in particular for sensing because the LSPR frequency is expected to be tuned by controlling the free carrier concentration and to be redshifted as compared to metals. Indeed, in metal nanoparticles such as Au or Ag, the high charge carrier concentration leads to resonance frequencies for LSPR in the visible spectrum. As the resonance frequency strongly depends on the dielectric constant of the environment, targeted molecules can be sensed by measuring the spectral shift of the plasmon resonance. Another sensing approach consists of coupling the molecular vibrational mode, characterized by a low cross section, with the near field around plasmonic nanoparticles. A high vibrational signal enhancement is expected if the overlap between LSPR and molecular vibrations is strong. With metals, micrometer sized particles or even more complex structures are usually required to reach an optical resonance in the near-infrared or mid-infrared range. To overcome the limitation of plasmonic metal nanoparticles, highly doped semiconductors NCs are interesting alternative plasmonic particles.

As a low cost, non-toxic and CMOS compatible material, silicon has emerged as a promising material for plasmonic application. The existence of LSPR in semiconductor nanostructures especially in silicon nanocrystals (Si-NC) embedded in silica as well as the role of dopant concentration on the plasmon resonance have been demonstrated [1,2,3]. In our group, phosphorus-doped Si-NCs were obtained by thermal evaporation of phosphorus-doped SiO/SiO_2 multilayers in ultrahigh vacuum. As-deposited multilayers were amorphous. Samples were then post-growth-annealed in a rapid thermal annealing furnace at 1100 °C for 15 minutes under a constant nitrogen flow. As a result, the SiO layers is destabilized leading to the formation of Si-NCs embedded in a silica matrix, as shown in Figure 1. The multilayer architecture hence enables accurate tuning of the Si-NCs size, controlled by the SiO thickness. The SiO_2 layer thickness was kept around 12 nm and that of SiO can be varied from 3 nm to around 20 nm. Phosphorus atoms were incorporated in both SiO and SiO_2 layers by a heated GaP decomposition source held at 800 °C during the whole deposition for all samples. The fixed GaP cell temperature allows us to keep a constant phosphorus content in the multilayers as well as in the Si-NCs regardless of their size. The nanocrystal size and the dopants localization were studied at the nanoscale by scanning transmission electron microscopy.

Here, the size dependence of the LSPR is investigated for a P content in the layer close 1 at.% and for a NC diameter varying from 7 to 16 nm. The LSPR is located at around 5 µm (2000 cm^{-1}). Infrared absorption spectroscopy revealed that both the energy of the resonance and the mobility of the charge carriers are increasing functions of Si-NCs size. The plasmonic response is modeled in the framework of the Mie theory, using the Drude model to describe the dielectric function of Si and a size-dependent scattering of free carriers at the NC/SiO_2 interface [4]. The temperature dependence of the plasmonic response, from 10 to 350 K, is in good

agreement with the metal-like behavior of the heavily doped nanocrystals and the carrier transport can be modeled taking into account electron-lattice and electron-defects interactions.

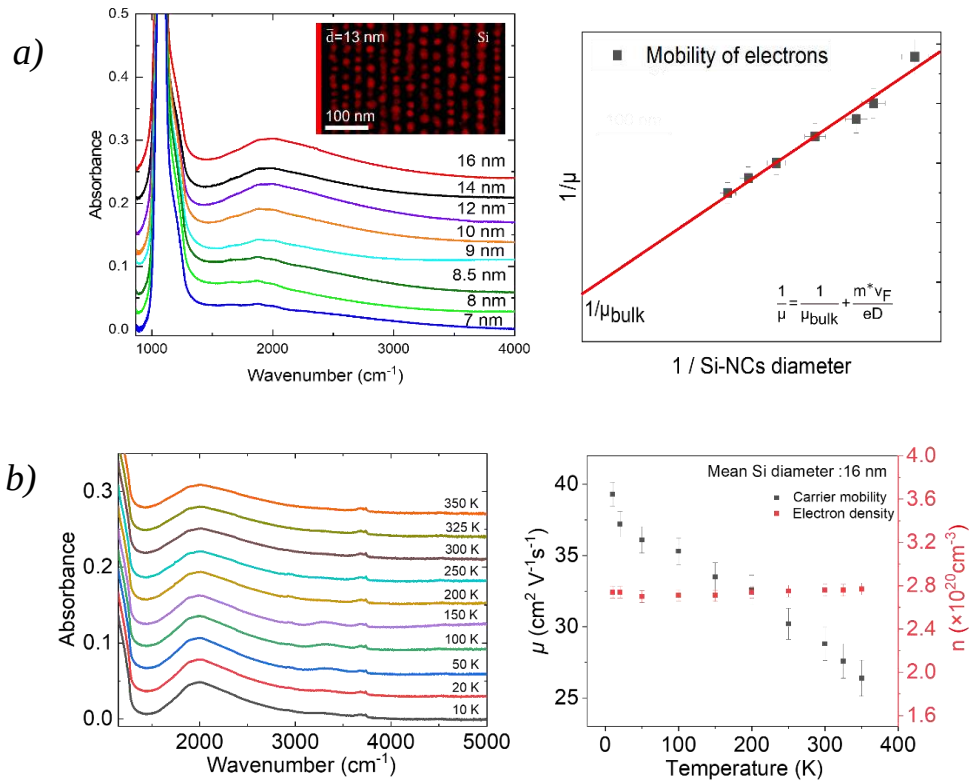

Figure 1: a) Size dependence of the LSPR of P-doped Si-NCs (left) and of the carrier mobility (right); b) Temperature dependence of the LSPR response (left) and of the mobility and free carrier density (right) for Si-NCs with a diameter equal to16 nm.

Controlled Self-Assembly of Polymer-Grafted Nanoparticles Toward Hyperuniform Materials

Kyoungweon Park,[1,2] Derek Huang, [1,2] Kenya Hazell, [1,2] Anesia Auguste, [1] Andrew Gillman, [1] Rich Vaia[1], Larry Drummy[1]

[1] Materials & Manufacturing Directorate, Air Force Research Laboratory, Wright-Patterson Air Force Base, Ohio 45433-7750
[2] Bluehalo, Dayton Ohio, 45432

Hyperuniform materials combine local disorder with long-range uniformity, enabling control over wave propagation. Here we developed a synthetic protocol for highly concentrated, monodispersed gold nanoparticles (AuNPs) with tunable size and shape. Using bimodal size distributions, we fabricated thin films of polymer-grafted AuNP assemblies, achieving macroscale packing and statistically verified hyperuniformity.

The interplay of order and disorder across length scales has long fascinated materials scientists. Recently, hyperuniform materials—exotic disordered systems that exhibit local randomness alongside globally suppressed density fluctuations—have garnered significant interest. In two-phase materials, hyperuniformity combines the short-range disorder of amorphous systems with the long-range uniformity of crystals. In nanocomposites, particle packing is a critical parameter for tuning material properties, and hyperuniform packings enable precise control of electromagnetic and mechanical wave propagation.

Polymer-grafted nanoparticles (PGNs) represent a novel class of materials that are compatible with polymer additive manufacturing techniques and offer diverse functionality through their tunable nanoparticle (NP) cores—ranging from plasmonic and semiconducting to magnetic NPs. PGNs offer a level of structural control beyond traditional composites, with tunability stemming from core size/shape and polymer grafting parameters such as density and molecular weight.

Gold nanoparticles (AuNPs) are particularly attractive NP cores due to their tunable size, versatile surface chemistry, and strong interactions with optical fields. Despite advances in synthesis, producing highly monodisperse AuNPs larger than 10 nm in high yield remains a challenge. Here, we present a robust, scalable synthesis of concentrated, monodisperse AuNPs with tunable diameters from 10 to 50 nm via optimized seed-mediated growth and strategic regrowth techniques.

Using these AuNPs, we fabricated PGN assemblies with bimodal core size distributions, demonstrating macroscale packing and confirming large-area hyperuniformity through statistical analysis. Furthermore, we show that the degree of hyperuniformity correlates with the composite's mechanical properties, as measured by Brillouin light scattering.

These concepts offer a pathway to multifunctional materials capable of manipulating propagating energy—such as light, sound, and heat—and are expected to guide the design of next-generation structural and component-level materials.

A Platform for Single-Crystal Nanomaterials and Metasurfaces with Application in Nanophotonics, Sensing and Energy Harvesting

S. V.-Grayli[1], A. Adserias[2], F. MacNab[2] and G. W. Leach[2*]

[1]Institute for Quantum Computing, University of Waterloo, Canada
[2]Department of Chemistry, Simon Fraser University, Canada
[*]corresponding author: gleach@sfu.ca

Abstract: We describe a versatile platform for single-crystal (SC) plasmonic nanomaterials and metasurfaces. Au(100) metasurfaces provide tailored fields that produce large surface enhanced Raman scattering yields for sensing. Metasurfaces of single-crystal split ring resonators provide flat optics for polarization manipulation, and hybrid SC plasmonic alloys provide improved electrocatalysts for energy harvesting.

Material quality plays a critical role in the performance of nanometer-scale plasmonic structures and represents a significant hurdle to large-scale device integration. Progress has been hindered by the challenges of realizing scalable, high quality, metal deposition strategies, and by poor pattern transfer and device fabrication yields characteristic of most metal deposition approaches, which yield polycrystalline metal structure. Here we highlight a novel, scalable and versatile platform to deposit ultrasmooth, single-crystal (SC) gold films ideal for subtractive patterning of nanostructures through ion beam milling, and high definition, sub-wavelength SC nanostructures through lithographic patterning methods to yield SC metasurfaces.[1,2]

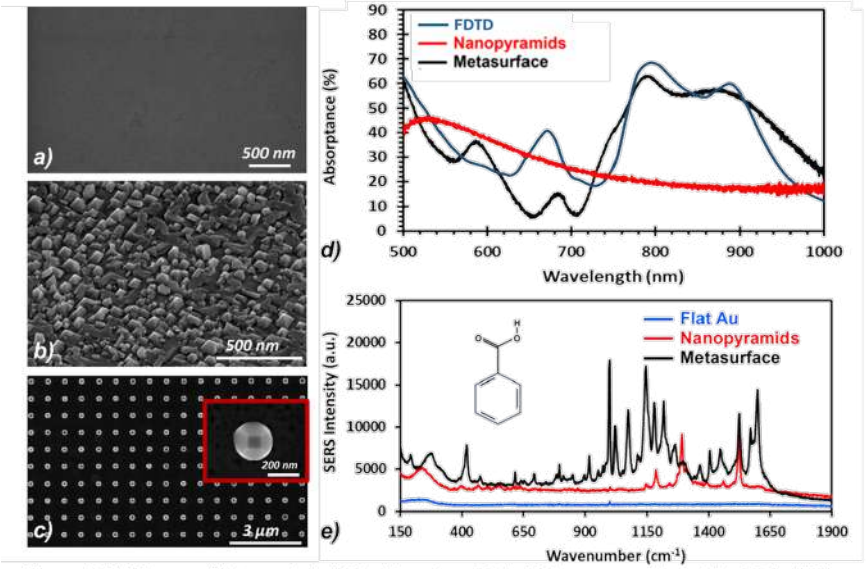

Figure 1. SEM images of (a) smooth Au(100), (b) random SC Au(100) nanopyramids and (c) SC-Au(100) metasurface. (d) Experimental absorptance spectrum of random nanopyramids (red), SC Au(100) metasurface (blue) and FDTD spectrum (black) of the BA-covered metasurface. (e) SERS spectra of BA-coated surfaces (a)-(c); flat gold (blue), random nanopyramids (red) and SC Au(100) metasurface (black).

SC Au(100) metasurfaces comprised of square pyramidal nanostructures with dominant Au(111) facets have been fabricated to tailor the local plasmonic fields to provide resonant enhancement of the surface enhanced Raman scattering (SERS) spectra. Finite Difference Time Domain (FDTD) simulations guide the design of the metasurfaces through nanostructure size and periodicity to provide local field enhancement resonant with the 785 nm laser employed for SERS measurements. This resonant enhancement provides significantly larger SERS response from Raman marker molecules such as benzoic acid (BA), compared to the SERS response from BA-covered SC gold surfaces comprised of SC square pyramids of random disposition.[3]

Metasurfaces comprised of SC gold split ring resonators (SC-SRRs) provide an example of the fabrication of more complex nanostructures and of the high-fidelity pattern transfer that can be achieved. Large area arrays of

SC-SRRs provide a path toward scalable, reflective “flat optics” (Figure 2). The structures are variants of more traditional SRRs and have been designed to impart broadband polarization control. The diffracted reflection of incident white light shows 2-D structure with each diffraction order comprised of different spectral components having similar polarization characteristics.

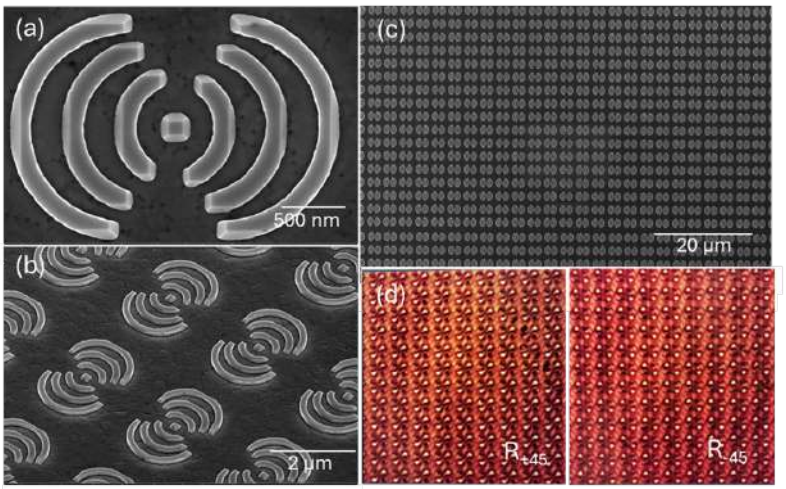

Figure 2. (a) top-view SEM of an individual SC-SRR, (b) angle-view SEM of several SC-SRRs, (c) large area-view SEM of the SC Au(100) SC-SRR metasurface array, (d) polarized reflectivity images of 800 nm light from the SC-SRR metasurface.

The polarization characteristics of the SC-SRR metasurface have been analyzed through control of both the linear incident polarization and the polarized output. Our results indicate that the metasurface imparts circular polarization to the diffracted output, providing broadband polarization control.

Current strategies for renewable energy harvesting necessitate the storage of intermittent electricity sources and typically employ batteries, or the production of “solar fuels” such as hydrogen, as a means of intermediate energy storage. We have investigated the use of plasmonic surfaces and nanostructures to improve the electrocatalytic production of hydrogen and other small hydrocarbons through the deposition of new SC plasmonic alloy materials of controlled composition. When deposited in smooth single-crystal form, the electrocatalytic production of solar fuels can be characterized as a function of alloy composition to define improved electrocatalysts with common electroactive surface areas (ECSAs). Here we describe the fabrication of SC alloy catalysts for the hydrogen evolution reaction (HER) and for the electrocatalytic CO_2 reduction reaction (CO2RR) in alkaline environments. We show that Pt:Ag and Pt:Au HER electrocatalysts provide lower overpotentials and activation barriers than the benchmark Pt. Likewise, the formation of new SC Au:Cu alloys help to define electrocatalyst compositions that provide small hydrocarbon product selectivity. We also describe our recent efforts to control surface texture to form high surface area nanostructures of controlled composition to generate improved electrocatalysts with high activity and photocatalytic response.

Abstract: We present plasmonic sensors functionalized with photopolymerized molecularly imprinted polymers (MIPs) for selective detection of small molecules and enantiomers. Controlled MIP growth on metallic substrates preserves plasmonic properties and enables highly selective recognition in SPR and SERS configurations. Applications include pollutants, pharmaceuticals, and chiral analytes.

Molecularly Imprinted Polymers (MIPs) are synthetic recognition materials with tailor-made selectivity toward specific analytes (also called « plastic antibodies »), including small molecules, biomarkers, and even enantiomers. Coupling MIPs with plasmonic nanostructures opens promising avenues for enhancing the selectivity, sensitivity, and stability of surface-based detection techniques such as Surface Plasmon Resonance (SPR) and Surface-Enhanced Raman Scattering (SERS).

In this work, we present the use of photopolymerization to fabricate and pattern MIP layers directly on metallic surfaces or nanostructures. Light-assisted processes allow precise spatial control over the polymer growth, enabling nanoscale patterning and conformal coating of complex plasmonic architectures. These strategies are compatible with various SPR configurations, including Kretschmann geometry and optical fiber-based sensors.

The resulting hybrid systems combine the molecular selectivity of MIPs with the near-field enhancement of plasmonic substrates. We demonstrate their performance for the selective detection of pollutants (such as PFAS), pharmaceutical residues, and chiral compounds, including enantiomer-specific recognition. Spatial localization of polymerization is shown to correlate with plasmonic field distribution, supporting the use of these hybrid structures for high-performance, miniaturized sensing platforms..

Finite Element Analysis of Light Scattering in Resonant Multi-Dielectric Coverslips for Enhanced Total Internal Reflection Fluorescence Microscopy

Abstract: We investigate the optimization and implementation of resonant dielectric multilayers (DM) coverslips to enhance total internal reflection fluorescence microscopy contrast. These DM can support surface waves resulting in amplifying the local excitation field, directly acting on fluorescence enhancement. However, scattering from substrate roughness can degrade performances that will be discussed.

Total Internal Reflection Fluorescence (TIRF) microscopy is a powerful imaging technique that enables selective excitation of fluorophores in a thin region near the interface between a coverslip and a biological sample. This is achieved using evanescent waves generated under conditions of total internal reflection. However, TIRF microscopy suffers from several limitations, such as uneven illumination due to beam divergence and a trade-off between excitation angle and evanescent field intensity, which can reduce image quality. Enhancing the local excitation field without compromising angular tolerance is thus critical for improving image contrast and sensitivity.

Dielectric multilayer (DM) thin films, when properly engineered, provide an effective approach to enhance the evanescent field at the sample interface. These multilayers can be designed to create optical resonances at specific wavelengths and incident angles [1-4], thereby increasing field confinement without requiring alterations to standard TIRF microscope optics. Such stacks can also provide spectral and angular tunability, crucial for achieving optimal fluorescence enhancement. We demonstrated up to a 4-fold fluorescence signal enhancement using such resonant stacks compared to a standard glass coverslip [5-6]. However, discrepancies between numerical predictions and experimental measurements prompted a deeper investigation and especially into light scattering effects that become significant under resonant conditions [2-3].

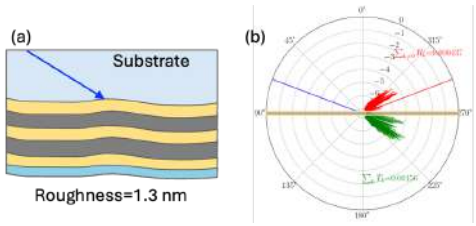

Figure 1: (a) Schematic of the multilayer structure with alternating high/low materials layers with roughness (b) Calculated radiation pattern showing scattering response caused by surface roughness under resonance conditions.

To understand the mismatch between simulations and experimental results, we investigated light scattering due to surface roughness, which becomes more significant under resonance. Rough surfaces in multilayer stacks act like diffraction gratings, modifying both field distribution and angular emission patterns (see Figure 1). We used atomic force microscopy to measure the substrate and free surface roughness's of the fabricated samples and incorporated these features into a Finite Element Method (FEM) model [7]. The roughness, often inherited across layers from the

substrate, was assumed to be periodic, allowing for a computationally efficient truncated simulation domain. By FEM, we calculated the diffraction efficiencies and angles of each diffracted order under resonant excitation. These results revealed additional scattering channels and angular redistribution of the emission, which main explain the higher background noise observed in experiments.

Resonant multi-dielectric coverslips represent a viable route to enhance the sensitivity of TIRF microscopy through tailored field enhancement. However, practical implementation requires careful balance between field amplification and scattering enhancement. Our combined experimental and FEM-based numerical approach shows that scattering from surface roughness is influencing the system's optical response, especially under resonant conditions. By incorporating realistic surface features into the simulations, we achieved a better match with experimental observations, paving the way for more accurate design and interpretation of enhanced TIRF systems for biological studies, particularly pathogen dynamics at cell membranes.

Abstract: Traditionally, nanostructuring is accomplished through etching of films and substrates using standard photolithography or electron beam lithography (EBL) which limit these structures to flat two-dimensions or fixed height. To overcome these challenges, we developed fabrication of gray scale masks using two-photon polymerization using a Photonic Professional GT2 Nanoscribe 3D printer.

Dielectric nanostructures are used in photonic applications, such as sensing, wavefront manipulation, light detection, and quantum computing. Traditionally, two-dimensional structures are fabricated by patterning and etching a dielectric substrate using standard photolithography or electron beam lithography (EBL) methods. While these well-established methods are powerful, limitations such as their mask requirement, resolution limit, and limitations to create beyond two-dimensional patterns hinders their use. To overcome these challenges, we explore fabrication of gray scale masks using two-photon polymerization using a Photonic Professional GT2 Nanoscribe 3D printer. We combine this digital laser writing (DLW) technology, and reactive ion etching (RIE). Using this maskless laser-writing technique, the Nanoscribe is capable of writing 2.5-dimensional polymer structures which are etched to the substrate to create metasurfaces of different shape, several lateral sizes, and varied heights. This fabrication technique enables the production of one dimensional and two dimensional periodic and aperiodic gratings. The quality of these structures is explored optically through infrared reflectivity using a Fourier Transform infrared (FTIR) spectrometer equipped with an infrared microscope as well as Raman scattering mapping. Our results are compared to COMSOL models of the achieved nanostructures.

To demonstrate the power of this fabrication technique, we cover several examples of the structures fabricated as well as the novel physics of these 2.5D nanophotonic structures. In particular, we present the first observation of traveling surface phonon polariton modes on a nanostructured surface of an isotropic ionic crystal (i.e., SiC). This achievement represents a development towards utilizing SPhPs in novel nanophotonic devices such as metatronics , waveguides and nanoscale optoelectronic devices. Surface phonon polaritons (SPhPs) are a low-loss alternative to surface plasmon polaritons with the potential for mid-infrared to terahertz nanophotonic devices. One requirement for the development of nanophotonic circuitry is the transport of information (i.e., polaritons) from one circuit component to the next. Traveling surface phonon polaritons in isotropic media presents a potential mechanism to achieve the desired interconnects. While localized surface phonon polaritons have been widely implemented, no traveling surface phonon polaritons in nanostructured isotropic ionic crystals have been demonstrated or explored up to date. In this study, we experimentally and theoretically demonstrate traveling surface phonon polaritons in one-dimensional grating. Furthermore, Raman mapping, when compared with phonon distribution based on selection rules, provided additional evidence for the presence of both traveling and localized modes. We provide mechanisms to control the group velocity, propagation length, and confinement of the traveling modes by engineering the geometric parameters of the gratings. Our results show that the group velocity can be slowed down at least to 4% speed of light in the vacuum, while achieving propagation lengths higher than 150 μm and confinement below 2μm.

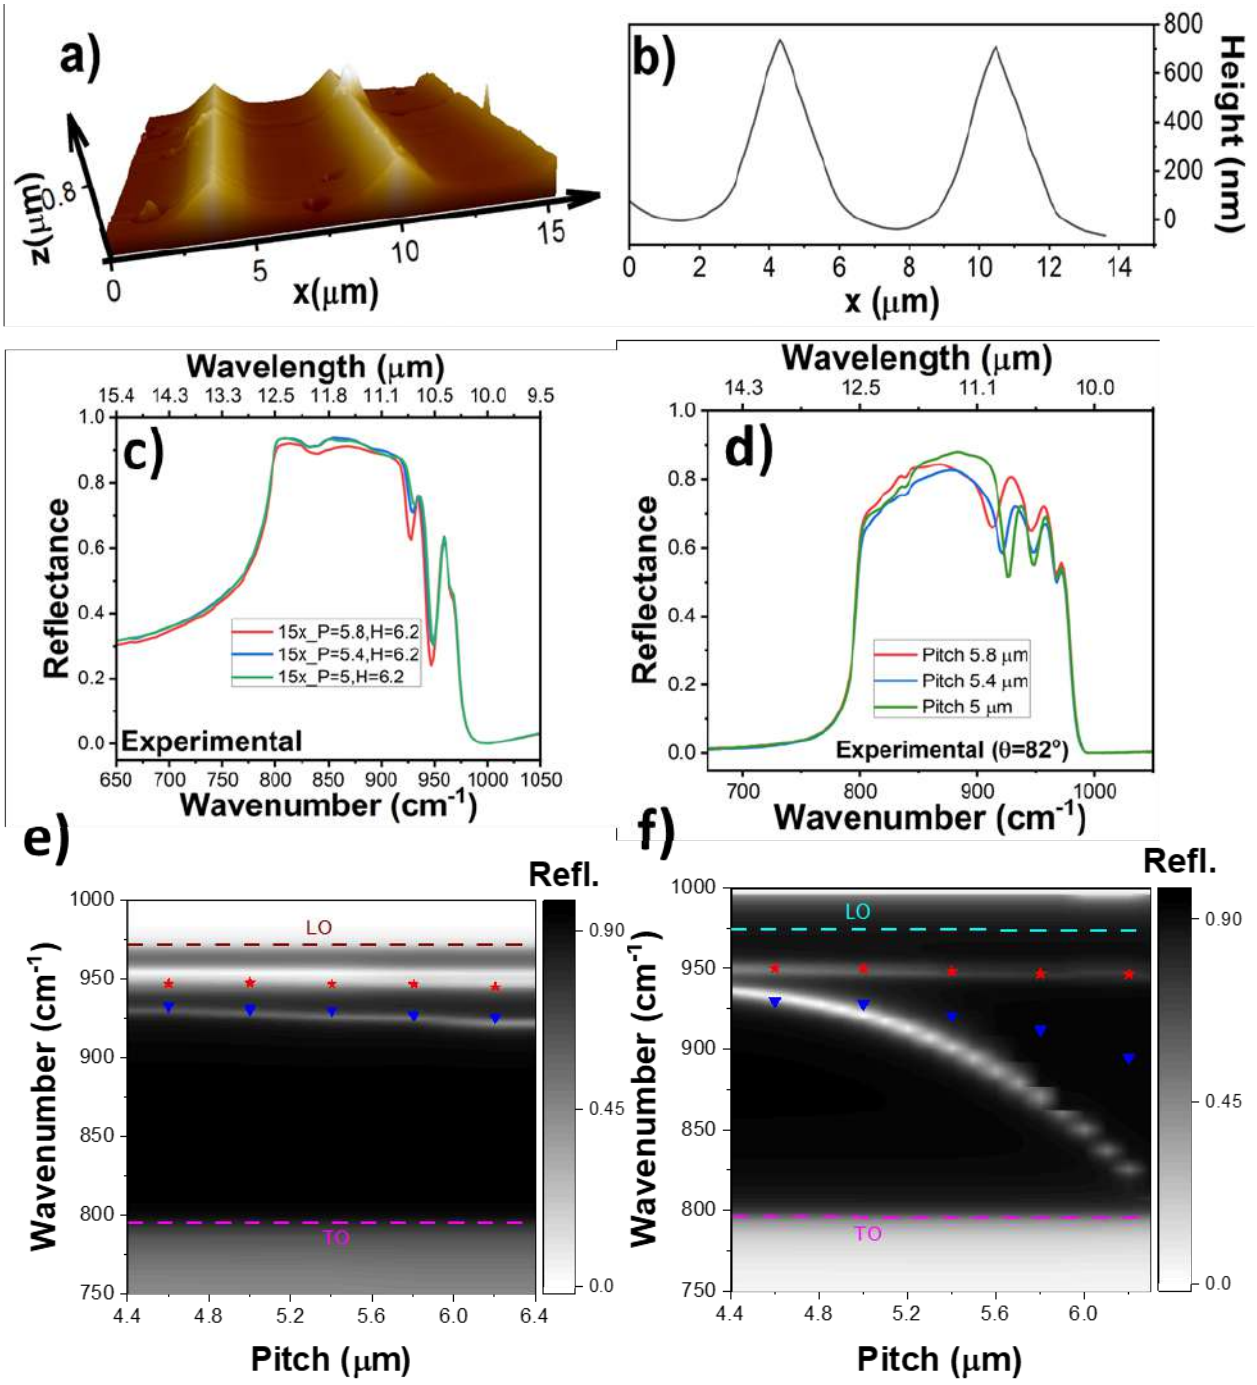

Figure 1(a) AFM image of a 1D grating made of 4H SiC, displaying the surface morphology of the sample. (b) Cross-sectional view of the surface grating. (c-d) Experimental reflection spectrum with p-polarized light at (c) a 15° angle of incidence and (d) a 75° angle of incidence, for a fixed height (0.8 μm), demonstrating resonance position shifts with varying pitches for the lower energy mode. (e-f) Simulated reflection spectra for varying pitches with a fixed height of 0.8 μm at (e) 15° and (f) 75° angles of incidence. Experimental traveling and localized modes are marked by triangular and star symbols, respectively. Dotted lines illustrate the LO and TO modes, depicting the Reststrahlen band.

Hybrid Self-Assembled Plasmonic Metasurfaces for Applications in Photonics

Abstract: Chemically synthesized monodisperse plasmonic nanoparticle colloids self-assembled into soft lithography replicated elastomer templates and transferred onto desired surfaces serve as macroscopic scale metasurfaces. Regular noble metal nanoparticle arrays in organic dyes or semiconductor layers couple the scattered localized plasmon light into high-Q surface lattice resonances serving in nanolasing and photocatalysis.

Precise average size, high monodispersity, shape control, and reproducibility of wet-chemically synthesized plasmonic nanoparticles (NPs) [1-2] enable their applications for photonic devices which are originally made employing top-down methods [3-4]. Template-defined nanoparticle self-assembly from concentrated nanoparticle colloids is an established method for the manipulation and deposition of NPs into lithography-defined positions originating desired photonic coupling and controlled local field enhancements [3-6]. Regular sub-wavelength spaced noble metal NP arrays can diffractively couple the scattered light from broad localized surface plasmons (LSPs) into narrow and high-Q resonances termed plasmonic lattices or surface lattice resonances (SLRs) [3-7]. The wavelength taylorability of SLR positions rises from the size-dependent LSPR coupling with the pitch-determined Rayleigh's anomaly [3-7]. The laterally confined light can act as an optical resonator for a dye nanolaser [7], can confine the electromagnetic radiation for desired wavelength Raman enhancement [5,6], and can contribute to efficient solar water splitting by metasurface photoelectrodes [8]. Electron beam lithography defined master replication with soft lithography into Polydimethylsiloxane elastomer deposition templates act as plasmonic metasurface for direct application or as a transfer carrier for integration into more complex photonic structures. Regular plasmonic hybrid structures in wide band gap semiconductor layers serve as efficient hot carrier injectors while NP arrays in organic days sustain resonance modes amplifying the stimulated emission.

The work was supported by the European Economic Recovery and Resilience Plan "New Generation Lithuania" and the budget of the Republic of Lithuania, Project No. 02-002-P-0001.

Abstract: In nanophotonics, we introduce permittivity-driven quasi-BICs (ε-qBICs), achieved by embedding identical resonators in a refractive index-contrasting medium. Integrating electro-optic polyaniline enables electrically reconfigurable ε-qBICs with rapid switching and durability, advancing tunable metasurfaces for on-chip optics, sensing, and adaptive photonic applications without modifying resonator geometry.

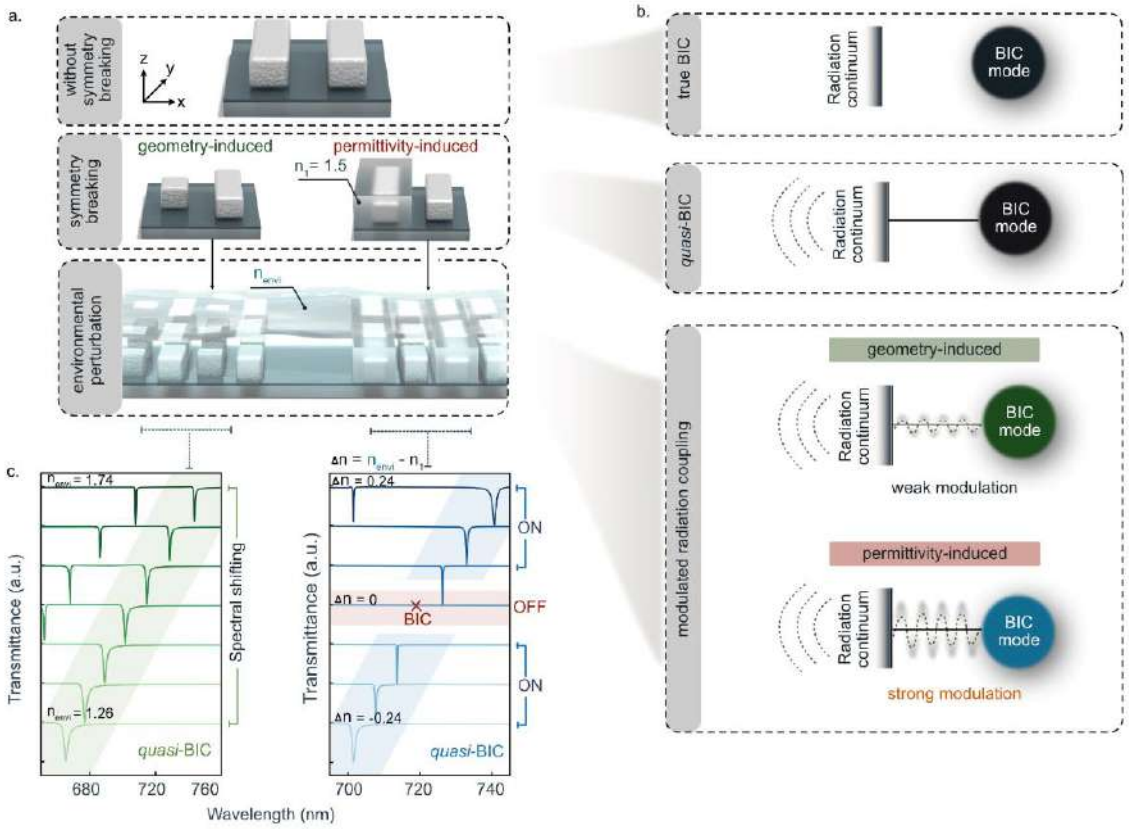

Figure 1. Modulation of radiation coupling in permittivity-asymmetric quasi-BIC metasurfaces under environmental perturbation. (a) Illustration of transition from symmetry-protected BICs to *q*BICs via

geometry- and permittivity-based symmetry breaking. (b) Schematic illustration of the BIC coupling mechanism. (c) Simulated transmittance spectra reveal that the geometry-induced *q*BICs only present spectral shifts when environmental RI changes, while permittivity-induced *q*BICs respond dynamically and present a transition between the 'ON' and 'OFF' states. Adapted from Ref. [1]

Photonic bound states in the continuum (BICs) have emerged as a powerful means of controlling light [2], their common reliance on geometrical symmetry breaking for obtaining tailored resonances makes them highly susceptible to fabrication imperfections and the fixed asymmetry factor fundamentally limits their application in reconfigurable metasurfaces [3].

Our research introduces a new approach for engineering BIC metasurfaces via permittivity-induced symmetry breaking in the surrounding environment of the resonators, a significant departure from traditional, geometry-reliant methods. This strategy not only overcomes the inherent constraints of geometric asymmetry manipulation but also unlocks the flexibility of post-fabrication control over the coupling to the radiation continuum, a governing aspect of BIC physics.

Additionally, our ε-qBICs metasurface design showcases enhanced optical response to the refractive index perturbations of the surrounding medium. In contrast to straightforward spectral shifts, our ε-qBICs metasurface concept opens possibilities to finely modulate between quasi and true BIC states.

We have experimentally demonstrated the generation of the ε-qBICs from specifically designed metasurfaces, where the coupling channel of BIC to continuum radiation is established by the embedding of two identical TiO_2 nano-rods into surrounding media with different permittivity (such as PMMA and air). The ε-qBICs concept is further exploited for realizing electrically reconfigurable BICs by integrating a conductive polymer into our metasurfaces.

The advantageous electro-optical properties of PANI endow the ε-qBICs with excellent electrical reconfigurability. By tuning the optical properties of PANI, the ε-qBICs can be dynamically switchable, exhibiting fully reconfigurable qBICs with high modulation contrast. Additionally, we have demonstrated the electrical switching performance of the reconfigurable ε-qBICs, with fast switching speed (12.2 ms and 18 ms for switch-on and switch-off processes, respectively), and excellent switching durability even after 1000 cycles. Our design is compatible with a range of active materials beyond PANI, including liquid crystals, phase change materials, and transparent conducting oxides.

The permittivity-induced BIC metasurfaces unlock an additional degree of freedom for manipulating and engineering BIC states. Thereby laying the groundwork for the on-demand integrated electro-optical devices.

Abstract: An all-fiber optical sensor with high resolution (2664 RIU^{-1}) and broad linear range (refraction index 1.330–1.430) is realized by coupling resonances from the Fabry–Perot cavity and plasmonic metasurfaces. The whole device is integrated on the fiber tip to enable in-situ liquid monitoring.

Summary:

Refractive index (RI) sensors play an important role in various applications including biomedical analysis and food processing industries. However, developing RI sensors with both high resolution and wide linear range remains a great challenge due to the tradeoff between quality (Q) factor and free spectral range (FSR) of resonance mode. Here, we address this challenge by coupling resonances from the Fabry–Perot (FP) cavity and metasurface, integrated in a hybrid configuration form on the end facet of optical fibers. Specifically, the FP resonance offers high resolution while the plasmonic resonance provides a wide linear range. Featuring asymmetric Fano spectrum due to modal coupling between these two resonances, a high Q value (~ 3829 in liquid) and a sensing resolution of 2664 RIU−1 are experimentally demonstrated. Meanwhile, a wide RI sensing range (1.330–1.430 in the simulation and 1.3403–1.3757 in the experiment) is realized, corresponding to a spectral shift across several FSRs (four and two FSRs in the simulation and experiment, respectively). The proposed steelyard RI sensing strategy is promising in versatile monitoring applications, e.g., water salinity/turbidity and biomedical reaction process, and could be extended to other types of sensors calling for both high resolution and wide linear range.

N-Heterocyclic Carbene as Robust and Conductive Linkages to Couple Gold Nanoparticles and Conductive Polymers

Ningwei Sun[1], Franziska Lissel [1, 2]*

[1]Leibniz-Institut für Polymerforschung Dresden, Hohe Straße 6, 01069 Dresden. Germany

Abstract: N-heterocyclic carbene (NHC) anchors enable electron delocalization over the gold/conductive polymer (CP) interface, resulting in an improved conductivity. Here we developed a new class of real hybrid nanocomposites using NHC to coupling AuNPs and CPs, including small Au NP@NHC-CP by bottom-up methods and large Au NP@NHC-CP by top-down methods.

Due to their excellent stability and conductivity, *N*-heterocyclic carbenes (NHCs) have attracted great attention as versatile ligands for the functionalization of gold surface and gold nanoparticles (Au NPs) [1-3]. Yet so far, these efforts are confined to non-conjugated ligands – i.e. focused on exploiting the stability aspect. Using NHCs to link Au NPs and electronically active organic components, e.g. conjugated polymers (CPs), will allow to capitalize on the stability as well as the inherent conductivity of the NHC anchors. Here, we developed several types of real hybrid nanocomposites using NHC to coupling Au NPs and CPs, including small Au NPs by directly reduction from the precursor of poly(3-hexylthiophenes)-NHC-Au (P3HTs-NHC-Au) and large Au NPs with NHC-based initiators to grow CPs (polyaniline). The corresponding NPs show excellent thermal as well as redox stability. The NHC anchors enable electron delocalization over the gold/CP interface, resulting in an improved conductivity. This work demonstrates for the first time that CPs functionalized with NHCs can serve as ligands for the stabilization of Au NPs, paving a way for potential (opto-)electronical applications of Au NP@NHC-CP nanomaterials.

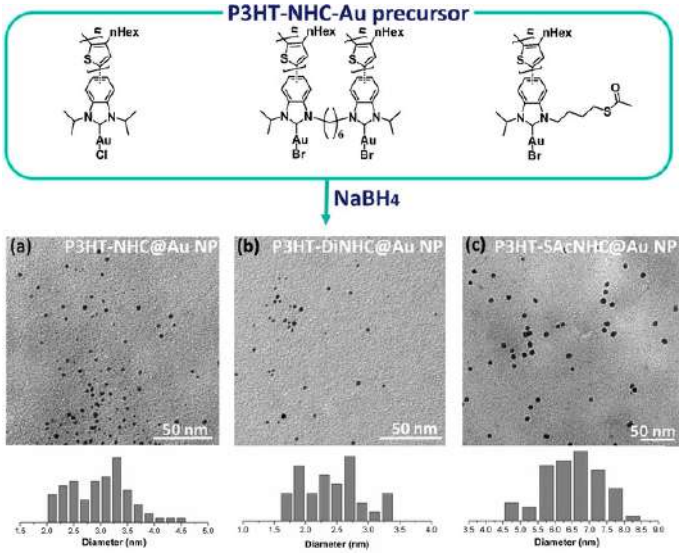

Figure 1 Bottom-up method for synthesis of small Au NP@NHC-P3HT by using P3HT-NHC-Au precursors.

For the bottom-up method to synthesize small Au NPs, a series of P3HT using NHC-Au as end functional group were synthesized by Kumada polymerization (Figure 1). The resulting polymers can be readily reduced to form Au NPs, leading the Au NP@NHC-P3HT architecture. TEM images of all Au NPs revealed small spherical particles with

average diameters of 2-6 nm. NHCs are highly conductive linkages, and one can assume that binding the polymer to Au NPs via a conductive NHC anchor group will increase the electrochromic response speed, allowing to estimate the organic/inorganic electron transfer of Au NP@NHC-P3HT. The response time, was found to be 1.21/1.05 s for neat P3HT-NHC-Au and 0.79/0.52 s for the composite containing 10 % Au NP@NHC-P3HT. indicating that the NHC promote the electron transfer in the electrochromic films.

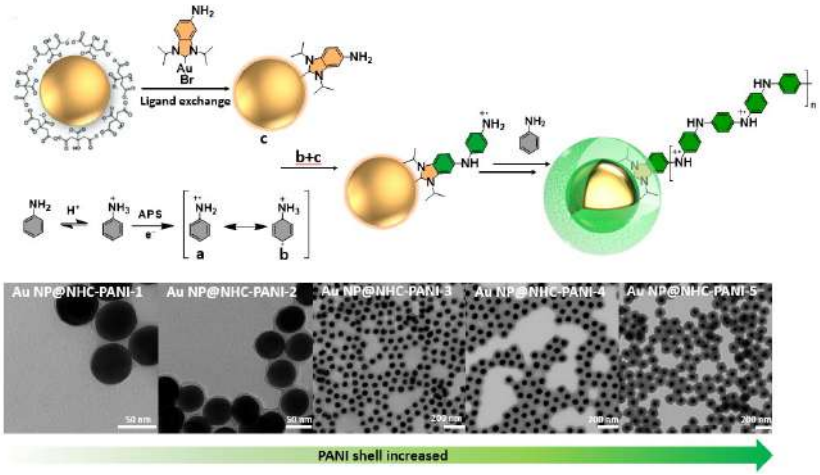

Figure 2 Top-down method to synthesize large Au NP@NHC-PANI.

For the top-down method to synthesize large Au NPs, an amino-substituted NHC–Au(I) complex was synthesized and grafted onto citrate-stabilized AuNPs, where the amino group serves as a nucleation site for oxidative polymerization of polyaniline (PANI) to form an Au NP@NHC-PANI composite (Figure 2). By assembling these hybrids into SAMs, we have, for the first time, experimentally demonstrated the conductive role of NHC as a linker at the metal-polymer interface. Compared to conventional Au NP@PANI hybrids, the incorporation of NHCs significantly improves electrical conductivity. Conductive atomic force microscopy (C-AFM) measurements revealed that at 300 mV bias, the contact current increased from 14.6 pA (Au NP@PANI) to 99.4 pA (Au NP@NHC-PANI). Similarly, four-probe lateral conductance measurements showed a remarkable enhancement from 0.17 nS to 3.5 nS upon NHC modification.

Abstract: Nowadays, the population is subject to a lot of stress, being one of society's most encountered problems affecting people worldwide. Cortisol is one of the main indicators of stress, long-term exposure to cortisol can lead to severe medical conditions, thus its rapid, facile and effective real-time monitorization is highly desired.

Being under a lot of stress for prolonged periods of time impacts the physical and mental health of the individuals, leading to severe medical conditions such as heart disease, lung issues, obesity, anxiety, depression, etc. In this context, the current work focuses on the development of a biocompatible, flexible hybrid plasmonic sensor for the non-invasive Localized Surface Plasmon Resonance (LSPR) detection of cortisol levels with high accuracy. To achieve this goal, firstly, silver nanospheres (AgNPs) and gold nanobipyramids (AuBPs) were chemically synthesized and optically and morphologically characterized. Additionally, their bulk sensitivity– AuBPs proving superior sensing capabilities, as well as their antibacterial effects were assessed. Further, biocompatible hydrogel matrices were prepared and doped with cortisol monoclonal antibody-functionalized plasmonic nanoparticles. To confirm the successful integration of the plasmonic nanoparticles, the optical and morphological properties were monitored along with their antibacterial activity. Finally, the developed hybrid plasmonic hydrogel was exposed to the cortisol hormone at medically relevant concentrations in order to evaluate the LSPR detection capabilities of the hybrid biocompatible plasmonic hydrogel, proving its versatility and high potential for cortisol monitoring while ensuring a facile utilization by the patients in the comfort of their home with a view to providing personalized medicine and improved health care.

Abstract: Nanomaterials with complex architectures were engineered using a dual pulsed laser source. Silver nanoparticles embedded in aluminum oxide thin films exhibit concentration-dependent maximum absorption, shifting from 432 nm at 2% vol. to 465 nm at 8% vol. Their integration with gold unlocks promising applications for sensing.

This communication lies on the development and synthesis of nanometer-scale complex materials made of gold (Au), silver (Ag) and aluminum oxide (Al_2O_3). The association of noble metals with a dielectric at nanometric dimensions, in the form of thin films or nanoparticles, can yield new materials with exotic physical and chemical properties, finding a wide range of applications such as photonic, optoelectronic, plasmonic devices, nonlinear optics and catalysis fields.

Synthetize well-controlled architectures integrating nanoparticles and thin film remains challenging.

Nanocomposites are fabricated using Pulsed nanosecond-Laser Deposition (PLD) combined with a free cluster generator. PLD, known for its ability to provide congruent transfer of the species, enables the deposition of Ag, Au and Al_2O_3 thin films with nanometer-scale thicknesses control, high density and crystallinity. The synthesis of metallic Ag nanoparticles (NPs) is achieved using a cluster generator developed by our group, based on Smalley's source principle [1]. The pulsed plasma plume generated by focusing a YAG (2ω) laser on the Ag target is strongly quenched by a synchronized helium (He) puff delivered in a specific nucleation chamber through a controlled pulsed valve. The opening date and the duration of the valve aperture are key-parameters to monitor the size of the nanoparticles. These formed NPs flowed through a nozzle designed to maintain the size and shape of NPs, from the nucleation site to the PLD chamber. In this ambient temperature process, the synthesized NPs with a diameter in the range 1-10 nm, present a quasi-monodisperse size distribution. The setup coupling PLD and cluster generator enables the synthesis of nanomaterials with exotic properties by using each technique separately, simultaneously or sequentially—resulting NP-stacks, nanocomposite thin films with embedded NPs or multilayers NPs/thin films respectively [2].

The aim of our study is the development of thin nanocomposite devices for biosensing applications based on plasmonic effect. It includes Ag NPs embedded in aluminum oxide thin film matrix and gold upper layer. Single continuous 50 nm Au films deposited on glass, with a low Root Mean Square (RMS) roughness below 1 nm provide an ultra-smooth surface, making them highly suitable for plasmonic applications such as waveguides, where minimizing scattering losses is essential for efficient light propagation. Additionally, four-probe measurements confirm that these films exhibit an electrical conductivity of 2.5×10^7 $S.m^{-1}$, close to bulk gold, even at such very low thickness. These films are therefore ideal for high-performance electrical contacts in nano and optoelectronic devices, ensuring efficient charge transport while maintaining excellent plasmonic behavior.

The synthesis of small Ag NPs with a diameter of 2.3 ± 0.8 nm was successfully achieved. The quasi-monodispersed size distribution makes this approach suitable for finely tune and control optical properties, as these

properties strongly depend on the size and shape of the particles. The incorporation of metallic NPs inside a dielectric film leads to a nanocomposite with novel electrical and optical properties. The stoichiometry of the Al_2O_3 matrix was verified through X-ray Photoelectron Spectroscopy (XPS). Atomic Force Microscopy (AFM) was used to analyze the roughness and thickness of the films. The Ag NPs randomly embedded in an amorphous Al_2O_3 matrix using the dual pulsed laser source described before, exhibit specific optical absorption at a wavelength of 432 nm, consistent with Mie theory. The amount of NPs embedded in the matrix influences the localized surface plasmon resonance, leading to a shift in the maximum absorption wavelength, from 432 nm for 2 %Vol., to 465 nm for 8 %Vol. The resonance position can thus be tuned by modifying the NPs concentration inside the Al_2O_3 matrix, making it an effective material for optical modulation applications. The dielectric function of the material is also modified, resulting in significant changes in electrical properties, such as increased conductivity, tunable permittivity and enhanced charge storage capabilities.

The ability to design a composite nanomaterial including Au thin film and Ag NPs surrounded by an Al_2O_3 matrix without contamination interfaces, is confirmed by Transmission Electron Microscopy (TEM) cross section analysis. These analyses show the capability of our laser ablation process to monitor, in one-way, complex materials with desired thickness, ensuring optimal nanocomposites properties. As a result, the association of a 12 nm Al_2O_3 matrix with embedded Ag NPs, covered by a 48 nm Au film already demonstrated excellent performances as a Surface Plasmon Resonance (SPR)-based biosensor. The detection of a specific cancer marker, namely Tumor Necrosis factor-α, was achieved at a concentration below the attomolar level, making it, to the best of our knowledge, one of the most sensitive SPR biosensors reported to date [3].

Abstract: Silicon nanoantennas have gathered a lot of interest in recent years because of their ability to manipulate light on the nanoscale with simultaneous excellent CMOS compatibility. Here we investigate their properties aiming to enhance the photoluminescence of colloidal WS_2 nanosheets, fabricated by a wet-chemical synthesis.

Nanoantennas give us the ability to manipulate light on the nanoscale. Made from a high index material, like silicon, these antennas can support Mie-like modes, manifesting as electric and magnetic resonances in their optical spectra [1]. These resonances lead to field enhancement around the particles. This confinement of light can be further applied in combination with other optical emitters to manipulate their properties.

Transition metal dichalcogenides (TMDCs) for example are known for their photoluminescence when appearing in mono- or few-layer form. The two-dimensional TMDCs are commonly realized by exfoliation methods or chemical vapor deposition (CVD). They can, however, also be prepared with a wet-chemical synthesis [2]. This synthesis generates colloidal monolayer nanosheets with sizes of a few to several ten nanometers. The photoluminescent properties of these TMDCs are not yet as strong as the ones of TMDCs gained from exfoliation or CVD. Therefore, the colloidal TMDC nanosheets can benefit greatly from silicon nanoantennas, as their high near fields and the Purcell effect can enhance the photoluminescence intensity.

In our study we combine colloidal semiconducting WS_2 nanosheets with truncated silicon cones. The cones can be fabricated in different sizes, tuning their resonance wavelengths over the whole optical spectrum, as can be seen in Figure 1 a). Figure 1 b) shows a scanning electron microscope image of the cones, fabricated with electron beam lithography. The nanosheets are dispersed around the nanoantennas by drop casting, placing them randomly around the cones. A sketch of the system can be seen in Figure 2 a). Depending on the size of the silicon nanoantennas, the enhancement of the photoluminescence changes. The radiation enhancement can also be theoretically approached with simulations, by approximating the TMDC's excitons as dipoles and taking into account the field enhancement around the nanoantennas and Purcell factors [3] (Figure 2 b)).

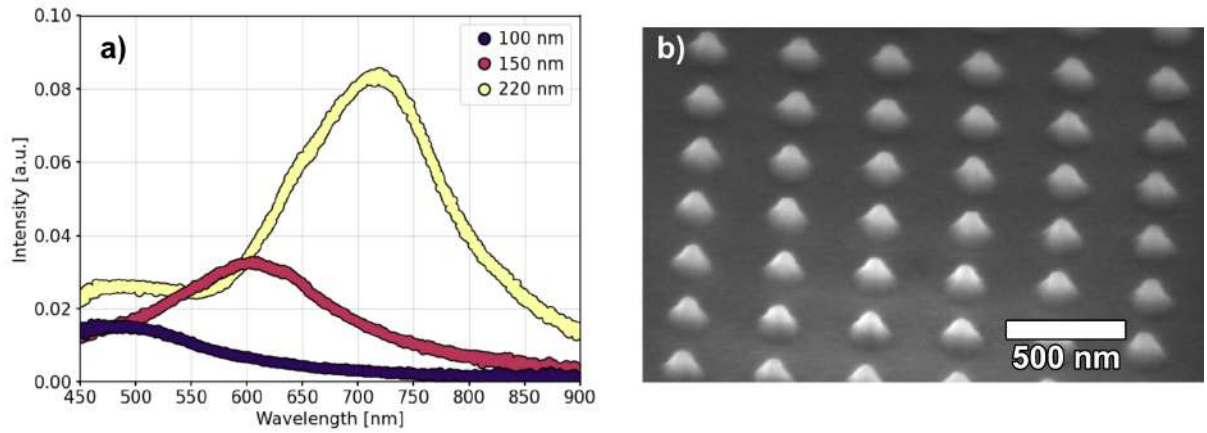

Figure 1: a) Dark-field scattering spectra of silicon nanoantennas with different diameters. For bigger particles the resonances appear at longer wavelengths. b) Micrograph of silicon nanoantennas arranged in a square lattice.

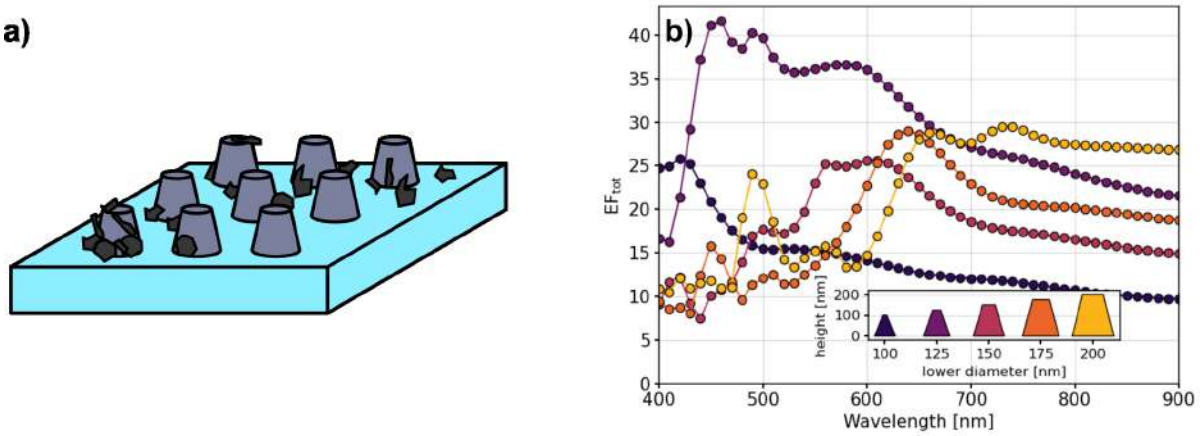

Figure 2: a) Sketch of the system of dropcast colloidal WS_2 nanosheets around truncated nanocones. b) Simulation of the photoluminescence enhancement factors for silicon nanoantennas of different sizes.

Abstract: In this work, 3D hybrid architectures on silicon substrate have been fabricated and employed to detect plastic particles using surface-enhanced Raman spectroscopy (SERS). The novel SERS platforms were obtained by embedding silver nanocubes synthesized using an eco-friendly route in two types of silicon nanostructures substrates, Si nanotrees and nanopillars, respectively.

Surface-Enhanced Raman Spectroscopy (SERS) is a non-destructive, fast, and label-free analytical method, with high sensitivity towards molecules containing polar/nonpolar functional groups, which has been used in recent years for the detection of microplastics [1]. In this field, there is still work to be done, in order to develop efficient SERS platforms towards small concentrations of these nanomaterials types and to understand the involved enhancement mechanisms.

Fabrication of the hybrid nano-assemblies started with the nanopaternation of the Si substrate. Thus, black silicon like nanostructures were fabricated using the cost effective Deep Reaction Ion Etching method. Adjusting the process parameters, both Si based nanotrees (SiNT) and nanopillars (SiNP) were obtained, having around 2 μm in heights, the walls of which were later decorated with synthesized AgNC, having the mean edge lengths of 42.7 ± 3.5 nm.

First, crystal violet (CV) was used as analyte molecule to evaluate the SERS performances and the enhancement given by the two novel platforms. Thus, 20 μl CV of concentrations ranging from 10^{-6} to 10^{-12} M were dropped onto the SERS substrates and left it to dry. Remarkable is that we were able to detect concentrations of 10^{-11}M, the SERS spectra being more intense for AgNC@SiNT platform. The average values of the enhancement factors are EFs were estimated [2] as 4.2×10^{9} for AgNC@SiNT and 1.9×10^{8} AgNC@SiNP,respectively. The higher enhancement of the AgNC@SiNT platform might be caused by, on the one hand, their morphology and, on the other hand, by the presence of more hot spots available on top of nanotrees, while numerous small nanocubes can be observed fallen down into the pores of the nanopillars.

The SERS substrates' sensitivity towards the plastics nanobeads was investigated using different concentrations of polystyrene nanoparticles (PS) having 500 nm in diameter, and both substrates were able to detect PS concentrations as low as 50 μg/ml. Moreover, we tested the substrates' reproducibility, which showed excellent relative standard deviation (RSD) values, about 8% for AgNC@SiNT, and even better, ~ 1% for AgNC@SiNP.

Abstract: Plasmon-based nanosphere systems are used for surface enhanced Raman scattering (SERS) of organic molecules. Angular excitation effects are investigated by varying the electric field distribution and incidence angle of the excitation radiation. We excite different plasmonic coupled or collective resonances to analyze the spatial emission behavior in the *k*-space.

Surface enhanced Raman scattering (SERS) has taken its firm place as a fundamental spectroscopy method to allow the observation of Raman scattering despite low scattering cross sections. Popular substrates consist of metallic nanostructures with strong plasmon resonances that provide electromagnetic enhancement in their vicinity. For single gold nanosphere-on-mirror systems, multiple resonances have been identified that show excitation-specific behavior[1]. Due to their different plasmonic resonances, the emission behavior of multiple resonances is expected to differ. Part of our work focuses on elucidating the spatial distribution of Raman scattering by angle-resolved spectroscopy in the *k*-space for varying electric field distributions in the focal field when exciting two different coupled gap-mode resonances. Furthermore, we will investigate angle of incidence excitation effects for SERS in hybridized collective resonances found on grating waveguide-structures assembled of nanospheres[2]. The collective resonance strongly depends on the angle of incidence that is used for excitation, which manifests a powerful tool for multiple applications in the same metasurface.

The single gold nanosphere-on-mirror samples were fabricated by deposition of super-spherical gold nanospheres[3] with 100 nm nominal diameter on a two-layer film of cobalt(II)-phthalocyanine (CoPc) on an ultrasmooth gold film. The nanosphere density was controlled to achieve single particle dispersion on the sample. The coupled system of nanosphere and film shows multiple resonances, with one resonance found about 600 nm and one found about 800 nm[1]. We excite both resonances using 633 nm and 785 nm continuous-wave lasers. The laser polarizations are varied between radial and azimuthal polarization to excite the system with purely in-plane (i.e., parallel to the gold surface) electric fields or dominantly out-of-plane (i.e., perpendicular to the gold surface) electric fields at both resonances. The back focal plane is sectioned into multiple angular ranges, of which the spectral information is collected to access the spatially distributed Raman scattering signal. Preliminary results indicate that the Raman scattering of CoPc is indeed linked to the radiation behavior of the plasmonic resonances, and that the excitation with different electric field directions in the focal field leads to strong intensity variations in the angular Raman scattering behavior of the system.

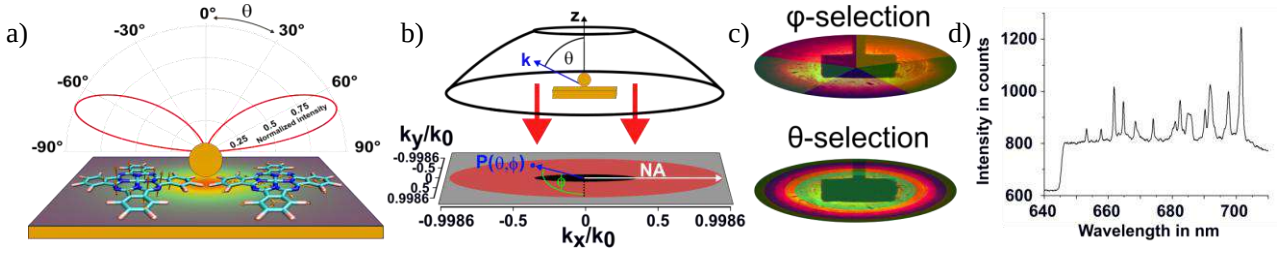

Figure 1: Angularly resolved Raman scattering of a single gold nanosphere-on-mirror configuration. a) Experimental setup with single gold nanosphere on CoPc. The simulated emission is shown as θ-plot above. b) Parabolic mirror collection scheme to access angular information. c) Sketch of the angular sectioning in the k-space to obtain angularly resolved spectral information in φ- and θ-sections. d) Exemplary Raman scattering spectrum obtained in one angular section.

We will extend the study of nanospheres by investigating guided mode resonances on waveguide-structures assembled from gold nanospheres. We expect the absorption to strongly depend on the angle of incidence[2], because the collective resonance gradually shifts, also depending on the waveguide periodicity. Thus, excitation with in-plane and out-of-plane electric field excitation are expected to yield significant differences in the Raman enhancement and due to a shift in the resonance energy depending on the angle of incidence. This will be confirmed by the plasmonic spectral shaping effect[4]. We will excite the guided mode resonances using 532 nm, 633 nm and 785 nm continuous-wave lasers while systematically blocking parts of the incoming radiation angles used for excitation. We will compare gradual changes of the angle of incidence and discuss its influence on the collective resonance, as the resonance energy is expected to shift across the wavelength-range we use for excitation. Successfully demonstrating this expected behavior will allow us to provide more insight into collective resonances commonly employed in metasurfaces.

Synthesis of silver and gold nanoparticles with tunable plasmonic properties for light-assisted anticancer therapy

A. Panáček[1*], L. Válková[1], L. Hochvaldová[1], A. Pedan[1], H. Kolářová[2], and L. Kvítek[1]

Abstract: Noble metal NPs with tunable plasmonic properties were synthesized using two step reduction process and applied for *in vitro* anticancer photothermal efficacy. The highest photothermal anticancer effect with cell viability decreasing under 20% was induced using AuNPs irradiated by 660 nm laser at irradiation energy of 20 J.

Light-based phototherapy is a promising technique used in anticancer approaches and, in combination with noble metal nanoparticles (NPs), represents an effective way to treat cancer diseases[1]. In this work, noble metal NPs with tunable plasmonic properties were synthesized using two step reduction process and applied for *in vitro* anticancer photothermal efficacy. Water dispersion of anisotropic silver NPs stabilized by citrate was synthesized by two-step reduction process, involving partial reduction of the $[Ag(NH_3)_2]^+$ complex cation by sodium borohydride in the first step resulting in the formation of the silver nuclei, which were subsequently in the second step grown up to anisotropic NPs by the reduction using hydrazine (Fig. 1a). In the case of gold plasmonic NPs stabilized by citrate, the first step involved synthesis of silver nuclei by reduction of $AgNO_3$ via sodium borohydride followed by addition of $HAuCl_4$ solution and subsequent reduction by ascorbic acid producing star-shaped AuNPs (Fig. 1b).

For the anticancer determinations, silver and gold NPs were deposited on a 96-well plate (Fig. 2a) using the layer-by-layer technique to evaluate *in vitro* photothermal anticancer efficacy to human cervical carcinoma cells (HeLa). To induce the photothermal effect, laser sources of different powers and wavelengths corresponding to the plasmon band of the metal NPs were used. A significant decrease in cell viability was observed in HeLa cells cultivated on both Ag and AuNPs-coated plates subjected to irradiation of various irradiation energy doses. The highest photothermal anticancer effect with cell viability decreasing under 20% was induced using AuNPs-coated plates irradiated by 660 nm laser (100 mW) at irradiation energy of 20 J (Fig. 2b). Viability of the cells cultivated on normal plates and subjected to the same energy doses remained unchanged. Based on the obtained results we can conclude that this relatively non-invasive and novel technique based on physicochemical properties of plasmonic materials is offered as an effective and promising tool to fight against cancer diseases.

Advanced passive and active metasurfaces and zero-index materials

Nonlocal metalens for far-field label-free super-resolution imaging

Bohan Zhang, Yuanmu Yang[1*]

[1] Department of Precision Instrument, Tsinghua University, China
[*]corresponding author: ymyang@tsinghua.edu.cn

Abstract: We introduce an alternative approach to far-field, label-free super-resolution imaging that surpasses the diffraction limit by breaking the fundamental shift-invariance assumption of conventional imaging systems.

The resolution of imaging systems has long been limited by the Abbe-Rayleigh diffraction limit. Although substantial advancements have been made in far-field super-resolution techniques, many methods depend on fluorescence labeling, multi-frame measurements, or involve compromises between field-of-view, energy efficiency, and resolution. Here, we present a novel far-field, label-free super-resolution imaging approach using a topology-optimized 3D metalens. By leveraging the nonlocal (angle-dependent) response of the metalens, we overcome the fundamental spatial shift-invariance of conventional imaging systems. This effectively increases the equivalent aperture and achieves resolution beyond the Rayleigh criterion without sidebands in the image plane, through a phenomenon we call momentum-space superoscillation. Prototype experiments conducted at microwave frequencies show a two-fold resolution enhancement over the diffraction limit, without the need for post-processing.

Room-Temperature, Tunable Lasing from Quasi-2D Perovskites Integrated with Plasmonic Lattices

Yu-Jung Lu[1,2]*

*E-mail: yujunglu@gate.sinica.edu.tw

[1]Research Center for Applied Sciences, Academia Sinica, Taipei 11529, Taiwan
[2]Department of Physics, National Taiwan University, Taipei 10617, Taiwan

We presented a stable, wavelength-tunable, room-temperature single-mode laser based on quasi-2D perovskites coupled with a waveguide-hybridized surface lattice resonance mode composed of aluminum nanoparticle arrays.

Abstract:
Room-temperature plasmonic nanolasers are crucial for advancing optical communication and quantum technologies. However, they face significant challenges, including material instability and high lasing thresholds. To address these issues, we leverage the unique properties of quasi-2D perovskites [1] and high-Q plasmonic nanostructures to enhance both optical gain and coupling strength. In this study, we introduce a stable, wavelength-tunable, room-temperature single-mode laser based on $PEA_2Cs_{n-1}Pb_nBr_{3n+1}$ quasi-2D perovskites coupled with a waveguide-hybridized surface lattice resonance (SLR) mode composed of aluminum nanoparticle arrays. This configuration leverages the enhanced light-matter interaction of the SLR cavity, tailored *via* finite-difference time-domain (FDTD) simulations. Additionally, amplified spontaneous emission (ASE) from trap states in the quasi-2D perovskite significantly boosts optical gain in the system. The results confirm the laser's performance and operational stability in an atmospheric environment; the gain medium maintained stable emission intensity up to 1.8×10^6 excitation pulses. By adjusting the periodicity of the surface lattice resonance (SLR) nanostructures, we achieved a tunable lasing wavelength across a 20 nm spectral range. Our findings establish a low-cost, energy-efficient approach for scalable plasmonic lasing. This advancement not only broadens the understanding of plasmonic systems [2, 3] but also unlocks potential in next-generation photonic applications such as sensing, optical communication, and computation. Finally, we will discuss the detailed working mechanisms of the room-temperature plasmonic nanolasers.

Keywords:
Plasmonic nanolasers, quasi-2D perovskite, surface lattice resonances, room-temperature, tunable lasing

Symmetry-Breaking and Disorder-Assisted Bound States in the Continuum

Qinghua Song[1*]

[1]Tsinghua Shenzhen International Graduate School, Tsinghua University, Shenzhen, 518055
[*]corresponding author: song.qinghua@sz.tsinghua.edu.cn

Abstract: In this talk, we discuss recent advances in metasurface singularities based on bound states in the continuum (BICs). We show that BICs with arbitrary polarization can be achieved using a bilayer twisted metasurface. Introducing magnetic materials enables robust circular polarization generation, and structural disorders facilitate real-momentum duality control.

BICs have been demonstrated to be associated with topological charge and vortex polarization singularities in momentum space. However, conventional BICs rely on symmetric and periodic structures. Here, we demonstrate that symmetry-breaking and disorder can be used as additional degrees of freedom to control light, while preserving the topology of the BIC.

Figure 1a shows the design of a structural symmetry-breaking using a bilayer photonic crystal (PhC) with a relative angle between the two layers. When the relative angle is non-zero, the symmetry is broken along the propagation direction, results in intrinsic chirality. However, the BIC is maintained regardless of the symmetry-breaking (Fig. 1b). This approach allows for the manipulation of the polarization, while keeping the BIC topology [1].

Figure 2a shows the design of a magnetic PhC that employs magnetic material to break the time-reversal symmetry. As a results, robust C points are generated at the center of the Brillouin zone (Fig. 2b), enabling unique chiral wave manipulations.

Figure 3 demonstrates that by designing special eigenmodes protected by a singularity, the structural perturbations will not alter the BIC topology. This allows the disorder to be used for encoding the useful information for wavefront modulation at BIC. Our findings may open up new avenues for applications in structured light, quantum optics and twistronics for photons.

Shaping photon emission with emitter-coupled metasurfaces

F. Ding

Centre for Nano Optics, University of Southern Denmark, Campusvej 55, DK-5230 Odense, Denmark

School of Electronic Science and Technology, Eastern Institute of Technology, Ningbo, China

*corresponding author: feid@mci.sdu.dk

Abstract: We propose general approaches to designing versatile photon sources using on-chip QE-coupled meta-optics that enable direct transformations of QE-excited surface plasmon polaritons into spatially propagating photon streams with arbitrary polarization states, directionality, and amplitudes *via* designed metasurfaces.

Optical metasurfaces, i.e., subwavelength planar nanostructures, have attracted increasing attention due to their unprecedented capabilities of molding classical light and revolutionized conventional optics by replacing bulky optical components [1]. In addition to controlling classical light, metasurfaces demonstrate the potential to efficiently manipulate nonclassical light and start to enter the realm of quantum photonics [2]. In this talk, I will discuss how to shape the directionality, polarization state, and amplitude of photon emission by using emitter-coupled metasurfaces [3-5].

Abstract: We theoretically model nonlinear optical effects produced by collision-driven electron dynamics in epsilon-near-zero heterogeneous nanostructures. We explore the potential of several setups based on poor metals for the development of compact extreme ultraviolet radiation sources and for integrated spectroscopy schemes.

Harnessing nonlinear (NL) effects in nanoscaled photonic systems is crucial for several applications including frequency conversion as in particular high-harmonic generation (HHG), but in standard bulk materials the NL effects are small, and nonlinearity acts as a perturbation. To amplify the NL effects, typically, one enhances the intensity by confining light under the wavelength scale to develop plasmonic nano-devices, by using noble metals or oxide-based transparent conductors in the middle-infrared (IR) range. Moreover, to obtain plasmonic functionalities in the extreme-ultraviolet (XUV) one can use poor metals, such as Aluminum (Al), Sodium (Na), Titanium (Ti), Tungsten (W), and Vanadium (V), that show marked epsilon-near-zero (ENZ) feature in this spectral region. Indeed, these materials are promising for guidance [1], for resonant third-harmonic generation (THG) in thin films [2], and for manipulation and guidance of XUV radiation.

Here, by considering that, for poor metals, the linear and NL response derives completely from free electron dynamics due to the lack of interband transitions, we model this NL response through a hydrodynamical model [3]. Indeed, by considering the Fokker-Planck-Landau (FPL) theoretical framework, we obtain a set of hydrodynamical equations (HDEs) by solving the Landau collisional integral in the weak coupling limit. In turn, thanks to a perturbative approach, we derive an analytical expression for the collision-driven NL-susceptibility and for the forward (FW) and backward (BW) THG intensity by both transverse electric (TE) and transverse magnetic (TM) pump polarisation for three different setups: the first one involves a Na – based thin film [2], the second one a Na/Al-based nanosphere [4], and the third one a Na-Al bilayer [5], all with nanometer-size thicknesses. In Fig. 1a, where we depict the dependence of the FW intensity of the THG signal over the pump wavelength λ and incidence angle θ for the latter configuration, one can see that the THG process exhibits a double resonance for TM pump excitation $\lambda_{THG} = \lambda/3$ in the ENZ regime due to the coupling of the pump field enhancement and the radiation of the microscopic dipoles. Moreover, in the ENZ regime of Na it's possible to excite surface plasmon polaritons (SPPs) at the Na-Al interface, because in this regime this setup is analogous to an Otto configuration, achieving a THG enhancement factor of three orders of magnitude greater than the single thin film [2]. Finally, Al/Na-based nanoparticles sustain localized surface plasmon excitations enabling enhanced functionalities in nanoscale environments [4]. These results suggest the potential of ENZ heterogeneous nanostructure devices in the development of integrated XUV sources.

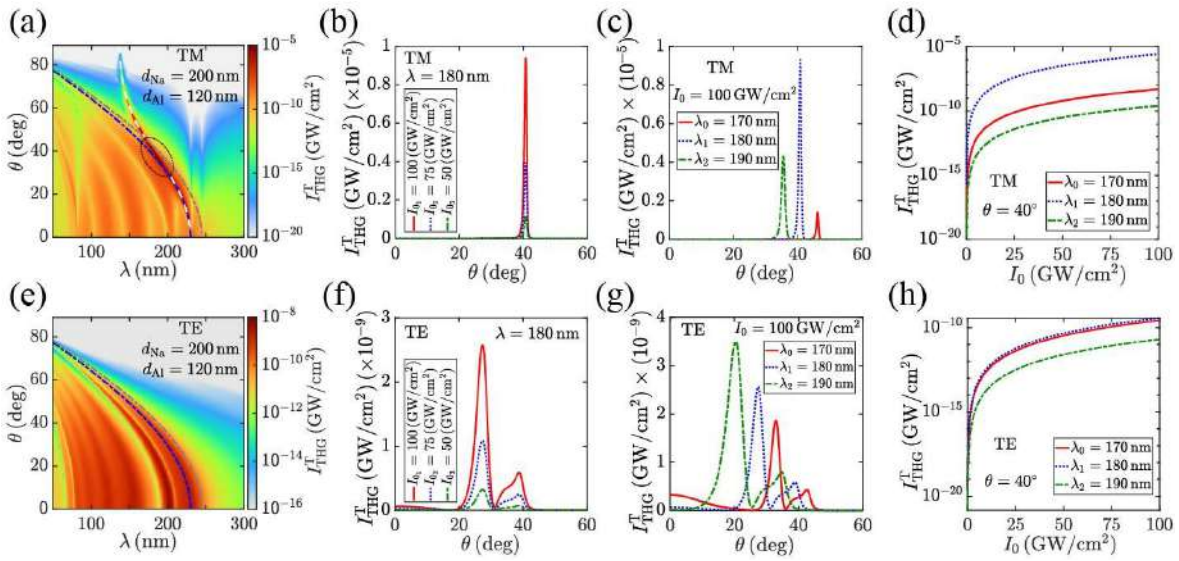

Fig. 1. **(a,e)** Dependence of the FW intensitiy of the THG signal I^T_{THG} over the pump wavelength λ and incidence angle θ for fixed pump intensity $I_0 = 100$ GW/cm^2. The dashed white curve in **(a)** indicates the SPP dispersion curve, while the dot-dashed grey and blue curves indicate the Al and Na NZI dispersion curves, respectively for λ_{THG} and λ. **(b,c,f,g)** Dependence of I^T_{THG} over the pump incidence angle for **(b,f)** fixed pump wavelength λ =180 nm and several intensities $I_0 = 50$, 75, 100 GW/cm^2, and **(c,g)** fixed pump intensities $I_0 = 100$ GW/cm^2 and several wavelengths λ = 170, 180, 190 nm [highlighted by the black circled area in (a)]. **(d,h)** Dependence of I^T_{THG} over the pump intensity I_0 for fixed incidence angle and several wavelengths λ = 170, 180, 190 nm. All plots are obtained for $d_{Na} = 200$ nm and $d_{Al} = 120$ nm and refer to either **(a-d)** TM or **(e-h)** TE polarisation of the impinging pump field.

Terahertz Modulators Enabled by Vanadium Dioxide: From Materials Optimization to Devices

Xi Wang

Department of Materials Science and Engineering, University of Delaware, Newark, DE 19716, USA
corresponding author: wangxi@udel.edu

Abstract: This talk focuses on optimizing the deposition techniques to produce high-quality, large-area vanadium dioxide (VO_2) thin films with precisely controlled phase transitions. Additionally, it introduces novel metasurface design concepts that may improve the scalability, performance, and tunability for various applications of VO_2-based terahertz (THz) devices.

Among the various approaches explored for Terahertz (THz) modulation, phase-transition materials have emerged as one of the most promising solutions. These materials undergo reversible transitions between distinct electronic and structural states under external stimuli, such as temperature, electric fields, or optical excitation, leading to substantial changes in their optical and electrical properties. In particular, vanadium dioxide (VO_2) has attracted significant attention due to its insulator-to-metal transition (IMT) near 68°C. VO_2-based THz modulators offer several advantages over traditional approaches, including low power consumption, broadband tunability, and compact device integration.

However, despite its promising properties, the practical implementation of VO_2-based THz modulation faces significant challenges. One of the most critical limitations is the synthesis of high-quality, large-area VO_2 thin films with precisely controlled phase-transition characteristics. The properties of VO_2 films, including transition temperature, hysteresis width, and optical contrast, are highly dependent on factors such as crystallinity, stoichiometry, and film thickness. Achieving large-scale VO_2 thin film with high uniformity and consistency while maintaining versatile growth capability remains an area of active research.

Beyond material synthesis, the design and optimization of device architectures play a crucial role in maximizing the performance of VO_2-based THz modulators. Metasurfaces, composed of subwavelength resonant structures, can significantly amplify the phase-transition response of VO_2 by locally engineering the electromagnetic field distribution. By integrating VO_2 with carefully designed metasurfaces, researchers have demonstrated tunable THz absorbers, beam deflectors, and spatial light modulators with improved performance[1].

Given the growing demand for dynamic and efficient THz modulation, it is vital to advance both material synthesis techniques and device engineering strategies. The development of high-quality VO_2 thin films with controlled phase-transition properties and the integration of novel metamaterial-based design architectures will be crucial for achieving high-performance THz modulators. These advancements will not only improve the efficiency, modulation depth, and response speed of THz devices but will also enable their widespread adoption in applications such as ultra-fast THz communication networks, adaptive THz imaging systems, and tunable THz spectroscopy platforms.

In this talk, I will focus on the fabrication of high-quality VO_2 thin films using pulsed laser deposition, emphasizing their uniformity and phase-transition characteristics. I will show VO_2 thin films deposited on 4-inch substrates with the resistance changes of 4 orders of magnitude and a thickness variation of less than 2%. The developed deposition recipe has shown consistency and stability over a two-year period. I will then introduce the

design, fabrication, and characterization of a VO_2-based THz beam steering metasurface. It highlights the metasurface's nearly 100% transmission in the 'OFF' state and its potential for broadband beam steering. I will also introduce the integration of VO_2 with MEMS-based actuators for dynamically tunable chiral THz metamaterials, demonstrating their ability to achieve tunable amplitude, phase, and polarization modulation [2].

Electrochemically-tunable oxide materials for metasurfaces

V. E. Ferry[1*]

[1]Department of Chemical Engineering and Materials Science, University of Minnesota-Twin Cities, Minneapolis MN 55455 USA

[*]corresponding author: veferry@umn.edu

Abstract: This talk will discuss the use of electrolyte gating to control the optical properties of materials, focusing on $La_{1-x}Sr_xCoO_{3-d}$ (LSCO) as an exemplary case. We create electric double layer transistors of LSCO, and show that on application of gate voltage there is sustained cycling between metallic and dielectric states.

Alternative materials for metasurfaces enable new properties and lay the foundation for advanced applications. Electrochemical phase-change materials that change optical properties in response to an applied stimulus, such as voltage, are highly attractive for the development of tunable and switchable metamaterials.

One convenient method to drive these transformations is to create electric double layer transistors, where the gate dielectric is replaced by an ion gel. This talk will focus mainly on $La_{1-x}Sr_xCoO_{3-\delta}$ (LSCO), one of the premier examples of an electrochemical phase change material. $Sr_xCoO_{3-\delta}$ (SCO) has attracted considerable attention recently as a voltage-tunable materials system; $La_{1-x}Sr_xCoO_{3-\delta}$ (LSCO) offers similar advantages, but with additional advantages in stability. As deposited, LSCO has a perovskite structure, but upon application of the positive gate voltage, oxygen vacancies are formed that drive a phase transformation to a brownmillerite crystal structure. This is accompanied by substantial change in magnetic, electrical, thermal, and optical properties.

This talk will discuss two key aspects of this work. First, we will demonstrate using spectroscopic ellipsometry measurements that LSCO is a versatile materials system for switchable metasurface systems. At $x < 0.18$, we measure $\Delta n > 0.6$ upon application of the gate voltage. For $x > 0.18$, as-grown LSCO has a perovskite structure and is a lossy metal. Application of the gate voltage transforms LSCO to an oxygen-vacancy-ordered brownmillerite crystal structure with high-index ($n > 2.5$) and low-loss. The talk will then discuss endurance in LSCO. Using operando FTIR measurements, we uncover mechanistic information about the transformation, and use this insight to increase the endurance of metal-insulator cycling in LSCO. The talk will conclude with perspectives on electrochemically tunable oxides for metasurfaces.

Electrochemically active mid-IR metasurfaces based on conjugated polymers

P.-C. Hsu[1*]

[1]Pritzker School of Molecular Engineering, University of Chicago, USA
[*]corresponding author: pochunhsu@uchicago.edu

Abstract: Electrochemistry can introduce substantial optical property change reversibly and efficiently, making it a promising tool for active metasurfaces. This talk will discuss our recent progress in co-designing hierarchical structures, charge transport properties, and optical cavities of conjugated polymers for mid-IR active metasurface with high performance and functionality.

An active metasurface's performances and functionalities hinge on rational designs of materials with largely and reversibly tunable optical property and strong light-matter interaction. Electrochemical reactions are powerful approaches that enable electrical controllability on chemical reactions by decoupling the electron and ion pathways to ensure charge neutrality, so they can avoid the limitations of Coulombic repulsion and drastically vary the carrier density or even trigger a phase transformation. Although (electro)chemical reactions are inherently slower than electrostatic phenomena, their large tunable range and non-volatility are ideal for certain applications such as building thermoregulation, display, and spacecraft thermal engineering. Meanwhile, employing antenna and cavity design provide strong light-matter interaction and additional degrees of freedom to boost performance and achieve multifunctional control. To tap the full potential of electrochemically active metasurfaces, a systematic study of both fundamental materials science and optical engineering is needed.

In this talk, I will introduce our recent progress on conjugated polymer-based active metasurfaces in mid-IR frequency, particularly for dynamic radiative thermoregulation. We used solid-liquid interfacial polymerization to synthesize high molecular weight polyaniline with both decent crystallinity and electrochemical activity, allowing significant tunability between the metallic and the dielectric states. Complex permittivities at both doped and dedoped states were measured by mid-IR ellipsometry, followed by metasurface design to maximize the thermal emissivity contrast in both spectral and angular domains. We will also elaborate on polyaniline's unique structure-property relationship and the anisotropic polaronic transport.

Abstract: The combination of photothermal and thermo-optical effects in dielectric nanoresonators open new opportunities for contactless manipulation of metasurfaces.

In the last decade, optical nanoantennas have revolutionized light manipulation and control at the nanoscale. Light absorption was initially considered a purely detrimental process, reducing the efficiency of optoelectronic devices. Recently, however, it has attracted growing interest, enabling novel light-energy conversion pathways and offering intriguing opportunities for reconfigurable systems.

In this talk, I will discuss self-induced optical heating effects in highly absorbing dielectric nanoresonators, with a special focus on Silicon ones. In particular, I will show recent calculations demonstrating that, due to thermo-optical effects, self-heating can give rise to a complex, non-linear relationship between illumination intensity and temperature, even for moderate illumination intensities relevant for applications such as Raman scattering [1]. Subsequently, I will discuss how self-induced optical heating could be employed for thermally reconfigurable optical devices and metasurfaces [2]. Concurrently, I will discuss our recent effort in controlling the temperature field in multi-dimensional arrays of nanoantennas, highlighting the importance and opportunities offered by thermo-optical effects [3]. Then, I will discuss how the non-linearity introduced in the system by thermo-optical effects can be leveraged to achieve fast (MHz) transmission modulation with a decoupling of the thermal and optical characteristic times [4]. Finally, I will show how thermal effects can be leveraged for chirality detection [5] and conclude with a perspective on emerging opportunities of applications for photo-thermo-optical effects.

Abstract: A heterogeneous system has been designed in the form of gold or high-entropy alloy (HEA) nanoparticles, as well as silicon nanowires (SiNW) and molybdenum disulfide (MoS_2) nanofilms (PNP/SiNW/MoS_2), which exhibits excellent photocatalytic hydrogen evolution reactions (PC-HER) up to 477.5 mmol g^{-1} h^{-1}.

Plasmonic nanoparticles (PNP) can hybridize with atomically thin transition metal dichalcogenides (TMD), to dramatically intensify the weak light–matter interaction of those functional semiconductors. Herein, such a heterogeneous system has been designed in the form of gold or high-entropy alloy (HEA) nanoparticles, as well as silicon nanowires (SiNW) and molybdenum disulfide (MoS_2) nanofilms (PNP/SiNW/MoS_2), which exhibits excellent photocatalytic hydrogen evolution reactions (PC-HER). The resonance frequency of the 0D-PNP, the antireflection frequency of 1D-SiNW and the absorption frequency of 2D-MoS_2, match with the visible range simultaneously, for effectively harvesting the free solar energy. In addition, to enable superior efficiency and low cost of PC-HER, there present the following synergetic mechanisms. First, PNP not only show strong electromagnetic enhancement, but also offer photochemical to be a powerful co-catalyst. Next, the SiNW substrate exhibits high antireflection of 95% within the visible light absorption. Besides, an optimal MoS_2 structure that is a hybrid of both 1T and 2H phases was prepared by using reproducible and facile pyrolysis. Moreover, a p–n junction formed at the MoS_2/SiNW interface, facilitates charge separation to further boost the efficiency. In the end, our Au and HEA heterogeneous plasmonics demonstrate exceptional H_2 hydrogen generation rates of 246 and 477.5 mmol g^{-1} h^{-1}, respectively.

Accelerating the Design of Photonic Metamaterials with Artificial Intelligence

Yongmin Liu[1*]

Abstract: I will discuss how to accelerate the design of novel metamaterials by deep learning. Different from the conventional approaches, deep learning can produce fast and accurate designs without the need of case-by-case and time-consuming numerical calculations, helping to push the function capacity of metamaterials towards their physical limits.

Over the past decades, we have witnessed tremendous progress and success of photonic metamaterials. By tailoring the geometry of the building blocks of metamaterials and engineering their spatial distribution, we can control the amplitude, polarization state, phase and trajectory of light in an almost arbitrary manner.[1-2] The design process of metamaterials can benefit from physics-inspired methods, resorting to human knowledge such as physical insights revealed by simplified analytical modeling, similar experience transferred from previous practice, and intuition obtained by scientific reasoning. Very often, we rely on electromagnetic modeling based on finite-difference time-domain method, finite-element method, finite integration technique, the method of moments and other numerical simulation methods either with or without optimization algorithms. However, theses physics- or rule-based approaches are insufficient for designing multi-functional and multi-dimensional metamaterials, since the degrees of freedom in the design space become extremely large.

Deep learning (DL) could potentially accelerate the development of complex metamaterials with high efficiency, accuracy and fidelity. As a very powerful tool, DL has been applied to many other research fields such as material science, chemistry, laser physics, particle physics, quantum mechanics and microscopy, showing great potential to circumvent the drawbacks of traditional methods in these areas. The application of DL in the design of photonic structures and metamterials has also emerged as an exciting direction over the past a few years.[3-4] Advanced model architectures, such as convolutional neural network (CNN), recurrent neural network (RNN), recurrent neural network (RNN), generative adversarial network (GAN) and variational autoencoder (VAE), are employed to solve various tasks in photonic design.[5-9]

We propose to embed machine-learning models in both gradient-based and nongradient optimization loops for the automatic implementation of multifunctional metasurfaces.[10] The proposed end-to-end framework facilitates full exploitation of the prescribed design space and pushes the multifunctional design capacity to its physical limit. With a single-layer structure that can be readily fabricated, metasurface focusing lenses and holograms are experimentally demonstrated in the near-infrared region. They show up to eight controllable responses subjected to different combinations of working frequencies and linear polarization states, which are unachievable by the conventional physics-guided approaches. These results manifest the superior capability of the data-driven scheme for photonic design, and will accelerate the development of complex devices and systems for optical display, communication, and computing.

We also demonstrate multiwavelength infrared image sensors based on dielectric freeform metasurfaces, which are designed by the deep learning approach.[11] The metasurfaces can separate the mixed near-infrared light

into distinct wavelengths. To effectively modulate the complex amplitude of the transmitted light at three distinct near-infrared wavelengths (1150, 1350, and 1550 nm), we utilize high-index silicon freeform nanostructures supporting pronounced resonant modes. An inverse design model based on deep learning is employed to generate individual freeform nanostructures pixel by pixel, satisfying the complex amplitude requirement for a multiplexed metalens design. Both the simulated and experimental results show that the wavelength-multiplexing effect of the devices is in good agreement with the target with negligible crosstalk. Finally, a metasurface is employed to realize near-infrared multispectral imaging, which allows for the distinct detection and decoding of images at the three target wavelengths. The proposed technology has a wide range of applications in clinical medicine, biological tissue imaging, and deep-space exploration.

The concept of deep learning has far exceeded a computational analogy of biological neural systems, and emerged as a powerful tool that solves extremely complex problems, such as photonic metamaterials in arbitrary shape with prescribed optical responses, by building up multilevel abstraction of massive data. For photonics community, deep learning and other AI techniques are currently transforming the areas of optical design, integration and measurements. Using the developed novel photonic structures, in return we may implement all-optical platforms to perform deep learning and other AI algorithms at the speed of light.

Dynamic IR Beam Steering and Switching with Active Metasurfaces

M. S. Jang[1*]

[1] School of Electrical Engineering, Korea Advanced Institute of Science and Technology (KAIST), Korea
[*]corresponding author: jang.minseok@kaist.ac.kr

Abstract: This presentation reports our recent works on dynamic infrared beam steering and switching based on active metasurfaces. Full 2π phase-only transmission modulation, single-gate beam switching, and thermal emission steering will be discussed.

The growing demand for ultra-fast telecommunications, autonomous driving, and futuristic technologies highlights the crucial role of active beam steering at the nanoscale. In most studies, such devices rely on gate arrays composed of a large number of independently-controllable local gate electrodes that address local scattering response of individual metaatoms. While this approach in principle enables arbitrary wavefront control, the complicated driving mechanism and low optical efficiency have been hindering its practical applications. In this presentation, we experimentally demonstrate an active beam switching device that provides high directivity, consistent efficiency across diffraction orders, and a wide field of view while operating with only a single-gate bias. We then theoretically expand the idea of single-gate beam switching from two-level to multi-level configurations by utilizing a low-loss dielectric metasurface platform with freeform inverse-design approaches. Finally, we present that active metasurfaces can steer not only the input beam with high spatial coherence, but also incoherent thermal emissions by employing a laterally delocalized optical mode.

Towards tunable metamaterial-based torque sensing

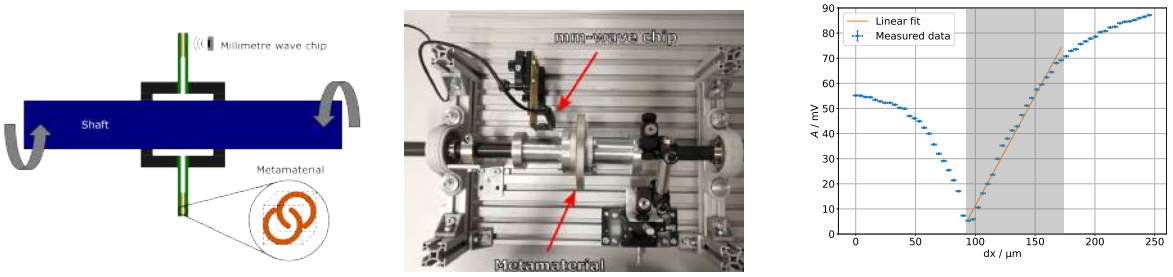
Abstract

We show the potential application of tunable metamaterials in torque sensing systems. Our concept comprises broad-side coupled split-ring resonators as passive sensor components and state-of-the-art millimeter wave transceiver for read-out. We provide a proof-of-concept demonstration for torque measurements on a fixed shaft.



1 Tunable millimeter wave metamaterials

Tunable metamaterials are an emerging field of research in the context of novel sensor technologies [1]. Their unique properties, going beyond the capabilities of natural materials, derive from the structuring and the arrangement of resonant building-blocks on a sub-wavelength scale. Particularly in the millimeter wave regime, the requirements for structuring these building-blocks are already met with low-cost state-of-the-art technologies, such as printed circuit board (PCB) manufacturing. Tunable metamaterials in this work are characterized by two distinct properties: first, their resonant behavior is highly sensitive to the smallest structural changes in their building-blocks [2]. Second, their resonant behavior is measurable telemetrically as a change of reflection signals. These two properties are the basis for our concept of measuring torque on rotating drivetrain components.

2 Metamaterial-based torque sensor concept

Our approach is based on a circular array of broadside-coupled split-ring resonators. Two disks with one split-ring layer each are separately fixed to a shaft, as shown in fig. 1. Torque along the shaft leads to a shift in the relative angular arrangement between the discs and the coupled split-rings and thus changes their resonant behavior. This finally changes amplitude and phase at frequencies within the bandwidth of the metamaterial resonance. We designed the metamaterial to show a characteristic resonance at 60 GHz and, thus, a distinct minimum in the reflection spectra. The design was achieved by adjusting only the geometrical parameters of the split-rings within the capabilities of PCB manufacturing, using finite element calculations. We studied the sensor concept with a demonstrator as depicted in fig. 1b. We used a state-of-the-art millimeter wave chip transceiver for read-out and implemented a quadrature continuous wave radar architecture as it is used for vital sign detection [3]. In contrast to the latter, the amplitude of the quadrature signal was evaluated. The idea is that the metamaterial modifies both the amplitude and phase of the reflection signals, whereas small changes in distance to the antenna mainly affect the phase. We used a micrometer stage to precisely adjust the shift between the metamaterial discs in the demonstrator. The raw data of the millimeter wave chip was read out with a digital oscilloscope connected to a PC. Figure 1c shows the measured quadrature amplitude as a function of the shift dx between the metamaterial elements. To study the sensor

concept, we chose the data in the grey-shaded area in fig. 1c. A linear fit gives a sensitivity of $(0.88 \pm 0.02)\,\mathrm{mV\,\mu m^{-1}}$. The shift is related to an applied torque M by the linear relationship $M = \alpha \cdot dx$, with α determined by the stiffness and dimensions of the shaft. Our demonstrator showed a sensitivity of $(15.7 \pm 0.4)\,\mathrm{mV\,N^{-1}\,m^{-1}}$, which is comparable to state-of-the-art E-bike sensors [4].

(a) (b) (c)

Figure 1: Metamaterial-based torque sensor concept: (a) Sectional drawing of setup. (b) Demonstrator setup. (c) Measurement data of quadrature amplitude as a function of shift dx.

3 Challenges towards a torque sensor system

To realize a driveshaft torque sensor, measuring with rotating metamaterial is crucial. This requires that the resonance shift of the metamaterial is constant and known when rotated and no torque is applied. The underlying sensor effect, the tuning of the characteristic resonance, is also sensitive to variations in the distance between the discs and variations in the permittivity of the materials. This requires calibration, particularly for the sensing of starting torque. Our ongoing work focuses on the study of calibration requirements and possible migitation strategies based on anisotropic metamaterial designs, which comprises characterizing the rotating metamaterial in a laboratory setup.

Abstract: Tunable subwavelength metasurfaces will enable low energy consumption and compact computing, communications, and sensing devices. Towards this, we will discuss our work leveraging electro-optics and high quality factor nanoantennas to demonstrate high efficiency phase gradient modulators operating at GHz speeds.

The ability to sculpt electromagnetic radiation with subwavelength optical antennas has enabled fundamental advances in small form-factor and high performance optical devices[1]. Reconfigurable metasurfaces can advance key optical technologies[2,3] including light detection and ranging[4], optical communications[5], and augmented or virtual reality. However, it remains a fundamental challenge to create dynamical optical devices that have simultaneously high efficiency, contrast, low switching voltages, and high modulation bandwidths, as either the optical properties or geometry much change by a significant amount to modify the optical transfer function.

Demonstrations of dynamic devices based on phase change materials[6], liquid crystals[7], and doped semiconductors[8] have shown promise in this space. In addition, electro-optic materials provide a platform for high speed and low-loss modulation[9-12], but are limited in the refractive index difference because of the second order nonlinearity being used. Indeed, the electro-optic coefficient of commonly available lithium niobate is approximately 31 pm/V, requiring integrated photonic modulators to be much longer (~1 cm) than metasurface devices can allow for significant optical phase shifts.

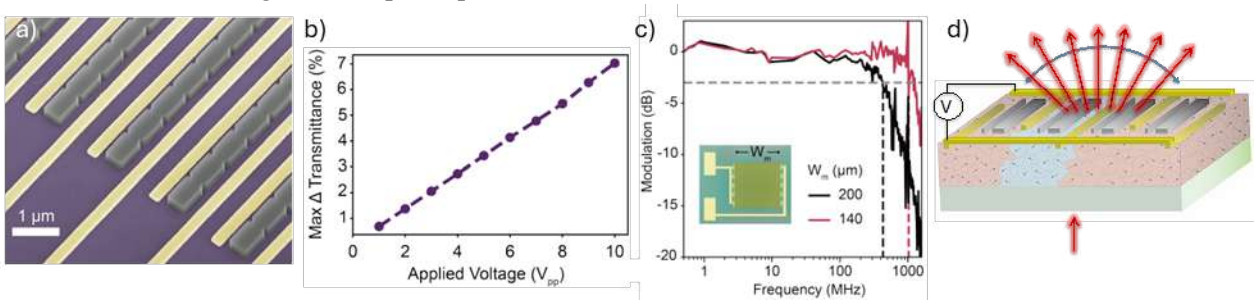

Figure 1: Electro-optic metasurfaces. a) Silicon on lithium niobate metasurface. Scale bar: 1 um. b) Ffficient modulation tuning with >7% modulation within 10 Vpp. c) >GHz bandwidth beamsplitting metasurfaces, limited by device size. d) Future materials integrated with high-Q antennas will enable efficient reconfigurable metasurface elements.

Here[13], we will show how rational design of nanoantennas in conjunction with transparent electro-optic materials can enable high efficiency and GHz-speed modulation of metasurfaces. Utilizing electro-optic materials like Lithium Niobate on Insulator can guarantee high efficiency devices without significant absorption at the cost of low refractive index tuning through the Pockel's effect. We show that this can be overcome using resonant nanoantennas based on guided mode resonances (GMRs)[14, 15] (fig. 1a). An optical resonance in the transmission profile leads to significant variation in transmitted amplitude and phase when an electric field is

applied through the electro-optic material. We demonstrate that guided mode resonant silicon nanoantennas 300 nm tall on top of a thin film of lithium niobate can be used to create electro-optically tunable optical devices. Using this as a prototype device, we demonstrate >0.7%/V shifting efficiency and 7.1% absolute transmission modulation with ±5 V applied to the metasurfaces. We then show how beamsplitting metasurfaces can be designed and demonstrate GHz- bandwidth modulation between a beamsplitting state and a transmissive state (fig. 1b). The bandwidth is limited by the RC delay of the electrodes, as shrinking the devices down increases the 3 dB bandwidth (fig. 1c).

Finally, we will discuss our further work developing electro-optic material platforms that leverage resonant optical modes for spatially programmable metasurfaces. Developing nanofabrication techniques and new integrated electro-optic materials will enable advances towards broadband and low energy consumption metasurface modulators. Together this work demonstrates the value of wide bandgap nonlinear materials for electrically-controllable wavefront shaping devices, and further demonstrates that combined electronic-photonic interfaces for control of free-space light is a meaningful platform for future photonic systems.

Metasurface for multi-functional edge imaging and quantitative phase imaging

Zhaowei Liu*
Department of Electrical and Computer Engineering, University of California, San Diego
9500 Gilman Drive, La Jolla, California, USA
*Corresponding author: zhaowei@ucsd.edu

Abstract: Metasurfaces have been proved to be a promising approach for various optical imaging techniques with advanced functionalities. In this talk, I will summarize some of our recent progresses in the field and showcasing quantitative phase imaging and edge detection imaging using metasurfaces.

Edge detection is of fundamental importance in optical imaging analysis since it preserves important geometric boundaries and significantly reduces the amount of data to be process. We demonstrated the effectiveness to perform optical edge detection using dielectric metasurface with high optical efficiency[1-3]. Combined with nonlinear materials, metasurface can be used for power dependent edge detection or performing complex optical transformation [4,5]. The quantum edge imaging has also been demonstrated if entangled photon source is used [6]. Compared to the classical cases, quantum edge imaging scheme comprises significantly improved signal to noise ratio. Switchable edge imaging has also been studied by incorporating the phase changing materials into the edge detection metasurface [7].

Quantitative phase imaging (QPI) and microscopy is another field with extensive explorations by using metasurfaces. We proposed a QPI methodology named Fourier optical spin splitting microscopy (FOSSM) by placing a single metasurface at the back focal plane [8]. A pair of metasurface can be placed at any place in the optical path for single-shot QPI imaging by using a polarized camera [9]. Single-shot QPI without polarized camera was achieved by combining deep learning with the transport-of-intensity equation [10]. The metasurface fabricated directly inside a traditional lens was used to showcase its advanced QPI capability for bioimaging [11].

Highly confined, low-loss infrared phonon polaritons in perovskite oxide membranes

Yin Liu

1. Department of Materials Science and Engineering, North Carolina State University, Raleigh, NC 27695, United States

*corresponding author: yliu292@ncsu.edu

Abstract: Phonon polaritons (PhPs), excitations arising from the coupling of light with lattice vibrations, enable light confinement and local field enhancement, which is essential for various photonic and thermal applications. To date, PhPs with high confinement and low loss have been mainly observed in the mid-infrared regime and mostly in manually exfoliated flakes of van der Waals (vdW) materials. In this work, we demonstrate the existence of low-loss, thickness-tunable phonon polaritons in the far-infrared regime within transferable free-standing $SrTiO_3$ membranes synthesized through a scalable approach, achieving high figures of merit, which are comparable to the previous record values from the vdW materials. Leveraging atomic precision in thickness control, large dimensions, and compatibility with mature oxide electronics, functional oxide membranes present a promising large-scale two-dimensional (2D) platform beyond vdW materials for on-chip polaritonic technologies in the far-infrared regime.

Liquid-Metal-Based Reconfigurable Metasurfaces for Display and Sensing Applications

Peter Qiang Liu

Department of Electrical Engineering, State University of New York at Buffalo, Buffalo, NY 14260, USA

Email: pqliu@buffalo.edu

Abstract

The flexibility, conformability and transformability of room-temperature gallium-based liquid metals are unique advantages over widely used solid metals [1]. In this talk, I will discuss our recent explorations into using such liquid metals to realize dynamically reconfigurable metasurfaces for different spectral regions and various applications, such as display and molecular sensing [2-4].

Abstract: Metasurfaces are vital for creating flat optical components with tailored functionalities. By manipulating light properties such as amplitude, phase, and polarization, metasurface-based optical elements enhance biomedical imaging system' performance. This work explores recent advancements in our laboratory applying metasurface optical components in biomedical instruments.

Optical sectioning microscopy is vital for biomedical imaging. We integrated metalenses into multiple imaging modalities.

Biophotonics applications require precise optical energy delivery to specific sites without affecting surrounding areas. Metasurfaces integrated in light sheet fluorescence microscopy enables compact, and high-resolution imaging of biological samples. We also show the benefits of using a variable focus metalens in a telecentric design with HiLo imaging for high-resolution optically sectioned images. The varifocal dielectric Moiré metalens delivers promising fluorescence imaging performance with standard test targets and biological samples. In addition, abrupt autofocusing (AAF) beams are ideal for laser-tissue interactions due to high energy contrast between the input and focal plane. We present the design and implementation of a metasurface optical element for the AAF beam. Experimental demonstrations show fluorescence-guided laser micro-profiling of mice heart tissues and photocoagulation in skin tissue using the AAF beam. These experiments highlight AAF beams' unique propagation and focusing properties, such as ballistic dynamics, high-intensity contrast, and self-reconstruction. Traditional bulky spatial light modulators can be replaced with metasurface optical elements in optical tweezers. We developed a two-dimensional Airy beam in the visible region for lateral shifting and guiding particles along the axial direction. Quantitative measurements for optical trap characterization demonstrate the potential of metasurface optical elements in miniaturizing optical tweezer setups. Implementing ultrathin optical devices in biomedical instruments opens new avenues for creating compact and high-performance systems. Our work has important applications in interdisciplinary research, including metasurface, optical microscopy, and biomedical optical instrumentation.

Confinement-Induced Nonlocality, Topological Darkness, and Goos-Hänchen Effect Enhancement in Transdimensional Plasmonic Film Systems

I. V. Bondarev[1*] and S.-A. Biehs[2]

[1]Department of Mathematics and Physics, North Carolina Central University, Durham, NC 27707, USA

Abstract: We classify topologically protected singularities for the reflection coefficient of transdimensional plasmonic films. Originating from their nonlocal electromagnetic response due to vertical electron confinement, these singularities lead to lateral (angular) Goos-Hänchen shifts on the millimeter (milliradian) scale in the visible range, greatly exceeding those reported previously for artificially designed metasurfaces.

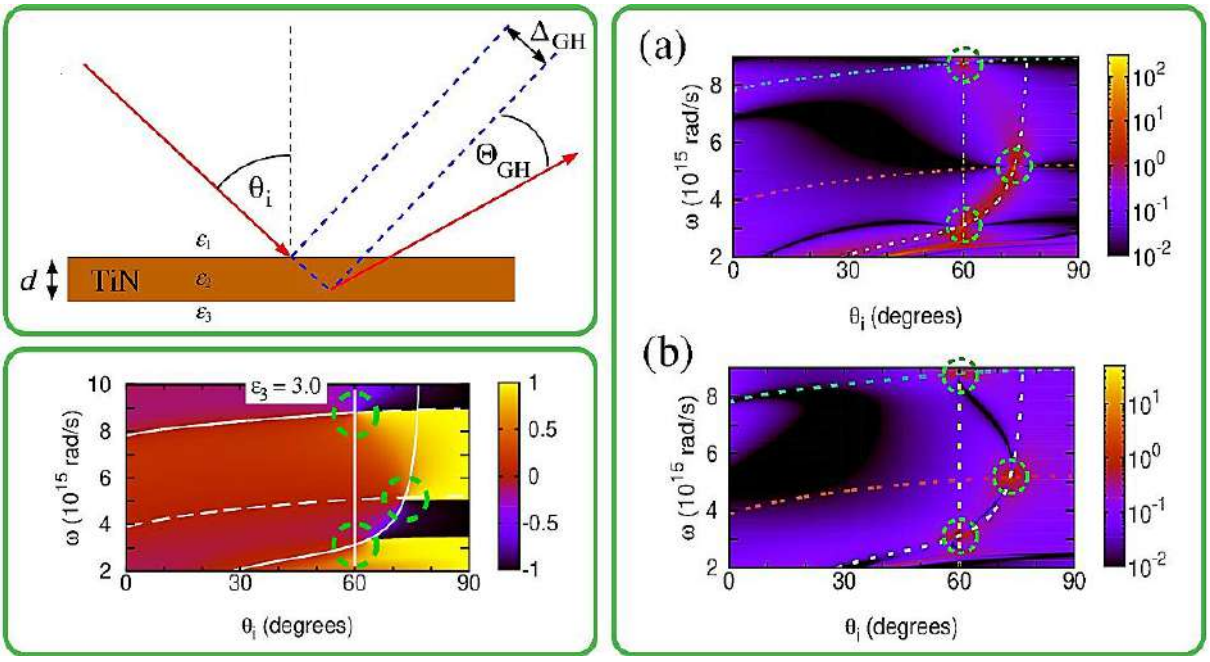

Figure 1. *Top left*: Sketch of the lateral and angular GH shifts for finite cross-section light beam incident on a TiN plasmonic slab of broken in-plane reflection symmetry. *Bottom left & Right*: Reflection phase φ_p/π and absolute values of the lateral/angular GH shifts (a)/(b) in mm/mrad, calculated for a 40 nm thick TiN slab with ε_1=1 and ε_3=3 (MgO) neglecting dissipation. Lines show the EM eigen modes of the system. Circles indicate the topological singularity points at the eigen-mode intersections. See Ref. [5].

Plasmonic transdimensional (TD) materials are atomically thin metal, semimetal or doped semiconductor films of precisely controlled countable number of monolayers [1]. Due to current progress in nanofabrication techniques [2–4], such materials can be reproducibly grown and offer high tailorability of their optoelectronic properties not only by altering their chemical and/or electronic composition (stoichiometry, doping), or strain, but also by varying their thickness. Here we show theoretically [5] that the in-plane electromagnetic (EM) response nonlocality induced by the vertical electron confinement in the ultrathin TD films leads to topologically protected singularities of their nonlocal reflection coefficient (Fig.1). These singularities result in the giant lateral and angular Goos-Hänchen (GH) shifts in the millimeter and milliradian ranges, respectively, exceeding greatly those reported for light beams of finite

transverse extent with no material-induced nonlocality [6,7]. The singularities appear in the plasmonic TD film systems with broken in-plane reflection symmetry (substrate and superstrate of unequal permittivities) where the EM eigenmode degeneracy is lifted to create the points of topological darkness in the visible range, which do not exist in local (Drude-like) plasmonic materials. The topological darkness points are intersection points of the non-degenerate EM eigenmodes of the TD film system. We demonstrate by direct calculations (Fig.1) that they can lead to the lateral and angular GH shifts as large as ~0.4 mm and ~40 mrad, respectively, for typical 40 nm thick TD plasmonic TiN films, which can be observed by using for example the conventional He-Ne laser light. The remarkable opportunity to bring the giant GH effect to the visible range comes from the fact that the nonlocal plasma frequency of the TD plasmonic films can be red-shifted not only by decreasing their thickness [2–4] but also by in-plane momentum reduction through the incident angle change [5].

Ultra-sensitive infrared gas molecular measurement using three-dimensional broadband metasurface absorber

Takuo Tanaka[1,2]

[1]RIKEN Center for Advanced Photonics, Japan
[2] Institute of Post-LED Photonics, Tokushima University, Japan
[*]t-tanaka@riken.jp

Abstract: A broadband metasurface absorber featuring three-dimensional metal double-cylinder structures was fabricated and applied to an ultra-sensitive infrared spectroscopic gas measurement technique. Owing to its strong and broadband resonant absorption, the signal-to-background ratio has been improved, enabling the measurement of IR spectroscopic signals from different gas molecules.

Ultra-sensitive biomolecular sensing technologies are becoming increasingly crucial in modern life. Among the various available techniques, infrared (IR) absorption spectroscopy is highly promising due to its label-free and noninvasive detection capabilities. However, practical applications are often hindered by weak signals, due to the intrinsically low IR absorption of natural substances and substantial background noise. To address these challenges, we introduced metamaterial absorbers to enhance the sensitivity of infrared spectroscopy by suppressing parasitic background signals. Through the use of plasmon-enhanced electromagnetic fields and plasmon-molecular coupling within the metamaterial absorbers, we achieved molecular sensitivity down to the attomolar level (10^{-18} mol). This was demonstrated using self-assembled monolayers of 16-Mercaptohexadecanoic acid, which formed a complete monolayer on the device surface [1].

We extended this sensing mechanism to liquid samples by successfully developing a three-dimensional metal-insulator-metal (MIM) metasurface absorber, which integrates a nanofluidic channel, several tens of nanometers in depth, as the insulating layer [2, 3, 4]. In this hybrid metamaterial-nanofluidic device, analyte molecules are precisely delivered to the metamaterial's hot-spot region. Owing to the strong interaction between the analyte molecules and the metamaterial, we attained molecular sensitivity at an approximate density of 10^{-4} molecules/Å^2, representing a two-order-of-magnitude improvement over previous plasmonic-enhanced IR detection methods.

We further applied this advanced sensing mechanism to gas-phase samples. Since the molecular signal strength is highly dependent on the density of hot spots in the metamaterial, we designed and fabricated a vertically aligned MIM (v-MIM) structure featuring a 25 nm nanogap, designed as a small footprint MIM configuration to enhance hot spot density [5].

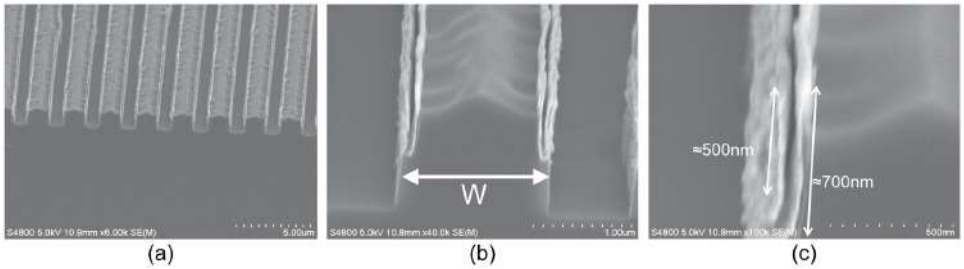

Figure 1. Scanning electron micrographs of 3D vertically aligned MIM structure.

This v-MIM metamaterial absorber was applied to carbon dioxide and butane detection, designed to exhibit resonances at 4033 cm^{-1} and 2945 cm^{-1}, which spectrally overlap with the C=O and $–CH_2$ vibrational modes, respectively. The coupling between these two resonant modes induces a Fano resonance, with their distinct peaks clearly observed as corresponding transmission dips.

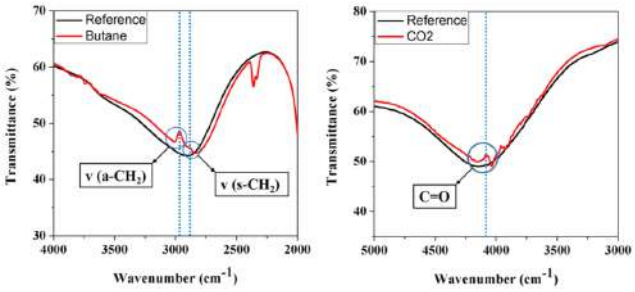

Figure 2. Experimental results of butane and carbon dioxide gas detection.

To achieve a more durable and optically efficient structure, we propose a three-dimensional coaxial double-cylinder metamaterial, as shown in Figure 3(a). This 3D metamaterial absorber exhibits a broad absorption band ranging from 2.5 μm to 7 μm, as shown in Figure 3(b). Owing to the broad absorption band of this coaxial double-cylinder metamaterial, we clearly observed absorption peaks of multiple gases. Figure 3(c) presents the absorption spectra of methane, butane, and carbon dioxide gases, while Figure 3(d) displays the absorption spectrum when a dimethyl ether and carbon dioxide gas mixture was introduced into the gas chamber.

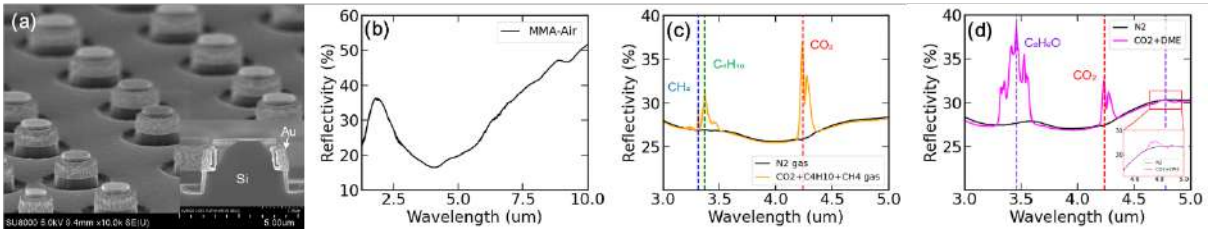

Figure 3. Three-dimensional coaxial double-cylinder metamaterial absorber and its experimental results of multiple gas sensing. (a) SEM image of a three-dimensional coaxial double-cylinder metamaterial, (b) its reflection spectrum showing broad absorption band, (c) experimental results with methane, butane, and carbon dioxide, and (d) experimental result with dimethyl ether and carbon dioxide gases.

Multi-Layer Flat Optics: Challenges & Opportunities

Ahmed H. Dorrah[1,*]

[1]Department of Applied Physics & Science Education, Eindhoven University of Technology, The Netherlands
a.h.dorrah@tue.nl

Abstract: Metasurfaces have enabled advanced imaging, sensing and communications due to their CMOS compatibility, versatility, and compactness. However, challenges in diffraction efficiency, bandwidth, scalability, and limited polarization control persist. Multi-layer metasurfaces address these issues, enabling high-efficiency devices with full polarization control, achromatic response, and improved performance for many applications.

Introduction: Optical metasurfaces are planar nano-optics patterned with sub-wavelength resolution to control light's phase, intensity, and polarization over a compact thickness [1]. A single lithography step enables tailoring a variety of meta-atoms, offering versatile functionalities within the same planar form factor. Metasurfaces have enabled numerous applications, including diffraction-limited focusing, computational imaging, holography, and polarization imaging, and has inspired multifunctional and reconfigurable devices [2]. While metasurfaces have simplified fabrication compared to 3D metamaterials, their limited thickness poses fundamental challenges in wavefront shaping, particularly at high numerical apertures (NA). As a result, new multi-layer, cascaded, and 3D meta-optic architectures have gained attention, driven by advancements in multi-level nanofabrication.

Motivation: Compound meta-optics have emerged due to limitations in single-layer metasurfaces, which often result in trade-offs between diffraction efficiency, bandwidth, field of view, high NA, and complex amplitude modulation. For example, ultrathin metasurfaces, such as plasmonic nano-antennas, require balanced loss and gain to achieve unitary efficiency, due to impedance mismatch between the input and target fields [3]. This limits the range of phase control and causes undesired reflections. Stacking multi-layer metasurfaces can enhance transmission without sacrificing phase control [4-5]. Furthermore, using high-index contrast dielectrics or nonlocal metasurfaces can relax these constraints. Nevertheless, complex amplitude modulation still requires compound or cascaded architectures [6-7]. Additional challenges remain in achieving achromatic response at high NA due to the thin form factor and delay-bandwidth product, necessitating thicker or multi-layer metasurfaces [8]. Distributing wavefront transformations across multiple layers introduces additional degrees of freedom, offering redundancy and enabling multifunctional devices with high diffraction efficiency, broadband performance, wide field of view, and controllable dispersion. To this end, we highlight our free-standing bilayer metasurface platform and focus on the advances in polarization optics and dispersion control that it brings [9].

Advances in Polarization Optics: Shape-birefringent dielectric nanofins function like waveplates, with their transmission behavior described by a 2x2 unitary and symmetric Jones matrix. While this enables technologies like single-shot Stokes and Mueller imaging, and vectorial holograms, it has limitations for more complex functionalities as depicted in Fig. 1(a) [10]. For example, a single-layer non-chiral nanofin cannot serve as a circular analyzer, as this requires decoupling the off-diagonal components of the Jones matrix. Rectangular non-chiral nanofins only provide linear shape-birefringence with a symmetric Jones matrix. This limitation arises from the 2D symmetry of single-layer metasurfaces and cannot be overcome with topology optimization. Bilayer metasurfaces, Fig. 1(b-c), allow for more general polarization transformations by decoupling all elements of the Jones matrix, enabling arbitrary, non-symmetric polarization control [11]. This not only allows the most general polarization transformations but also inspires a new class of directional metasurfaces with asymmetric focusing.

SEM images of the fabricated metalens operating in the visible range, 400 to 800 nm, with 0.5 NA [14]. Panels (a-b) adapted with permission from [11], panels (d-g) adapted with permission from [12], panels (h) and (i) adapted with permission from [13] and [14], respectively.

Advances in Dispersion Engineering: Controlling phase and group delay independently is limited by the delay-bandwidth product, influenced by the geometry, height, and composition of the meta-atom [8]. This results in dielectric metalenses with inadequate phase coverage, restricting performance, Fig. 1(d-e). Additionally, inverse design for larger devices is computationally intensive, and adjoint methods may encounter local minima. New metasurface designs are needed to achieve high transmission, broadband, and polarization-insensitive responses without these limitations. Multi-layer meta-optics address these drawbacks (Fig. 1(f)). In first-order approximation, the phase and group delays of a bilayer meta-atom are the sum of the individual layers. By stacking materials like titanium dioxide and silica (Fig. 1(g)), phase and group delays can be independently controlled, pixel-by-pixel. Precise freeform design further enhances this decoupling, enabling the development of advanced dispersion-engineered metasurfaces with up to 80% efficiency from 420 nm to NIR wavelengths [12]. These devices are fabricated using two-step nanolithography, atomic layer deposition, and plasma etching.

Outlook: We envision the future of flat optics being driven by 3D techniques (Fig. 1(h-i)), supported by recent advancements in multi-step lithography, nanoimprint lithography, two-photon polymerization, and thermal scanning probe lithography. With these tools, a new generation of high-performance metasurfaces will be capable of meeting the strict performance requirements of many emerging classical and quantum applications.

Far-Field Radiation and Polarization Engineering using Luminescent Metasurfaces

E. Bailly[1], A. Nguyen, J.-P. Hugonin[1], J.-J. Greffet[1] and B. Vest[1]

1[1]Université Paris-Saclay, Institut d'Optique Graduate School, CNRS, Laboratoire Charles Fabry, 91127, Palaiseau, France.

*corresponding author: benjamin.vest@institutoptique.fr

Abstract: Intrinsically incoherent luminescent emitters can be coupled to metasurfaces to establish some coherence in emission and therefore to enable structuration of the emitted field. We present here light-emitting metasurfaces designed using a Kirchhoff's law approach demonstrating a control of the polarization and of the angular radiation pattern.

Designing a light-emitting system means shaping light emission so that it matches requirements in terms of radiation pattern, polarization, or spectrum. However, non-lasing sources rely on spontaneous emission processes: the intrinsic randomness of emission prevents the structuration of a light beam by interference effects and most often results in isotropic and unpolarized emission. This has a straightforward solution: optical components such as lenses, filters or polarizers. However, components increase the bulkiness of light-emitting devices, affecting their total energy footprint, introducing losses and limiting integration and miniaturization.

We exploit the concept of Light-Emitting Metasurfaces (LEMs): devices consisting typically of a substrate covered with arrays of nanoresonators in interaction with luminescent emitters, distributed over the surface of the device. LEM support extended electromagnetic modes which play the role of a resonator. Although emitters are incoherent, their decay into the surface modes establishes a non-zero degree of coherence at long range. Besides, the surface modes can be coupled to the far-field. Light emission engineering is achieved by tailoring the properties of this leaky mode. At this end, we use a Kirchhoff's approach. Here, the power emitted for a polarization (l) in a solid angle dΩ around the direction u at wavelength λ is given by [1] :

$$\mathrm{d}^2 P_e^{(l)}(\mathbf{u},\lambda,\mu) = d\lambda d\Omega \int_V d^3\mathrm{r}' \alpha^{(l)}(-\mathbf{u},\mathrm{r}',\lambda,\mu)\frac{hc^2}{\lambda^5}\frac{1}{\exp(\frac{hc}{\lambda k_B T}-\frac{\mu}{k_B T})-1} \qquad (1)$$

where α is the local absorption rate, computed by considering the system illuminated by a plane wave at wavelength λ, from the direction u and with polarization state (l). The second factor is the blackbody radiance evaluated at hc/λ-μ, where μ is the photon chemical potential. This relation shows that the local absorption rate is the key to tailor quantitatively the spectral, angular, and polarization dependence of the emission. We use the Kirchhoff's approach to design and fabricate a LEM consisting of a 2D silver grating covered with nanoplatelets emitting around 610 nm. Most of the light is emitted within 20° from the normal direction (Fig. 1), therefore establishing directional emission out of an ensemble of incoherent emitters [2].

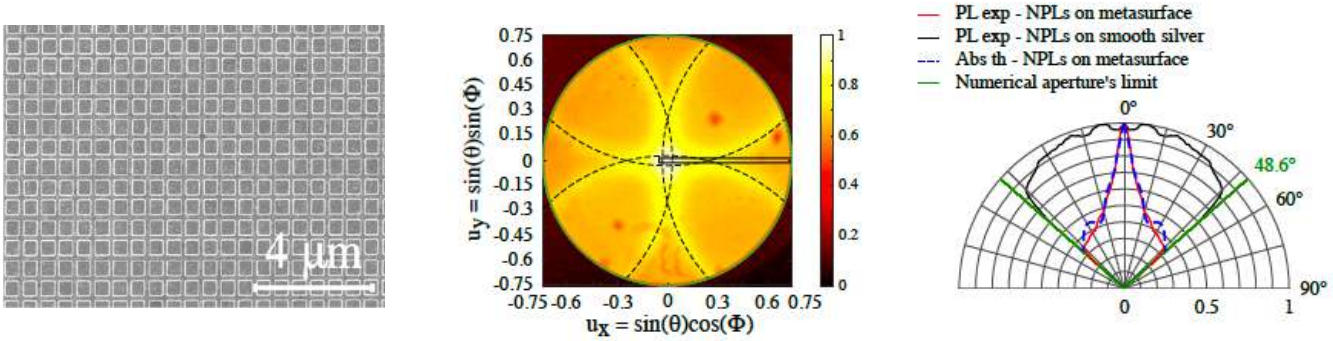

Fig. 1 2D Photoluminescent LEM for directional emission [2]. (Left) SEM image of the 2D silver grating forming the base of the LEM (Center) Fourier plane image of the photoluminescent emission **(**Right) Experimental angular radiation pattern (solid red) compared to simulated absorption using the Kirchhoff's formalism (blue dotted). Emission occurs within a 20° FWDH angular cone. Emission from unstructured emitter layer is isotropic (solid black)

The same Kirchhoff's law approach can by used to design **incandescent LEM** providing chiral emission in the MWIR (see Fig. 2) [3]. It consists of an array of thin metallic wires, heated by Joule effect on top of a transparent substrate. While the whole wire is heated at once, only the central fraction of the pattern, where inversion symmetry is broken, contributes to dichroism.

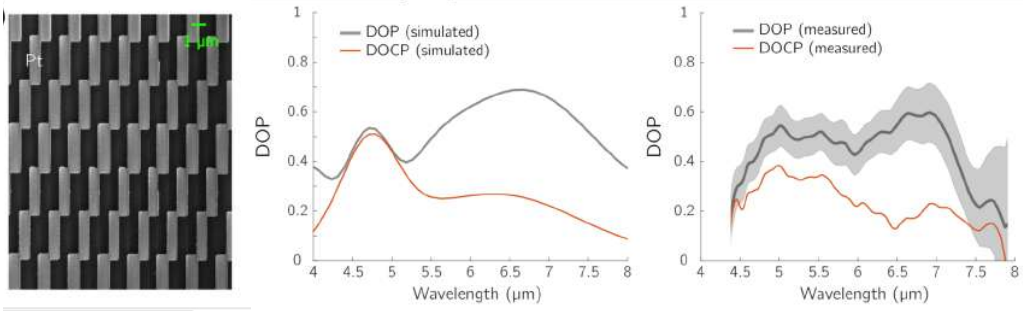

Fig. 2 Incandescent LEM for chiral emission [3] (a) SEM picture of the fabricated device. (b) Simulated and measured degree of polarization (DOP) and degree of circular polarization (DOCP). Shaded areas represent one-sigma error bars.

We will further discuss approaches to move towards a more advanced control of far-field radiation over several degrees of freedom combining previous design ideas. We will highlight the advantages of a Kirchhoff's approach in the perspective of providing an engineering toolbox able to provide quantitative and reliable prediction of the performances as well as a way to compare different metasurface architectures.

Multi-polar high quality factor metasurfaces

Mark Lawrence, Bo Zhao, Shuqin Dai, Samuel Ameyaw, and Lin Lin

Department of Electrical and Systems Engineering, Washington University in St. Louis, St. Louis, Missouri 63130, USA

Email: markl@wustl.edu

Abstract: Highly resonant phase gradient metasurfaces represent an exciting development for nonlinear and programmable wave shaping, but simultaneous access to spatial, spectral and polarization multiplexing remains limited. Here, we introduce multi-mode high-Q metasurfaces for multi-functional image processing, including multiband and cross-color image thresholding, polarization independent narrowband wave-shaping, and high dimensional color-polarizers.

Nanofocusing of the orbital angular momentum laser beam for nanoimaging

Zhenrong Zhang

Department of Physics, Baylor University, Waco, Texas, United States

Optical vortex beam has been used in many applications such as nanoscale imaging, telecommunication, sensing, and so on due to its unique azimuthal phase distribution. In this talk, I present the development of plasmonic fiber probes for nanoscale chirality imaging. The vortex beam carrying an orbital angular momentum (OAM) has a phase singularity that can be used to distinguish the enantiomers of the chiral molecule. I will present the design, simulation, fabrication, and characterization of plasmonic OAM probes. The vortex beam was generated in free space and propagated through a polarization-maintaining ring core vortex fiber, making the setup easier and less optically sensitive. Simulations showed the nano-focusing of the OAM beam when plasmonic nanostructures are incorporated on the vortex fiber facet. The experimental helicity measurement showed stable transmission of the circularly polarized -OAM beam through the nanostructures fabricated on the straight-cleaved vortex fiber facet.

Metasurface for Bioimaging and Thermal Radiation Management

Guangwei Hu[1]

[1]School of Electrical & Electronic Engineering, Nanyang Technological University Affiliation, Singapore

[*]corresponding author: guangwei.hu@ntu.edu.sg

Abstract: Metasurface with full control of wave properties can be integrated into an optical system, thus unlocking new opportunities to customize the multidimensional transfer function of the system. In this talk, I will discuss our efforts along this path for two applications: passive metasurface with advanced bio-imaging that can simultaneously capture and process the bioimages and active metasurface for the thermal camouflage compatible with radiative dissipation channels.

Metasurface with full control of wave properties can be integrated into an optical system, thus unlocking new opportunities to customize the multidimensional transfer function of the system. With this, I will present our recent findings of optical computation for bio-imaging based on passive metasurface [1-4] and thermal radiation manipulation for camouflage capable of thermal dissipation channels with phase change active metasurface.

Specifically, I will show how a single-layer metasurface with 2f system could be exploited to implement various transfer functions in conventional 4f system. This includes the first-order derivation and cross-correlation operation [1], the differential contrast with dual-polarization channels for the isotropic and miniaturized differential interference contrast (DIC) microscope [2], the 3D double-helix point spread functions for 3D imaging and depth measurement [3] and others [4]. Our work here enables the advanced engineering of optical systems for simultaneous capturing and processing the biological sample [4].

I will also show the active metasurface could be harnessed for advanced thermal radiation manipulation. Particularly, I will discuss the camouflage application based on emerging non-volatile phase change materials, In_3SbTe_2 (IST). I will discuss how to realize the programmable modulation of thermal emissivity with IST nanostructures, thus enabling the colored camouflage [5,6]. More importantly, the camouflage actually perturbs thermal radiation channels and hence the thermal equilibrium. Using the multifunctional active metasurface, we further develop the camouflage-dissipation compatible metadevices, which can compensate the camouflage-induced thermal emissivity perturbations.

Our work will be important to unlock various applications of metasurface for bio-imaging, thermal management and others.

Abstract: We show that combining optical fibers with 3D nanoprinted nanostructures creates a new category of fiber-integrated devices - metafibers - that enable novel applications, including high-NA holographic meta-lenses on fibers for trapping and flexible light focussing, on-fiber achromatic metasurface-based lenses and beam shapers, and ring-like gratings to boost coupling efficiency.

High Contrast Nanoscale Chirality Imaging

Seongmin Im[1], Gayatri Chandran[1], and Y. Zhao[1,*]

[1]Department of Electrical and Computer Engineering, Grainger College of Engineering, University of Illinois Urbana Champaign, Urbana, IL 61801, USA
[*]corresponding author: yzhaoui@illinois.edu

Abstract: Near-field optical force imaging reveals nanoscale light-matter interactions but suffers from overlapping effects. I will present our recent advances in Decoupled optical force nanoscopy (Dofn), a technique that isolates optical forces to enable high-contrast, nanometer-resolution imaging of nanoscale light-matter interactions, in particular, chiral light-matter interactions in nanoparticle systems.

Summary:

Near-field scanning optical microscopy, including both aperture-type[1] and apertureless[2] configurations, provides near-field distribution with spatial resolution that surpasses the diffraction limit. However, the resolution of aperture-type near-field scanning optical microscopy is typically in the order of several tens of nanometers, which corresponds to the size of the aperture. In contrast, apertureless near-field scanning optical microscopy is limited by the fact that it inevitably incorporates far-field information while measuring the near-field scattering signal via the tip. On the other hand, electron energy loss spectroscopy[3] and photoemission electron microscopy[4], which utilize electron microscope systems, are also capable of measuring the near-field. However, these techniques require a high-vacuum environment, and controlling the incident light is not as straightforward as it is with optical microscope systems. Namely, despite advancements in nanophotonics using the near-field, achieving a near-field distribution of less than 10 nm with an optical microscope system remains challenging.

The acquisition of a high-resolution image by utilizing multiple low-resolution images is widely used in the fields of image processing and computational imaging[5]. In particular, structured illumination microscopy[6] and Fourier ptychography[7] are major examples, which enable the acquisition of low-numerical-aperture images into a high-numerical-aperture image through known illumination incidence. The multiple low-resolution images recorded under different illuminations are computationally merged to reconstruct high-frequency information about the object, producing a high-resolution image. Meanwhile, multiple scans of atomic force microscopic images with local maxima probability algorithm provide the unprecedented resolution[8]. However, to our

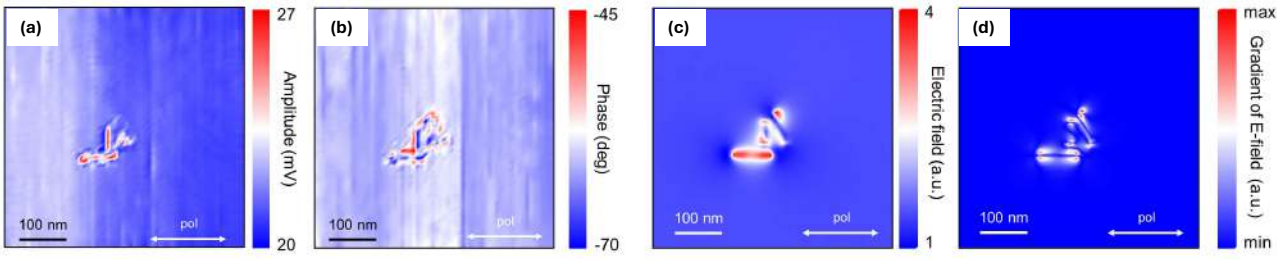

Figure 1. (a) Amplitude and (b) phase of experimentally measured optical force map. (c) Simulated electric field distribution of the trimer. (d) The gradient of electric field distribution.

knowledge, such super-resolution imaging algorithms have never been applied to near-field imaging or optical force mapping.

In this talk, I will discuss imaging of nanoscale chirality with Dofn. The resolution of Dofn is often limited by the radius of curvature of the atomic force microscopy (AFM) probes used in the scan. Chiral nanostructures, such as asymmetric trimers with gaps that are smaller than the radius of curvature of the probe, often miss important information during the scan. To further suppress the background noise and enhance imaging contrast, particularly optical forces at these gaps, I will introduce a Fourier-filling method. By combining multi-directional scanning and the Fourier-filling method to reconstruct high-frequency information, we identified optical forces induced by near-field at the gap between the nanostructures that are unavailable with regular optical force scans. Reliable near-field chirality near these gaps has been imaged with greater detail. Our method provides a high signal-to-noise ratio, which is essential for lock-in measurements, and thereby enables measurement of optical forces under a variety of illumination conditions, which were previously challenging to observe.

Bright and Dark Lasing in Nanoplasmonic Metasurfaces

Ortwin Hess[1]

[1]School of Physics and CRANN Institute, Trinity College Dublin, The University of Dublin, Dublin 2, Ireland
[*]corresponding author: ortwin.hess@tcd.ie

Abstract: We investigate the dynamic competition between bright (radiation-coupled) and dark (non-radiative) lasing modes in nanoplasmonic double-fishnet metasurfaces. Employing advanced Maxwell-Bloch Langevin simulations, we demonstrate methods for selectively enhancing bright mode lasing despite significant competition from dark modes, offering pathways toward controlled nanoscale coherent emission.

Nanoplasmonic metasurfaces offer revolutionary prospects in photonics, enabling unprecedented control of electromagnetic fields far below the diffraction limit. However, the intrinsic metal losses within these metasurfaces pose a significant challenge for their practical application. By integrating optical gain into nanoplasmonic structures, coherent amplification and lasing at deeply subwavelength scales become achievable, essential for applications in integrated photonic circuits, sensing, quantum optics, and communications.

In nanoplasmonic systems, lasing modes can broadly be categorized as bright or dark modes. Bright modes efficiently couple to radiation, providing strong emission to the far field, while dark modes remain localized and non-radiative, typically exhibiting significantly higher quality factors due to reduced radiative losses. However, despite the superior intrinsic quality of dark modes, experimental observations often highlight bright-mode lasing as the predominant emission. Understanding the mechanisms that facilitate bright-mode dominance and controlling mode competition dynamics is thus critically important for the future design and optimization of nanoplasmonic laser devices.

In this work, we focus on double-fishnet plasmonic metasurfaces, well-known for their negative refractive index properties and strong field localization capabilities. Employing rigorous, full-vectorial time-domain simulations coupled with Maxwell-Bloch Langevin equations, we explore the nonlinear dynamics of bright and dark lasing states. Our computational framework captures complex phenomena such as gain saturation, spatial hole burning, and ultra-fast transient dynamics, providing detailed insight into the competition between modes.

Through comprehensive simulations, we demonstrate that bright modes, despite having inherently lower quality factors due to their radiative nature, can dominate the lasing output under specific conditions. We attribute this dominance to two primary factors: spatial overlap and spectral alignment. Bright modes typically exhibit a superior spatial overlap with regions of high gain inversion, which allows them to effectively deplete the available population inversion, limiting the growth of competing dark modes. Additionally, spectral alignment between the gain emission profile and bright-mode resonances significantly enhances their effective gain.

Our simulations reveal complex temporal dynamics, including relaxation oscillations arising from the competitive interplay between bright and dark modes. These oscillations occur due to the mutual depletion of available gain, as bright and dark modes alternately experience growth and suppression in a dynamically balanced environment.

Understanding these transient dynamics is crucial, as they directly impact the stability and coherence properties of the resulting lasing emission.

To systematically investigate these dynamics, we introduce the concept of "local gain," combining spectral characteristics, spatial population inversion distributions, and mode profiles. Local gain analysis provides deep insights into the spatial and spectral conditions necessary for selective bright-mode enhancement. By precisely engineering the spectral overlap between the gain material's emission line and the metasurfaces's resonant modes, we establish conditions under which bright modes are strongly favoured. This strategy effectively suppresses dark-mode excitation, optimizing bright-mode lasing efficiency and coherence.

We further explore the role of spatial inversion profile management through polarization control of the pumping laser. Adjusting the pump polarization state influences the spatial deposition of gain within the metasurface. We demonstrate that, due to geometry-dependent field enhancements in the double-fishnet structure, polarization adjustments can drastically change local gain distributions, significantly affecting mode competition dynamics. By selecting appropriate polarization states, it becomes possible to further promote bright-mode lasing, offering another practical avenue for mode control.

The implications of these findings extend significantly into practical device applications. Controlling mode competition and enhancing bright-mode dominance improves emission coherence, spectral purity, and output stability, characteristics vital for advanced integrated photonic devices, nanoscale sensing technologies, quantum optics experiments, and next-generation communications platforms.

Our results highlight the importance of mode engineering in nanoplasmonic systems, providing clear pathways for designing and optimizing future metasurface-based lasers. Specifically, the capability to selectively suppress or enhance particular modes through spectral and spatial gain engineering allows unprecedented flexibility and efficiency in nanoscale photonic device design.

In conclusion, this comprehensive study elucidates the fundamental dynamics of bright and dark lasing modes in nanoplasmonic double-fishnet metasurfaces, identifies critical factors underpinning bright-mode dominance, and presents effective strategies for selective mode control. Our findings significantly advance the understanding and practical capabilities of nanoscale lasing, promising substantial impacts on future nanophotonics and integrated device applications.

Abstract: This study presents a novel method for remote focus control in multicore meta-fibers using 3D nanoprinted phase-only holograms. By integrating computationally designed holograms onto single-mode multicore fibers, we achieve precise, crosstalk-free focus manipulation at visible wavelengths. This innovation enhances applications in optics, telecommunications, laser micromachining, and biomedical imaging.

Remote focus manipulation is a critical capability in modern photonics, with applications spanning biological imaging [1], laser micromachining [2], telecommunications [3], and laser surgery [4]. Conventional optical systems rely on bulky components, limiting flexibility and scalability. Recent advances in photonic integration have highlighted the potential of optical fibers as compact platforms for precise light delivery and beam shaping [5]. However, existing on-fiber optical elements often suffer from static focusing limitations, lack of reconfigurability, and modal crosstalk.

In this study, we introduce a novel method for advanced remote focus control by integrating computationally designed 3D nanoprinted phase-only holograms onto the end face of single-mode multicore fibers (SM-MCFs). This approach enables precise, tunable light focusing within a monolithic metafiber device, overcoming the constraints of conventional lenses and static optical systems. The proposed SM-MCFs feature 37 cores arranged in a hexagonal lattice, designed to suppress modal crosstalk, ensuring independent light propagation at visible wavelengths. The phase-only holograms were computationally optimized using a modified Gerchberg-Saxton Algorithm (GSA) in conjunction with the Angular Spectrum Method (ASM) to accurately map input wavefronts to predefined focal positions. Fabrication was performed using femtosecond direct laser writing (fs-DLW), a high-resolution 3D nanoprinting technique that allows precise structuring of polymeric phase elements directly on the fiber surface (Fig. 1a).

The functionality of this metafiber device was experimentally validated across three distinct focusing configurations: cross-axis focusing, same-side focusing, and line-array focusing. Figure 1 (b-e) presents the experimental realization of the line-array focusing configuration, demonstrating robust agreement between computational design, simulations, and measured intensity distributions. The generated focal spots exhibit high localization with minimal background noise, while inter-core crosstalk is effectively suppressed, ensuring reliable and independent operation of each core.

This research represents the first successful implementation of nanostructured holograms for remote focus control in SM-MCFs, with significant implications for a wide range of applications. Potential uses include biological microscopy, high-speed laser micromachining, optical tweezers, and next-generation fiber-optic

telecommunications. Future advancements could leverage adaptive holograms, machine-learning-based design optimization, and dynamic reconfiguration via spatial light modulators (SLMs) to further enhance tunable focus control [6]. The results of this study establish a foundation for the development of next generation metafiber devices with superior optical performance, paving the way for transformative progress in nanophotonics, integrated optics, and reconfigurable photonic systems.

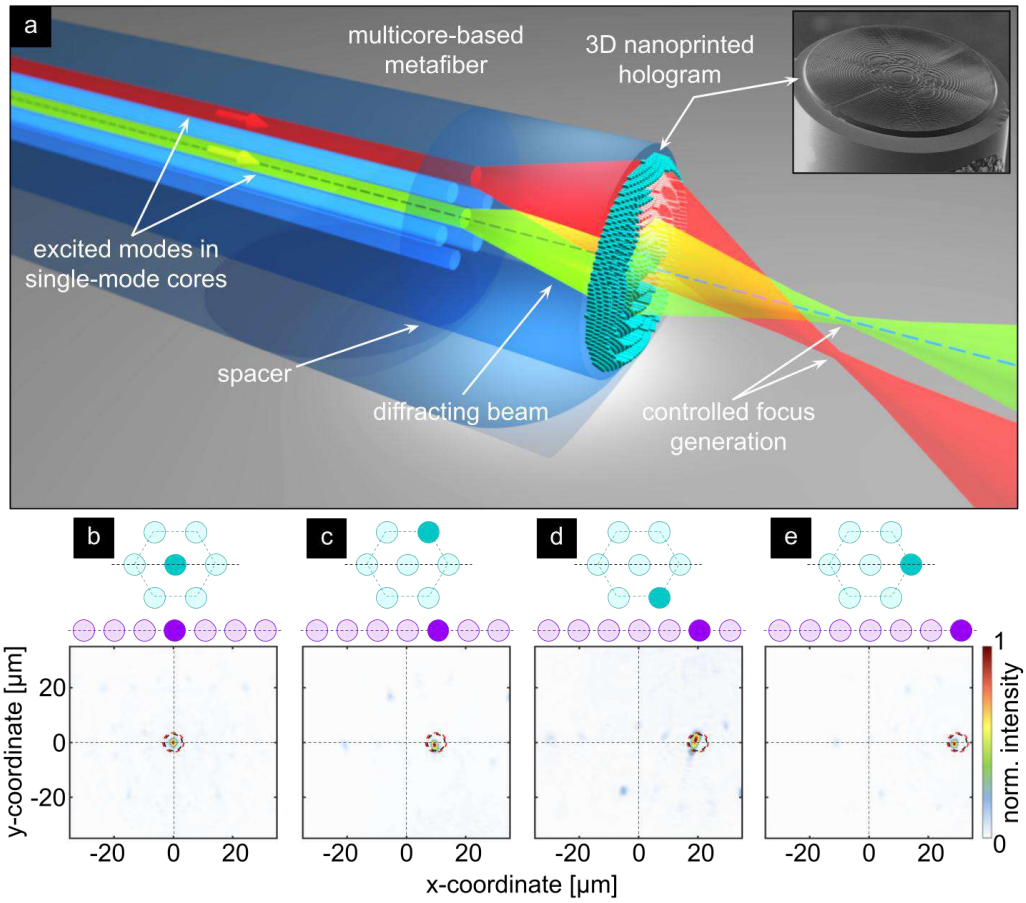

Fig. 1: Tunable focus manipulation using a multicore fiber with a phase-only hologram: (a) schematic illustration showing two cores excited, producing two focal points at different image plane locations. The top-right inset shows a realized hologram on the fiber. (b-e) show examples of measured intensity distributions of the line-array focusing configuration. Each plot corresponds to a combination of addressed core and foci in the SM-MCF.

Transient optical symmetry breaking for the ultrafast switching of a metasurface quasi-BIC

Abstract

We theoretically propose an innovative strategy to obtain an ultrafast, fully reversible switch from a photonic bound state in the continuum (BIC) to a quasi-BIC leaky mode in a semiconductor metasurface via transient optical symmetry breaking, by exploiting inhomogeneities of the photo-induced free carriers population at the nanoscale.

1 Introduction

Electromagnetic bound states in the continuum (BICs) are of interest both for their fundamental properties and their potential for applications in photonic systems. They correspond to solutions of Maxwell equations which are spatially confined and completely decoupled from radiation, albeit having the same energy of propagative waves [1].

If coupling channels are opened, the bound state transforms into a "quasi-BIC" leaky mode, which can be excited in scattering and manifests as an ultra-sharp resonance in the transmission or reflection spectrum. In photonic metasurfaces, this mechanism has been exploited for the particular class of symmetry-protected BICs, by modifying the unit-cell geometry to slightly break the in-plane rotation or reflection symmetry of the electromagnetic problem. This makes it possible to control the quasi-BIC quality factor, which scales as the squared inverse of a properly defined asymmetry parameter [2]. This strategy allows to tailor the optical response of the system for various applications, from filtering and modulating light to obtaining high-sensitivity sensors. However, a dynamical control is often desirable, which cannot be achieved once geometrical parameters are fixed with fabrication.

In this direction, we propose an innovative approach for achieving an ultrafast switch between a BIC and a quasi-BIC state, by actively inducing symmetry-breaking in semiconductor metasurfaces (Fig. 1a), designed to work in the near-infrared region of the electromagnetic spectrum. This is obtained by relying on the spatial inhomogeneities of the electron-hole population, generated in the dielectric medium upon the absorption of an intense fs-laser pump (left part of Fig. 1b). We present a theoretical model of the ultrafast photoexcitation, including a description of (i) the spatio-temporal transients of the free carriers, which are distributed non-uniformly at the meta-atom scale and undergo diffusion and recombination (see the middle panel in Fig. 1b), and (ii) the lattice temperature, which gradually increases as a result of phonon emission from the nonradiative recombination of the electron-hole pairs.

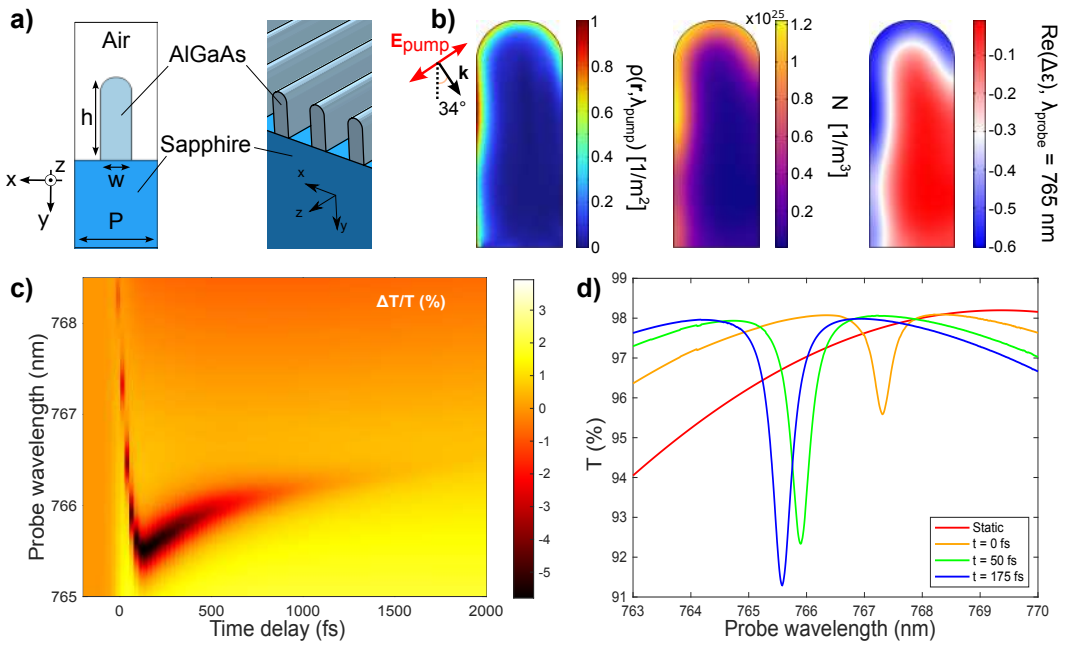

Figure 1: a) Metasurface design. The geometrical parameters are $w = 150\,\text{nm}$, $P = 400\,\text{nm}$, $h = 400\,\text{nm}$. b) Inhomogeneous photoexcitation. From left to right: normalized pump absorption pattern $\rho(\mathbf{r}, \lambda_{\text{pump}})$; spatial distribution of the electron-hole pair population at 100 fs after the pump peak; real part of the permittivity variation at 100 fs, for a probe wavelength of $\lambda_{\text{probe}} = 765\,\text{nm}$. c) Simulated pump-probe transmission map $\Delta T/T$. d) Transmission spectra at selected time delays.

We demonstrate that the ensuing (spatially inhomogeneous) third-order nonlinearity entails an almost instantaneous breaking of the in-plane left-right symmetry, as shown in the right part of Fig. 1b. In turn, this translates into the switching from a steady-state, symmetry-protected BIC (i.e., a non-resonant state) to a quasi-BIC leaky mode, which is revealed in full-wave scattering simulations as an extremely sharp resonance, appearing in the transmission spectrum of the structure (see Fig. 1c-d). The recovery of the symmetry, which is regulated by diffusion of the photogenerated carriers, marks the disappearance of the narrow resonant feature in $\sim 2\,\text{ps}$. This ultrafast process allows to overcome the intrinsic time limit of carriers relaxation towards the lattice, which is the usual bottleneck for the design of reconfigurable optical devices.

Addressing the Challenge of Phase-only Dynamic Modulation of Transmissive Metasurfaces

J. Y. Kim[1,2,†], R. Sokhoyan[1,†], H. A. Atwater[1*], M. S. Jang[1,2*]

[1]Thomas J. Watson Laboratories of Applied Physics, California Institute of Technology, USA

Abstract: Dynamic phase-only modulation in transmissive metasurfaces is instrumental to on-chip photonic applications, but has been elusive due to zero transmission near the resonance frequency in two-port, single-resonance systems. We show that by introducing extra diffraction ports in reflection we are able to evade this issue, and demonstrate a proof-of-concept metasurface with around 300° phase modulation while keeping the transmission amplitude nearly constant.

The ability to manipulate wavefronts in real-time is the centerpiece technology in nanophotonic applications. To achieve this, actively modulating the scattered phase while keeping the amplitude uniform is one important aspect, and for compact, on-chip integration purposes, enabling this in a transmissive setup is highly sought-after. However, due to the phenomenon of zero transmission near the resonance frequency in two-port, single-resonance systems (*1*), it has been difficult to: 1) span the full 2π scattered phase range due to the π phase jump, and 2) modulate the phase independently from the transmission amplitude, as they tend to be highly coupled to one another. Many research teams have therefore utilized the Huygens metasurface condition by engineering two specific resonances (such as the electric dipole and the magnetic dipole) and overlapping them spectrally, thereby cancelling reflection through destructive interference between the two resonances and allowing for a smooth 2π phase change (*2*). For active tuning purposes, however, this method has been problematic due to the fact that the two resonances spectrally shift at different rates with the tuning parameter change, breaking the Kerker condition required for the full 2π phase modulation. There have been efforts to use two different tuning mechanisms such as voltage and temperature to compensate for the differences in the spectral shifting (*3*), but this complicates the device architecture and is also susceptible to thermal fluctuations.

In this paper we propose a methodology to enable full 2π phase-only modulation utilizing a single resonance. Our idea utilizes additional ports, namely diffraction ports, and we illustrate the theory behind achieving 2π phase-only modulation using temporal coupled-mode theory (TCMT). If we have a single resonance system, the complex transmission amplitude according to TCMT is given by:

$$\mathrm{t} = t + \frac{id_1 d_2}{(\omega - \omega_0) + i\gamma} \tag{1}$$

The first term on the right-hand side refers to the direct transmission scattering parameter and the second term refers the resonance interaction term. The above complex transmission amplitude draws a circle on the

complex plane as frequency is evolves around the resonance frequency, and for a two-port system the circle goes through the origin with zero losses with the circle becoming even smaller for finite losses, preventing 2π phase-only modulation. We then demonstrate that adding diffraction ports allows us to engineer the complex transmission amplitude circle to be more centered, enabling 2π phase-only modulation, with the theoretical upper bound being a perfectly centered, phase-only varying circle with a complex transmission amplitude radius being 0.5, or 25% transmission efficiency.

To realize this theory on a feasible metasurface setup, we showcase a proof-of-example metasurface that achieves a near-centered complex transmission amplitude circle using full-wave simulations. This is accomplished by integrating an electro-optically tunable lithium niobate (LNO) layer into the high-Q resonant metasurface structure (*4*). The resonant metasurface structure is based on germanium (Ge) resonators that support higher-order Mie modes. These high-Q Mie modes exhibit quality factors as high as 10,000. Our full-wave electromagnetic simulations show that we can achieve a dynamically tunable phase shift of 300° while maintaining a nearly constant transmission efficiency of around 22% as the refractive index of the LNO layer varies from 2.114 to 2.126, nearing the theoretical upper bound.

Abstract: We present an all-dielectric phase-modulating metasurface composed of Si and SiO_2, at 940 nm with high efficiency and directivity. By tuning the resonance between the top high contrast grating and the bottom distributed Bragg reflector via thermal control, we achieve over 20%-efficiency and 12 dB-directivity for 1-D beam steering.

Optical metasurfaces are component that manipulate the amplitude, phase, polarization, and angular momentum of transmitted, reflected, or scattered light at subwavelength scales by arranging sub-wavelength-sized optical structures in periodic or aperiodic patterns on a planar surface. This enables diverse unprecedented applications, including ultrathin lenses, wide-angle holograms, and high-sensitivity sensors [1]. Notably, tunable metasurfaces with post-fabrication tuning capabilities can dynamically alter their functions in response to input control signals. These properties make them promising for real-time displays, free-space optical communications, and light detection and ranging (LiDAR) applications [2]. Over the years, various material platforms have been employed to develop tunable metasurfaces, including gate-tunable transparent conducting oxides, liquid crystals, phase change materials. However, exiting phase modulation-based metasurfaces often suffer from low efficiency, defined as the ratio of the desired beam intensity to the incident beam intensity, and limited directivity, as undesired beam directions exhibit intensities comparable to those of the desired direction [3]. In this study, we present a phase-modulating metasurface composed solely of Si and SiO2, aiming to reduce optical losses. By employing localized thermal control, we achieve high efficiency and directivity in phase modulation in the near-infrared regime (940 nm).

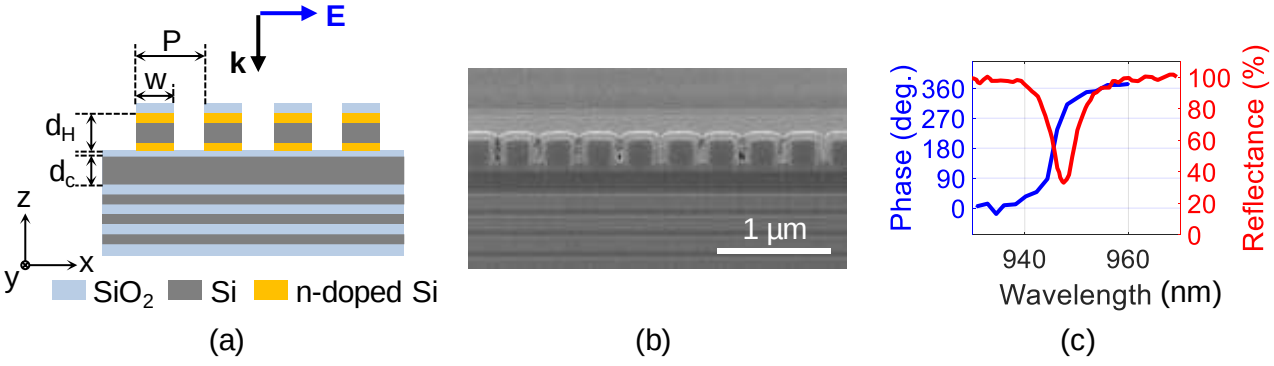

Figure 1. (a) Schematic diagram of the proposed Si-based tunable metasurface. (b) Scanning electron microscopy image of the fabricated sample. (c) Experimentally measured reflection phase and reflectance

Figure 1(a) shows the schematic diagram, where the Si cavity with the thickness d_c is located between the top high contrast grating (HCG) with the thickness d_H and the bottom 3-pair distributed Bragg reflector (DBR) of Si and SiO_2. The thicknesses d_{Si} and d_{SiO2} of Si and SiO2 are chosen as $\lambda_0/(4n_{Si})$ and $\lambda_0/(4n_{SiO2})$, respectively, where λ_0 denotes the operating wavelength (940 nm) in free space, while n_{Si} and n_{SiO2} correspond to the real part

of the refractive index of Si and SiO2, respectively. The period P, height d_H, and the width W of the HCG are designed as 330 nm, 205 nm, and 210 nm, respectively so as to contribute to the partial reflection 60% of light from cavity to air. This enables the over-coupling operation, which is advantageous for the high reflectance. By applying electrical bias between the upper and lower n-doped Si layers in the HCG, the thermal heat is generated, resulting in the refractive index increase and the phase change of light in reflection. We conduct the optical reflectance and phase measurement of the fabricated device (Fig. 1(b)) and show the data in Fig. 1(c), where the phase spans around 360° as a function of the wavelength and the reflection dip around 940 nm.

To analyze the beam steering characteristics, we apply spatially-varying two voltage signals across the 1-dimensional array of the proposed unit device (Fig. 2(a)). One voltage is to invoke the 0°-phase in reflection (off-state, $V_{0°}$), whereas the other one is for 180°-phase (on-state $V_{180°}$). As we manipulate the spatial period of two alternating voltages, denoted by Λ, we can control the angle $\theta = \pm\sin^{-1}(\lambda_0/\Lambda)$. Since the tuning mechanism is based on the thermal heating, we employ thermal isolation trenches between neighboring unit cells with the width of 500 nm as well as 5 μm-thick-SiO_2 block below the DBR. The design effectively prevents thermal leakage from the on-state cell to its adjacent off-state cell. By making the thermal path to the highly thermally conductive Si as long as possible, heat transfer to adjacent cells can be effectively blocked. As a result, we could obtain the stark contrast of 12 dB between the intensities between weakest intended beam and the strongest unintended beam as shown in Fig. 2(c). In addition, the absolute efficiency, defined by the ratio the sum of the intensities of the two intended beams over the input beam intensity, is measured around 20%.

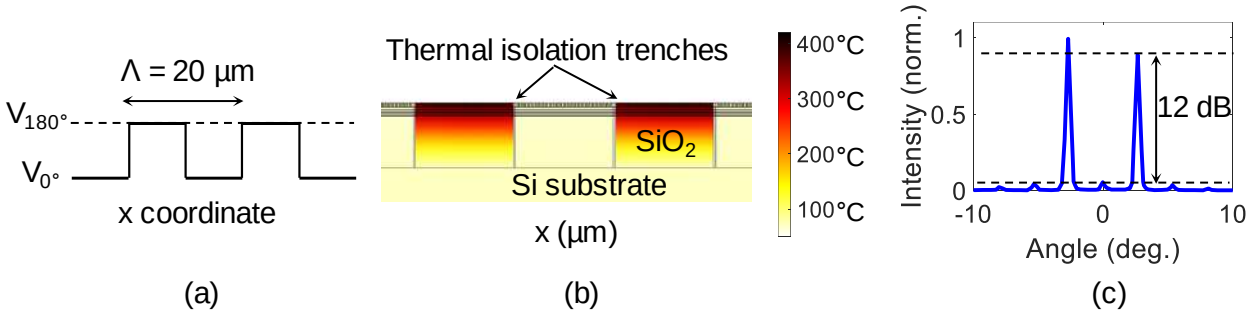

Figure 2 (a) Schematic diagram of the distribution of the applied bias, showing alternatively switching between one voltage for 0° in the reflection phase ($V_{0°}$) and another voltage for 180° in the reflection phase ($V_{180°}$) with the super cell period (Λ) of 20 μm. (b) Thermal simulation results of the device with the isolation trenches preventing the thermal crosstalk between neighboring cells. (c) Experimentally measured far-field distribution as a function of the angle under the binary phase grating (BPG) operation

In conclusion, we have demonstrated the all-dielectric electrically-tunable phase metasurface by using thermo-optic effect with carefully designed thermal isolation, which exhibits the efficiency of 20% and the directivity over 12 dB at the near-infrared regime. We believe the proposed device may shed light to the further research and development for various applications.

Abstract

Graphene/ZnO optical charge trap memory exhibits long retention via charge transfer quenching and electron trapping. Photodoping analysis confirms rapid charge transfer, with a high energy barrier preventing recombination. Adaptive learning reduces pulses needed for memory restoration. ANN simulations show fast convergence, making charge trap memory promising for energy-efficient neuromorphic applications.

Introduction

Neuromorphic on-device computing enables real-time biometric data processing while reducing the computational cost and energy consumption of traditional AI[1]. Optoelectronic neuromorphic devices, which modulate conductance via light exposure, offer advantages such as wider bandwidth, wavelength-dependent tunability, and lower computational power consumption[2]. However, challenges in biocompatibility, scalability, and long retention remain[3]. In this study, we present a graphene/ZnO (GZO) optical charge trap memory (CTM), demonstrating retention exceeding 54 hours, enabled by electron trapping at ZnO defect states and a high Schottky barrier, preventing charge recombination and sustaining photodoping effects. This retention enhances relearning efficiency, requiring fewer pulses for memory restoration. Artificial neural network (ANN) simulations validate its potential, demonstrating rapid convergence and near-unity accuracy within 20 epochs.

Results and Discussion

The GZO optical CTM exhibits a current increase in response to ultraviolet light, driven by electron doping from ZnO nanoparticles (NPs) into graphene. This effect is confirmed in transfer curve, where the leftward shift of the Dirac point with increasing irradiation time indicates progressive electron doping. The electron doping concentration can be calculated using capacitance model, reaching up to $1.38*10^{12}$ cm^{-2} after 30 seconds at an intensity of 1.131 mW cm^{-2}. Addtionally, higher UV power enhances both the drain current and retention time, due to a stronger temporal carrier concentration gradient, which drives charge transfer to graphene. However, at higher carrier densities, recombination processes become dominant, leading to saturation of the doping rate rather than a linear increase, as described by a multi-body recombination model.

The charge transfer quenching process in the GZO optical CTM is investigated using transient absorption (TA) spectroscopy, confirming rapid electron transfer from ZnO to graphene. The rapid absorption decay in GZO compared to ZnO highlights efficient charge dissociation. Retention analysis using stretched exponential fitting revealed a retention time exceeding 54 hours at 1.131 mW cm^{-2} optical stimulus, demonstrating the stability of the photodoped electrons and the effectiveness of the energy barrier in maintaining the excitation. Interaction between transferred electrons in graphene and trapped holes in ZnO further enhances charge retention. The Schottky barrier at the GZO interface, quantified as 2.02 eV, further hinders carrier recombination, enabling

long-term memory. Gate bias modulation experiments confirmed that increasing gate bias reduces the energy barrier, accelerating the recovery rate and demonstrating the Schottky barrier's crucial role in charge retention.

For the effective implementation of ANNs, the process of weight updating and validation are essential, typically performed iteratively over several epochs to optimize the network's performance. We examined the conductance increase behavior under different optical stimuli. System learns more rapidly when stimuli are applied more freuquently, over longer durations, and with higher intensity. The device exhibits enhanced relearning efficiency, requiring fewer pulses after memory loss, reducing power consumption. ANN simulations with the MNIST dataset validate the device's neuromorphic capabilities, showing rapid accuracy improvement despite its non-linearity. After 20 epochs, recognition accuracy reaches 93.75 %, comparable to 94.49 % in the ideal case.

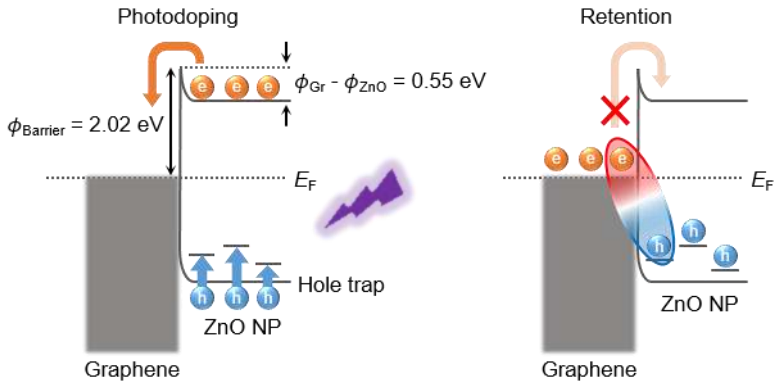

Figure. Schematic mechanism of photodoping (left); retention (right)

Conclusion

We demonstrated the neuromorphic capabilities of the GZO optical CTM, highlighting its potential for efficient ANN applications. The GZO optical CTM demonstrates long retention, high adaptability, and energy-efficient learning, making it a promising candidate for next-generation neuromorphic computing. The biocompatibility of graphene and ZnO further supports its application in bio-sensing and brain-computer interfaces.

Dynamic Multi-Wavelength Coded Aperture Imaging Using Reconfigurable Metasurfaces

[1]Reza Marzban, [1]Hamed Abiri, [1]Ali Adibi

[1]School of Electrical and Computer Engineering, Georgia Institute of Technology

Abstract

We present a reconfigurable coded-aperture imaging platform that harnesses the phase-transition properties of vanadium dioxide (VO_2) integrated with wavelength-selective metasurfaces in the near-infrared (NIR) range (1.1–1.6 μm). Each pixel in the metasurface array is designed for a specific resonant wavelength, allowing the device to generate a spatio-temporal "code" by switching individual pixels on or off. This on/off actuation is powered by the rapid insulator–metal transition of VO_2, triggered on millisecond timescales. In contrast to static coded-mask approaches, the dynamic system can be reconfigured to any desired pattern in real time, thus enabling high-resolution image reconstruction and enhanced signal throughput. Furthermore, the strong wavelength sensitivity provided by each pixel's metasurface design improves spectral control for applications ranging from telescope imaging to remote sensing. By combining programmable aperture coding with computationally efficient reconstruction algorithms, this platform offers a compact, tunable, and power-efficient solution for NIR imaging applications.

1. Introduction

Coded-aperture systems are widely used for imaging in energy regimes or wavelength bands where refractive or reflective optics are limited or impractical. Traditional coded apertures consist of patterned masks that modulate incoming light to produce an intensity distribution—a "shadow"—on a detector. The original scene or source distribution is then reconstructed from this shadow using computational algorithms. Such masks, however, are typically passive and fixed in their geometry, limiting their usability across broad wavelength ranges and restricting the ability to adapt the aperture pattern in real time. Here, we demonstrate a dynamic coded-aperture device in the short-wave infrared (SWIR) domain, specifically 1.1–1.6 μm, that leverages the unique properties of the phase-change material, vanadium dioxide (VO_2) integrated with metasurface nanoresonators. VO_2 undergoes a thermally driven phase transition near 68 °C, switching from an insulating to a metallic state and thereby changing its optical properties. By using transparent indium-tin-oxide (ITO) electrodes to deliver localized current for Joule heating, each pixel can be addressed individually and switched on sub-millisecond timescales. Figure 1 illustrates a conceptual rendering of the multi-wavelength metasurface array on a silicon dioxide (SiO_2) substrate, where each metasurface tile is designed to interact strongly at a different wavelength (λ_1–λ_5). In this manner, the array can serve as a spatio-spectral coded aperture that is reconfigurable on demand.

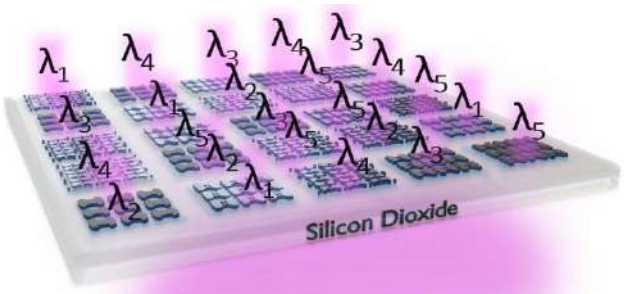

Figure 1. *Conceptual rendering of the multi-wavelength metasurface array fabricated on a SiO_2 substrate. Each metasurface tile is engineered to resonate at one of five distinct near-infrared wavelengths (λ_1–λ_5) to enable spatio-spectral modulation of incident light. By using VO_2 phase transition for rapid pixel switching, the array can be dynamically reconfigured into various coded patterns, facilitating high-resolution IR imaging in the 1.1–1.6 μm range.*

Device Architecture and Operation

Each pixel consists of a lower (negative) ITO backplane, an insulating alumina (Al_2O_3) pattern to define the active areas, and upper (positive) ITO lines arranged so that localized electrical current can be driven into specific pixels (Figure 2). A VO_2 layer and a metasurface—tuned for the desired resonant wavelength—are fabricated atop these electrodes. When voltage is applied, VO_2 rapidly heats past its transition temperature, changing from a low-loss insulating state to a more metallic state with high reflectivity and altered resonance behavior. By carefully designing the metasurface geometry for each pixel, the on/off optical contrast can be optimized at the target wavelength. Unlike static coded apertures that feature a single fixed pattern, the present approach allows each pixel to be toggled independently. This means the aperture can be reconfigured in real time, creating a new coded pattern whenever needed. The rapid phase transition of VO_2 allows the device to switch patterns on the order of milliseconds, which can be synchronized with computational imaging algorithms. Multiple patterns can be displayed sequentially, and each detector measurement captures a different coded projection of the scene. By fusing these snapshots, one obtains an improved reconstruction over what would otherwise be possible with a single static code. Since each pixel is tailored to a distinct resonant wavelength, the same device can encode and discriminate spectral information without bulky dispersive optics.

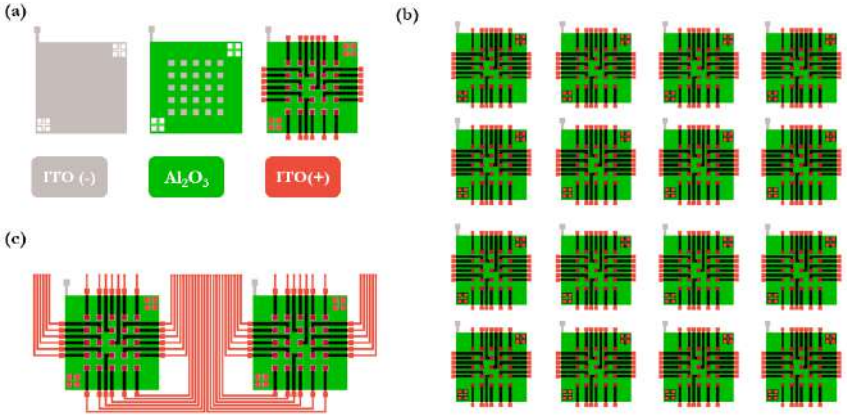

Figure 2. *(a) Each device layer comprises a large negative (–) ITO electrode (gray), patterned insulating Al_2O_3 squares (green), and positive (+) ITO lines (red) for individual pixel addressing. (b) An example 4 × 4 array of these addressable devices. (c) Expanded view illustrating how multiple devices are wired in parallel, enabling independent actuation of each pixel.*

The millisecond VO_2 switching capability, combined with independently addressable pixels, supports flexible spatio-temporal coding and higher signal-to-noise ratios than a simple pinhole configuration. Each pixel's wavelength selectivity provides built-in spectral discrimination, making the system well-suited to SWIR imaging for astronomy, remote sensing, or portable instruments. The dynamic aperture also enables advanced computational imaging strategies, such as compressed sensing or multi-pattern acquisition, enhancing resolution and speed. Details of the pixel design as well as the experimental demonstration of individual pixels and a small array will be presented.

Dynamic control of bound states in the continuum by MEMS-enabled hybridization of 1D and 2D metasurfaces

Abstract: We propose a tunable metasurface composed of coupled 1D and 2D metasurfaces. Our study demonstrates that this hybrid structure supports an ultranarrow quasi-BIC resonance, which can be tuned over 60 nm while maintaining a constant quality factor. This tuning is achieved through MEMS-enabled horizontal and vertical displacements within the structure.

The concept of Bound States in the Continuum (BICs) represents a fascinating phenomenon in modern physics, where certain states remain localized within a system despite existing at energies or frequencies that typically allow for radiation[1]. Originating from quantum mechanics, BICs have found significant applications in photonics and metamaterials, enabling strong confinement of electromagnetic waves and leading to the formation of extremely high-Q resonances[2,3]. Recent advancements have focused on the active control of BICs, where external stimuli, such as electric fields, temperature variations, or material phase transitions, are used to dynamically tune their properties[4]. The precise manipulation of quasi-BIC resonances in real-time could revolutionize photonic systems, enhancing device performance and functionality.

In this work, we propose a new approach to controlling quasi-BIC resonances in transmission within all-dielectric metasurfaces, enabled by microelectromechanical systems (MEMS). The quasi-BIC resonance is achieved via breaking the out-of-plane symmetry by introducing a 2D MEMS membrane that moves near a 1D metasurface. We demonstrate that the resonance quality factor approaches infinity as a MEMS structure moves farther from a 1D metasurface, thereby reducing the asymmetry, a defining characteristic of quasi-BIC resonances. Furthermore, the vertical movement of a MEMS membrane combined with horizontal displacement within a 1D metasurface enables the central wavelength of the quasi-BIC resonance to be shifted by more than 60 nm while maintaining consistent resonance bandwidth and Q-factor. The proposed all-dielectric metasurfaces achieve an ultranarrow resonance linewidth with dynamic tunability in the infrared range, making them promising candidates for advanced tunable filtering applications highly relevant for spectroscopy, remote sensing, and imaging.

Figure 1a depicts the tunable metasurface design consisting of silicon ridge pairs that can move horizontally relative to each other, while the 2D membrane moves vertically above the ridges. The polarization of the incident plane wave is shown using a triple of vectors. Two independent orthogonal tuning mechanisms enable precise control of both the central wavelength and bandwidth (or Q-factor) of the quasi-BIC resonance. Figure 1b presents the transmission characteristics for various distances between the ridges (d) when the distance between two layers (a) is equal to 900 nm. The horizontal movement of the ridges allows the resonance wavelength to shift by approximately 65 nm. By combining two independent orthogonal tuning mechanisms, complete control over the quasi-BIC resonance characteristics can be realized. Figures 1c and 1d illustrate the

dependence of the resonance central wavelength and Q-factor on two parameters: the distance between two layers (*a*) and the distance between the ridges (*d*). By precisely adjusting both parameters, as indicated by the black lines in Figure 1d, it is possible to maintain a constant Q-factor while tuning the central wavelength by more than 60 nm.

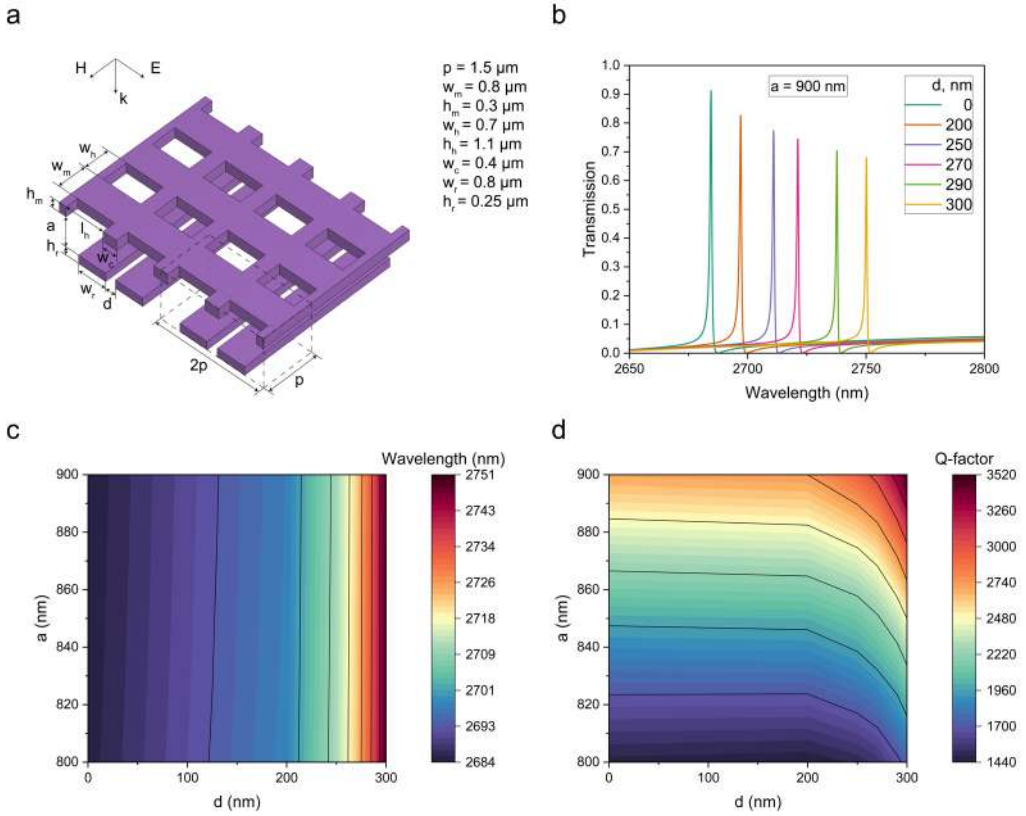

Figure 1. a) Schematic of the tunable metasurface design consisting of pairs of silicon ridges and an overlying MEMS membrane, depicting the unit cell indicated by the dashed lines; b) Transmission characteristics for varying distances between the ridges (*d*), with the distance between two layers (*a*) fixed at 900 nm; c, d) Dependence of the resonance central wavelength and Q-factor on two parameters: the distance between two layers (*a*) and the distance between the ridges (*d*). The black lines indicate examples of curves with constant wavelength and Q-factor, respectively.

Chirality, magnetism, and magnetoelectricity: Separate phenomena and joint effects in metamaterial structures

A QED Theory of Discriminatory RET Mediated by One or Two Polarisable Molecules

A. Salam

Department of Chemistry, Wake Forest University, Winston-Salem, NC 27109, USA
salama@wfu.edu

Abstract: QED theory is employed to study the influence of one or two mediator particles on the resonance energy transfer rate between a pair of chiral molecules. It is found that direct and relayed rates are discriminatory, maximised for collinear geometry, and require the bridging species to be multi-levelled systems.

An especially attractive aspect of non-relativistic or molecular quantum electrodynamics (QED) is that the interaction between light and matter, and between material particles, may be treated within a single theoretical framework [1,2]. A signature feature of this theory is that electromagnetic radiation, as well as atoms and molecules, obey quantum mechanical principles [3]. Thus, photons arise naturally because of quantisation of the electromagnetic field. They are classified as belonging to two types, real or virtual photons [4]. The former are associated with a change in the state of the radiation field as occurs in numerous linear and nonlinear spectroscopic and parametric processes. Virtual photons, on the other hand, are unobservable but their existence is allowed by time-energy uncertainty and manifests in processes in which the state of the radiation field remains the same, giving rise to an energy shift or transfer rate. It is the exchange of virtual photons between particles of matter that accounts for the coupling between them.

Perhaps the best-known example of a molecular process that involves the propagation of a single virtual photon between two centres is resonance energy transfer (RET) [5] in which typically electronic excitation is exchanged between an initially excited donor species and an acceptor particle that is in its ground state. A QED calculation of the probability amplitude shows that the tensor coupling the electric dipoles of the emitter and absorber is properly retarded, with the subsequent Fermi golden rule rate formula exhibiting an inverse square dependence on separation distance at long-range that is indicative of radiative transfer of energy. At the other extreme in the near-zone, the well-known Förster exchange rate is found to apply. Transfer of energy is radiationless, originating from inter-particle coupling that is static in origin.

When both molecules exchanging energy are chiral, there is an additional contribution to the transfer rate that is discriminatory, changing sign when one enantiomer of the pair is replaced by its isomer of opposite handedness [6,7]. Spectroscopic selection rules in such species are less restrictive relative to non-chiral substances enabling multipole moments higher than the leading electric dipole term to contribute to the transfer probability. In the dipolar approximation the interaction Hamiltonian is given by

$$H_{int}(\xi) = -\varepsilon_0^{-1}\vec{\mu}(\xi)\cdot\vec{d}(\vec{R}_\xi) - \vec{m}(\xi)\cdot\vec{b}(\vec{R}_\xi), \tag{1}$$

where $\vec{\mu}(\xi)$ and $\vec{m}(\xi)$ are electric and magnetic dipole moment operators of the donor or acceptor molecule, ξ, positioned at $\vec{R}_\xi$, and $\vec{d}(\vec{r})$ and $\vec{b}(\vec{r})$ are microscopic electric displacement and magnetic field operators, respectively. To leading order, the interference of electric and magnetic dipole coupling terms yields a

discriminatory rate, with purely electric and purely magnetic dipole contributions independent of handedness.

The modification of the migration rate between two optically active molecules is investigated when one [8] or two [9] identical, neutral, passive, electric dipole polarisable mediator particles are introduced. Their role is to relay energy from the chiral emitter to the chiral acceptor, remaining in the ground state before and after transfer. In the case of one bridging molecule, twenty-four time-ordered diagrams have to be evaluated and summed at fourth-order of perturbation theory when using an interaction Hamiltonian that is linear in the electric displacement field. To ensure a manageable number of time-ordered sequences occurs when two mediators are present, it is convenient to employ an interaction Hamiltonian that is quadratic in the electric displacement field and proportional to the ground state dynamic polarisability of each mediator. It has the form

$$H_{int}(M_i) = -\varepsilon_0^{-2}\alpha_{ij}(M_i)d_i(\vec{R}_{M_i})d_j(\vec{R}_{M_i}),\ i = 1,2, \tag{2}$$

where $\alpha_{ij}(M_i)$ is the ground state dynamic electric dipole polarisability of mediator M_i, i = 1, 2. Twenty-four diagrams again contribute to the matrix element at fourth-order of perturbation theory.

In both cases, the isotropic mediated Fermi golden rule rate is discriminatory, depending on the chirality of the species exchanging energy. Maximum rates are achieved when all three or four bodies are arranged in a collinear configuration. Interestingly, the energy transfer probability vanishes if each mediator is modelled as a two-level system. In the case of one bridging particle, the rate is found to be retarded at *all* separation distances and vanishes when the three molecules are oriented at right angles to one another.

As a result of this work, considerable insight is gained into the conveyance of excitation energy between chiral entities in a dielectric medium [10].

Theory of Unidirectional Magnetoresistance in Nanoscale Bilayers

X. R. Wang[1,2*]
[1]School of Science and Engineering, Chinese University of Hong Kong (Shenzhen), Shenzhen 51817, China
[2]The Hong Kong University of Science and Technology, Clear Water Bay, Kowloon, Hong Kong

Abstract

Unidirectional magnetoresistance (UMR) of bilayers arises from the influences of magnetization present in the magnetic material and the interfacial potential inherent in heterostructures. This theory explains unifiedly universal UMR and unusual anisotropic magnetoresistance and capture all experimental features such as dependence on current direction, film thickness, and magnetic field strength.

1 Introduction

The study of magnetoresistance (MR) in nanoscale multilayers has gained significant attention due to its fundamental interest and important applications in spintronic devices. Recent studies have given birth to many new concepts and phenomena, such as spin Hall MR (SMR) [1, 2]—termed as unusual anisotropic MR (UAMR) in this study—and unidirectional MR (UMR) [3]. UAMR and UMR have emerged as key phenomena that reflect the intricate interplay between charge transport and magnetism.

UAMR is the MR of bilayers at low current density. For a current density $\vec{j} \parallel \hat{x}$, flowing in the plane of a ferromagnet-nonmagnet (FM/NM) bilayer, the longitudinal and transverse resistivity depends on the direction of magnetization $\vec{m}$ as: $\rho_{xx} = \rho_0 + \rho_1 m_x^2 + \rho_2 m_z^2 + \rho_3 m_z^4 + \rho_4 m_x^2 m_z^2$ and $\rho_{xy} = \rho_5 m_z + \rho_6 m_z^3 + \rho_1 m_x m_y + \rho_4 m_x m_y m_z^2$. This is in contrast to the conventional anisotropic MR (AMR), which is given by $\rho_{xx} = \rho_0 + \rho_1 m_x^2$ and $\rho_{xy} = \rho_5 m_z + \rho_1 m_x m_y$. Here, the parameters ρ_i (where $i = 0, 1, \ldots, 6$) are independent of the magnetization direction. UAMR has stimulated the development of the SMR theory [1, 2], which attributes UAMR to the spin Hall effect and its inverse effect via the absorption/reflection of spin current at the magnetic interface. SMR theory predicts $\rho_{xx} = \rho_0 + \rho_1 m_x^2 + \rho_2 m_y^2$ and has been widely used to interpret UAMR ubiquitously observed in all kinds of nanoscale multilayers. Clearly, the original SMR theory cannot apply to this wide range of multilayers. As a result, alternative spin-current-related MR models have been proposed to explain the universal nature of UAMR. A natural question arises: Why does the same UAMR emerge from so many different microscopic origins? Why do so many different microscopic interactions exhibit the same angular dependence? Wouldn't it be more natural to expect a unified origin for UAMR? Indeed, a recent two-vector theory predicts exactly the observed ρ_{xx} and ρ_{xy} of UAMR [4–6]. In this two-vector theory, the key components are magnetization of ferromagnetic (FM) layers and the effective internal interfacial electric field arising at the interface between ferromagnetic (FM) and non-magnetic (NM) materials. These two ingredients result in the universal behaviors of UAMR in FM/NM bilayers and FM single layers, independent of the details of microscopic interactions among electrons, lattices, spins, and magnons.

UMR is the nonlinear part of MR of bilayers at high current density [above $10^{10}\mathrm{A/m^2}$] [3]. Different from UAMR whose resistivity does not depend on the current and follows $\rho_{xx} = \rho_0 + \rho_1 m_x^2$ when $\vec{m}$ rotates in the xy-plane, ρ_{xx} in UMR is linear in current density and is odd in m_y. Both ρ_{xx} and ρ_{xy} are sensitive to the magnetic field, film thickness, and temperature. Under an alternating current of frequency ω, single harmonic resistivity of ρ_{xx}^{ω} and ρ_{xy}^{ω} follow the behaviour of UAMR while the second harmonic resistivity of $\rho_{xx}^{2\omega}$ and $\rho_{xy}^{2\omega}$ reverses sign with the directions of current and transverse field, and has a strong 3-fold symmetry at low magnetic field and only a 1-fold symmetry of $\rho_{xx}^{2\omega} \propto m_y$ and $\rho_{xy}^{2\omega} \propto m_x$ at high magnetic field. The same behaviour is observed in a wide range of systems, including FM/NM, FM/semiconductor, FM/topological insulator bilayers, and 2D materialsits. To date, UMR is attributed to multiple origins including giant MR effect, spin Hall effect and inverse spin Hall effect, the Rashba-Edelstein effect, magnon effect, spin-flip and spin-dependent scatterings, and thermal effects. From the coexistence of UAMR and UMR in vast different systems, it is natural to ask whether two-vector theory can also explain the universal features of UMR.

We consider the electric field response $\vec{E}$ to an applied current density $\vec{j}$ flowing along the x-direction of a bilayer in the xy-plane under the influence of magnetization ($\vec{M} = M\vec{m}$) of the FM layer and an interfacial field ($\vec{n} \parallel \hat{z}$). Under a high $\vec{j}$, a thermal gradient $\nabla T = aj^2\hat{z}$ perpendicular to the bilayer is generated due to Joule heating [3], where a is a device parameter. The most general expression for $\vec{E}$, which is linear in both $\vec{j}$ and ∇T, is given by [4–6]

$$\vec{E} = C_0 \nabla T + C_1 \vec{m} \times \nabla T + \rho_{\vec{m},\vec{n}} \vec{j}, \tag{1}$$

where C_0 is the Seebeck coefficient and C_1 measures the anomalous Nernst effect. $\rho_{\vec{m},\vec{n}}$ is the rank-2 resisitivty tensor which can only be constructed from $\vec{m}$ and $\vec{n}$. It is straight to show

$$\begin{aligned} \rho_{xx} &= \rho_0 + \rho_1 m_x^2 + \rho_2 m_z^2 + \rho_3 m_z^4 + \rho_4 m_x^2 m_z^2 + C j m_y \\ \rho_{xy} &= \rho_5 m_z + \rho_6 m_z^3 + \rho_1 m_x m_y + \rho_4 m_x m_y m_z^2 - C j m_x, \end{aligned} \tag{2}$$

where ρ_i and C are angular-independent parameters. Eq. 2 is exactly the widly observed UAMR.

Under an alternating current (AC) of frequency ω, $\vec{j} = j\cos(\omega t)\hat{x}$, one can obtain, after some algebra,

$$\begin{aligned} &\rho_{xx}^{2\omega}(\alpha) = (C + c_1) j \sin\alpha - c_1 j \sin 3\alpha, \quad \rho_{xy}^{2\omega}(\alpha) = -(C + c_1) j \cos\alpha + c_1 j \cos 3\alpha, \\ &\rho_{xx}^{2\omega}(\beta) = (C + c_2) j \sin\beta + (c_3 - c_2) j \sin 3\beta - c_3 j \sin 5\beta, \quad \rho_{xy}^{2\omega}(\beta) = c_4 j \sin 2\beta + c_5 j \sin 4\beta, \\ &\rho_{xx}^{2\omega}(\gamma) = 0, \quad \rho_{xy}^{2\omega}(\gamma) = c_1 + c_6 - C j \sin\gamma - c_1 \cos 2\gamma - c_6 \cos 4\gamma, \end{aligned} \tag{3}$$

where C and c_i are material parameters. $\rho_{xx}^{2\omega}(\alpha)$ and $\rho_{xy}^{2\omega}(\alpha)$ are exactly what were observed in UMR. The dierction dependences of $\rho_{xx}^{2\omega}$ and $\rho_{xy}^{2\omega}$ can be used for future experiments to test.

In conclusion, we have presented a novel theoretical approach to understanding UAMR and UMR. According to this theory, UAMR and UMR do not depend on microscopic interactions and do not require the interconversion between spin current and charge current. In principle, materials with any spin-electron scattering under the influence of an interfacial potential should exhibit the universal UAMR and UMR discussed herein. Several predictions are new. Some of them are supported by existing experiments while the others are awaited for experimental confirmation.

New Topological Magnetic Photonic Crystals

C. T. Chan[1*]

[1]Hong Kong University of Science and Technology, Hong Kong SAR, China

[*]corresponding author: phchan@ust.hk

Abstract: We introduces several new types of magnetic photonic crystals, specifically photonic alloys and gyromagnetic double-zero-index materials. Photonic alloys can support topological edge states even at very low concentrations of magnetic components. The gyromagnetic double-zero-index photonic crystal exhibits special non-trivial topological characteristics in both near-field and far-field contexts.

We present the concept of some new magnetic photonic crystals that exhibit intriguing topological features. First, we explore “photonic alloys” [1], which are disordered, non-periodic topological materials. This new class of materials consists of two-dimensional (2D) photonic crystals made up of a mixed lattice of non-magnetized and magnetized components occupying randomly chosen lattice sites. These materials demonstrate non-trivial topology even at very low concentration of magnetic components, characterized by the winding of the reflection phase. Notably, we experimentally observe non-reciprocal chiral edge states resulting from a local breakdown of time-reversal symmetry, rather than a global one. The concentration of magnetic components required to induce non-trivial topological depends on the lattice structure. Interestingly, in certain lattice configurations, non-trivial topology and chiral edge states can be identified even at minimal concentrations of magnetic components.

Additionally, we introduce gyromagnetic double-zero-index materials (GDZIM) [2], a type of magnetic photonic crystal characterized by zero scalar permittivity and unique tensorial magnetic permeability with non-zero components, yet possessing a zero determinant. This is achieved by constructing a magnetized 2D photonic crystal that displays a spin-1/2 Dirac cone at the Brillouin center. This configuration is at the critical point of a topological transition between two Chern insulator phases. A key topological feature of GDZIMs is the presence of an unpaired spin-1/2 Dirac point at the center of momentum space. Through both theoretical and experimental validation, we demonstrate that the spin-1/2 Dirac topology of GDZIMs provides an intrinsic pathway for generating optical spatiotemporal vortex pulses (STVPs) with remarkable robustness. The central frequency and wavevector of the generated STVPs remain firmly anchored to those of the bulk Dirac point at the zone center, independent of material thickness or background medium. We show that this exceptional robustness arises from a novel form of topological correspondence—bulk-spatiotemporal reflection correspondence—which links the quantized jump of topological invariants at the phase transition point to the vortex charge of the generated STVPs. Our findings illuminate the connections between zero-refractive-index photonics, topological photonics, and singular optics.

Abstract: We provide free space microwave measurements of composites made from carbon fibers and ferromagnetic microwires inclusion focusing on the electromagnetic properties. We observed that a low frequency modulating AC magnetic field allows to distinguish the microwave signals originated by ferromagnetic microwires inclusions from that generated by the carbon fibers.

Glass-coated microwires prepared by the Taylor-Ulitovsky technique with diameters between 0.5 and 100 μm covered with thin, insulating, biocompatible and flexible glass-coating can present excellent magnetic softness, superior mechanical properties. Such features of glass-coated microwires allow development of new exciting applications in various magnetic sensors, as well as in smart composites with tunable magnetic permittivity [1,2].

One common challenge in composite materials is monitoring of stresses and temperature. Recently, stress dependencies of hysteresis loops and GMI effect have been proposed for the mechanical stresses monitoring in composites containing microwires inclusions [2].

In this paper, we present our latest results on studies of magnetic properties of glass-coated microwires and on our attempts to wireless health monitoring of composites containing both carbon fibers and ferromagnetic glass-coated microwires.

The composites containing both carbon fibers and Co-rich ferromagnetic glass-coated microwires were manufactured in the INFINITE EU project (Horizon Europe) at IDEKO's facilities (see Figure 1). For wireless measurements we used a free space microwave measurement setup (see Figure 1b) consisting of two broadband horn antennas (1-17 GHz) fixed to the anechoic chamber and a vector network analyzer, previously employed for the characterization of the composites with magnetic wire inclusions [2]. Such setup allows to characterize composites of dimensions 20 x 20 cm^2. $Co_{64.6}Fe_{5.0}B_{16.0}Si_{11.0}Cr_{3.4}$ microwires (metallic nucleus diameter d=38 μm) microwires with better MI effect have been selected for the carbon fiber composite preparation. The expected problem with composites containing electrical conductive carbon fibers is that they can substantially interfere with the microwave signal from the magnetic microwire inclusions.

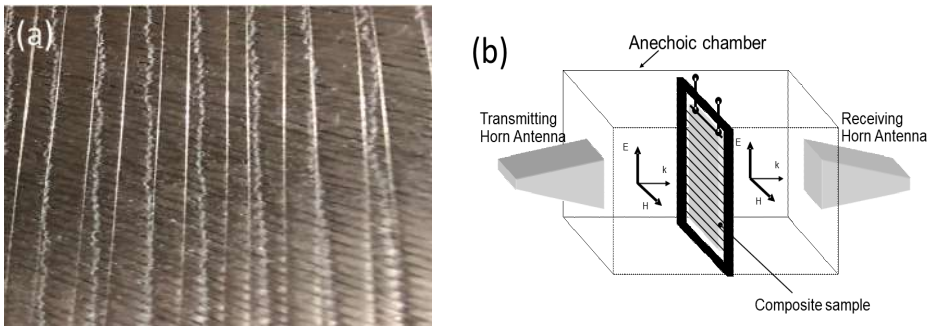

Figure 1. Image of the carbon fiber composite with magnetic microwire inclusions (the vertical lighter fibres) with 5 mm spacing (a) and the free-space setup sketch (b).

We proposed several solutions. Thus, in order to separate the microwave signal from ferromagnetic microwires, we used an external low frequency modulated magnetic field [2].

The other possibility is to separate the conductive carbon fibers from the magnetic microwires. Finally, use of magnetic microwires with better GMI performance can further increase the microwave response.

In Figure 2a,b the microwave signals (S_{11} parameters, reflection) measured at 2 GHz with no separation and with a separation between magnetic microwires and carbon fibers are shown. As illustrated, the position of carbon fibers in the vicinity of magnetic microwires critically affect the response signals obtained from such composites.

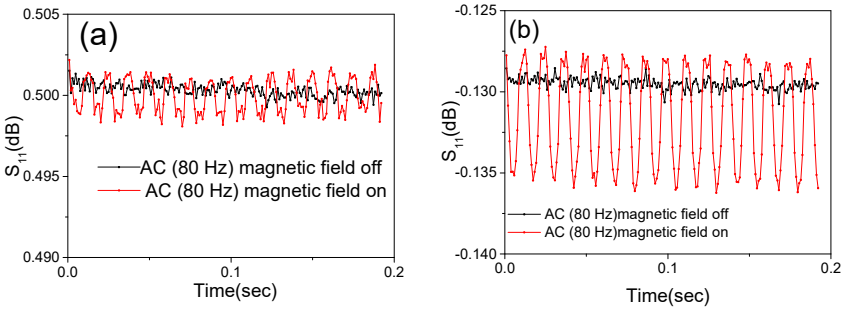

Figure 2. Effect of introducing an insulating plastic layer between the microwires and carbon fibre composite on the S_{11} parameter. Measurements without plastic layer (a) and with plastic layer (b).

Thus, the presence of a thin insulating plastic layer (30 μm thick) between the ordered microwires and carbon fiber composite can further increase the S_{11} parameters (see Figure 2b).

The aforementioned examples provide the routes for development of the composites made from the carbon fibers and magnetically soft amorphous glass-coated microwires inclusions.

Spin current generation due to differential rotation

M. Matsuo[1]
[1]Kavli Institute for Theoretical Sciences, University of Chinese Academy of Sciences, China
mamoru@ucas.ac.cn (corresponding author)

Abstract

We theoretically investigate nonequilibrium spin dynamics in differentially rotating systems, deriving an effective Hamiltonian for conduction electrons in the comoving frame. In contrast to conventional spin current generation mechanisms that rely on vorticity, our theory reveals spins and spin currents arising from differentially rotating systems regardless of vorticity-gradient.

1 Introduction

In this talk, we consider a novel mechanism of spin current generation from non-uniform rotational motion without relying on vorticity[1]. To date, theoretical descriptions of the interaction between spatially non-uniform rotational motion and spin have been primarily framed as an extension of the gyromagnetic effect, originally identified by Einstein and others[2,3]. The conventional approach was limited to introducing spin-vorticity coupling by replacing the rigid rotation with vorticity associated with non-uniform rotation[4,5]. We formulate an effective Hamiltonian for the conduction electrons in differentially rotating systems, demonstrating the emergence of effective gauge fields. We also derive microscopic expressions for the spin current driven by the emergent gauge fields and apply them to two examples of differentially rotating systems, such as a liquid metal and a non-magnetic metallic cantilever. Our estimation of the generated spin currents indicates that they are realistically measurable in experiments.

Experimentally testing the spontaneous disentanglement hypothesis using a ferri–magnetic resonator

Eyal Buks[1]
[1]Andrew and Erna Viterbi Department of Electrical Engineering, Technion, Haifa 32000 Israel
eyal@ee.technion.ac.il (corresponding author)

Abstract

The spontaneous disentanglement hypothesis makes the collapse postulate of quantum mechanics redundant, and enables meta-stability in finite quantum systems, which is otherwise excluded. We report on an experiment performed using a ferri–magnetic resonator, which indirectly supports the spontaneous disentanglement hypothesis.

1 Introduction

The spontaneous disentanglement hypothesis [1] is motivated by two outstanding issues in the foundations of quantum mechanics (QM). The first one originates from the collapse postulate. This postulate arguably gives rise to an internal inconsistency in QM [2], which was first introduced in 1935 by Schrödinger [3], and which is commonly known as the problem of quantum measurement. Moreover, the spontaneous disentanglement hypothesis is relevant to an apparent conflict between linearity of dynamics in standard QM , and experimental observations of multi–stabilities and phase transitions in quantum systems [4].

2 Experimentally testing the hypothesis

Here, the hypothesis that disentanglement spontaneously occurs in quantum systems is experimentally tested using a ferri–magnetic resonator. According to this hypothesis, time evolution is governed by a modified master equation having an added nonlinear term, which deterministically generates disentanglement [1]. The added term can give rise to multistabilities, which are otherwise theoretically excluded. Bistability is experimentally observed in the resonator's response to an externally applied monochromatic driving [5]. Experimental results are compared with predictions derived from the disentanglement–based model, and an alternative model, which is based on the method of Bosonization and the Holstein–Primakoff transformation. It is found that better agreement with data is obtained from the disentanglement–based model (see Fig. 1). This finding, together with a difficulty to justify the Bosonization–based model, indirectly support the spontaneous disentanglement hypothesis.

Optical quasiparticles induced structured materials

Abstract: Optical quasiparticle carries topologically protected polarization textures in a two- or three-dimensional space. We here demonstrate the direct imprint of polarization textures of optical quasiparticles onto a material. This demonstrates a modern approach for materials manipulation, such as the optically induced direct creation and annihilation of skyrmion textures in materials.

Structured light, such as an optical vortex and vector beam, carries a unique physical property, including an annular spatial form and an orbital angular momentum (OAM), associated with its on-axis phase/polarization singularity, and it has been widely utilized in versatile applications across optical manipulation, optical communication, and high spatial resolution optical microscopy. Furthermore, it twists the irradiated materials to fabricate chiral surface structures at a nano/micron scale. Thus, structured light opens new avenues towards advanced materials manipulation.

To date, structured light involves a new class of optical waveforms, such as a particle-like optical waveform with spatially inhomogeneous polarization structures in space, referred herein to as optical quasiparticle.

Optical skyrmion, most commonly studied as optical quasiparticle, encompasses all polarization states mapped on a Poincaré sphere, and it has been experimentally demonstrated by the coherent superposition of orthogonally oriented, circularly polarized fundamental Gaussian and Laguerre–Gaussian (LG) modes with the appropriate relative phase. Interestingly, it exhibits space-invariant characteristics under propagation even through turbulent media (topologically protected polarization textures), and thus, it is rapidly finding ability in advanced applications, such as free-space communications, and polarization nanoscale-metrology. However, in contrast to more conventional optical vortex, the optical quasiparticle is still in its infancy.

In this presentation, we review the fundamentals and applications of optical quasiparticles and also address the demonstration of microfabrication of exotic structures with optical quasiparticles (direct imprint of optical quasiparticles) onto a material. Intriguingly, the fabricated structures possess sub-wavelength-scale periodical ripples and knots, manifesting the polarization textures of optical quasiparticles. This demonstration gives rise to a new and modern approach to microfabrication and materials processing.

Abstract: We demonstrate the magneto-optical Kerr effect (MOKE) induced by the skyrmion formation, i.e., topological MOKE, in insulating GaV_4Se_8. The observed optical rotation is comparable to the that reported for itinerant systems, which establishes the significant impact of emergent magnetic field even on the Mott insulator driven by strong electron correlation.

Magnetic skyrmions are nanometric whirlpools of spins, where the directions of the constituent spins wrap the unit sphere [1], attracting enormous attention as potential information carriers in next-generation memory/logic devices. Due to their non-coplanar spin arrangement, the resultant scalar spin chirality gives rise to the fictious magnetic field (emergent magnetic field) acting on the conduction electrons, which leads to unique electromagnetic phenomena, as represented by the topological Hall effect (THE). Recently, some of us discover the novel magneto-optical effect by the emergent field, which we call the topological magneto-optical effect, in the skyrmion-hosting itinerant magnet Gd_2PdSi_3 [2]. The magneto-optical Kerr effect (MOKE) is remarkably enhanced by the skyrmion formation, being similar to the THE. This topological MOKE should be universal even for the system where the emergent field effect is not explicitly observed in the dc electrical transport measurement, which has remained elusive.

In this presentation, I show the observation of topological magneto-optical effect in the skyrmion-hosting Mott insulator GaV_4Se_8. While the THE is never observed because of insulating nature, we find that the MOKE is substantially enhanced by the skyrmion lattice (SkL) formation, as is the case for the THE in itinerant systems. This topological magneto-optical effect is observed at the particular photon energy, which directly demonstrates the resonantly enhanced THE in the optical region. The spectral characteristics are well captured by a minimal theoretical model, revealing the crucial role of momentum-space Berry curvature induced by band reconstruction through SkL formation. The observed Hall angle at the resonance energy is comparable to the THE reported for itinerant systems, which establishes the robust and significant impact of the emergent magnetic field even on the Mott insulating state driven by strong electron correlation. These findings demonstrate the universal light-skyrmion interaction mediated by the emergent field in the optical region, potentially enabling the functional operation of skyrmion-based devices integrated with the versatile laser technology.

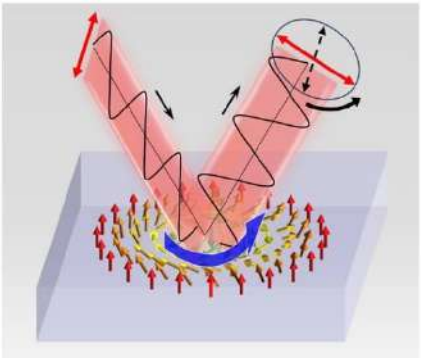

Fig.1. Schematic illustration of topological magneto-optical effect by skyrmion formation.

Listening to nanostructures' absorption and chirality: widely tunable photo-acoustic spectroscopy

E. Petronijevic[1*], C. Skubisz[1], G. Leahu[1], C. Sibilia[1], R. Li Voti[1] and A. Belardini[1]

[1]Sapienza Università di Roma, SBAI Department, Italy

Abstract: Photo-acoustic spectroscopy (PAS) is a low-cost, scattering-free and non-destructive method of measuring material absorption. Here, we enrich PAS with many degrees of freedom: laser wavelength, polarization, direction, focus, and the possibility of spatial and frequency mapping. We show its potential in characterizing both commercial and specially designed nanostructures.

Sensing chirality by direct absorption characterization is of great interest in the fields of plasmonics and nanophotonics, where the nanomaterials are specially designed to enhance otherwise weak chiro-optical light-matter interaction. Circular dichroism (CD) is a differential absorption of circular polarizations of opposite handedness, which defines the chirality of a material. Besides intrinsically chiral nanostructures[1], chirality can be induced in asymmetric samples by exciting them at oblique incidence, obtaining CD via extrinsic chirality[2]. We previously showed that unconventional, photo-thermal methods can be used to directly reveal absorption and chirality in nanostructures[3]. Specifically, in photo-acoustic spectroscopy (PAS), periodically modulated light absorption creates pressure changes in the vicinity of the sample closed in the photo-acoustic cell: these changes correspond to an acoustic signal, caught by a microphone. PAS is scattering-free, low-cost, non-destructive and sensitive. We applied it to measure absorption in asymmetric plasmonic-dielectric metasurfaces[4] and GaAs nanowires asymmetrically covered by gold[5]; however, to precisely measure extrinsic chirality, the photo-acoustic response was obtained at single laser wavelengths.

Here, we enrich the PAS set-up with new degrees of freedom, overcoming previous limitations such as low power and inability to precisely tune the polarization. The set-up is shown in Fig. 1(a). We use a widely tunable laser, covering the near-infrared (680-1080 nm) and visible (340-540 nm) ranges, and modulate its output with a tunable mechanical chopper. The laser polarization is defined by a linear polarizer and a quarter-wave plate, and the laser can be focused before impinging on the sample in a closed PAS cell. Moreover, the cell is attached to rotation and translation stages, which allows for incidence angle control, and surface absorption scanning, respectively.

In Fig. 1(b), we show the possibility to map extrinsic CD in metasurfaces asymmetrically covered by Ag[4]; as such samples are large areas of self-assembled nanospheres (with plasmonic semi-shells), no focusing was required. As expected, CD signal, defined as normalized differential absorption of left and right circular polarizations (LCP and RCP, respectively), falls to zero at normal incidence, and changes sign for the opposite angles of incidence. In Fig. 1(c), we show spatial mapping on commercial nanostructures covered by Ag, conventionally used in Surface Enhanced Raman Spectroscopy (SERS) and purchased from Silmeco. We set the laser wavelength to 800 nm and focus it to 70 μm beam diameter at normal incidence; the chopper frequency is 81 Hz, and the maps are scanned with 100 μm step in both planar directions. In the upper part of the absorption maps, the local absorption increase is due to the vicinity of the sample border. Finally, the overall CD of the

zone goes to zero, as the sample is intrinsically achiral.

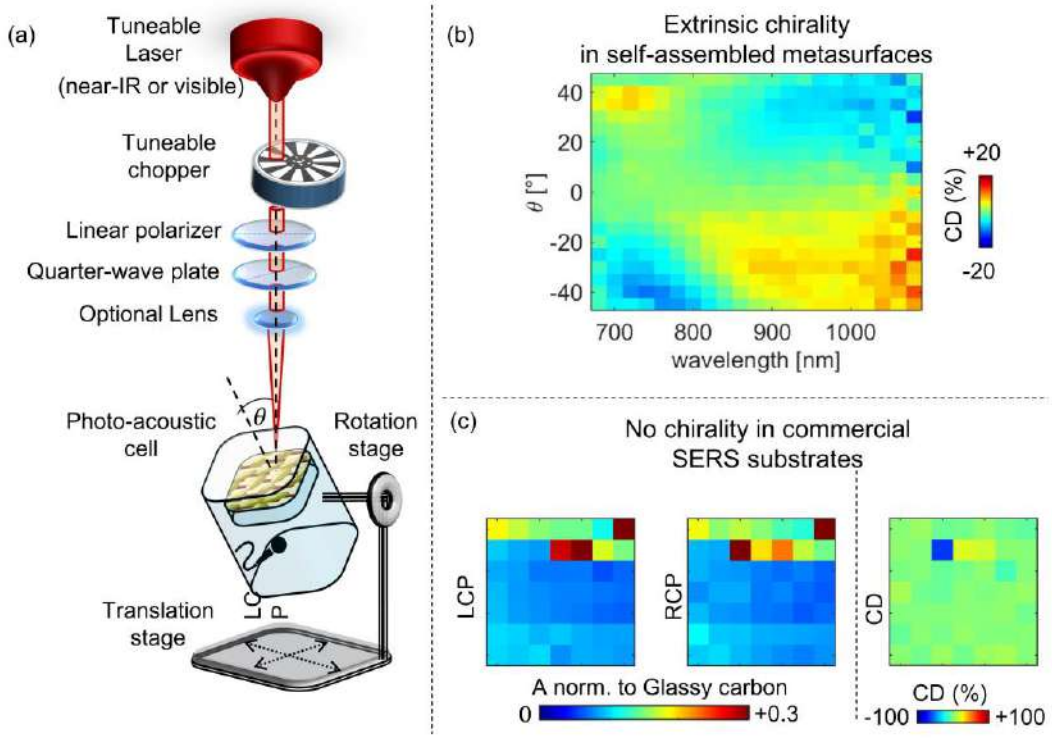

Figure 1 (a) Photo-acoustic set-up positioned on rotational and translation stages allows for multiple tuneable parameters: laser wavelength, chopper frequency, polarization, beam-waist, angle of incidence. (b) Detection of extrinsic chirality: example of circular dichroism (CD) characterization of asymmetric, self-assembled metasurfaces (without lens). (c) Spatial mapping of commercial achiral nanostructures (Silmeco Ag SERS substrates); uniformity and CD mapping is obtained by exciting the sample with 800 nm laser beam, focused to 70 μm beam-diameter; chopper frequency is set to 81 Hz. Top parts of the spatial map show the local absorption increase due to the vicinity to the sample's border.

We strongly believe that such enriched boosted PAS can be used to sensitively map absorption and chirality of nanostructured media in a broad wavelength range and with many degrees of freedom.

Abstract: We conducted imaging of nanoscale local chiro-optical effects utilizing photoinduced force microscopy, a force imaging technique. This study successfully achieved enantio-selective chiro-optical force nanoscopy of individual nanostructures.

Microscopic analysis of nanomaterials using circularly polarized light is crucial in materials science, chemistry, and biology. It determines structural characteristics like chirality and local magnetic properties such as magnetic circular dichroism (MCD). Novel applications include interactions between chiral molecules and high refractive index nanomaterials. Historically examined through macroscopic spectroscopy, there is a demand for nanoscopic observation of circular dichroism, which is challenging due to weak signals and limited spatial resolution.[1] Breakthroughs in microscopy techniques are needed, with photoinduced force microscopy (PiFM) being a promising method.[2, 3] PiFM leverages optical forces on tips to enhance detection and analysis of chiral materials at the nanoscale, advancing pharmaceutical and biological sciences. The present study focuses on imaging chiro-optical forces around individual chiral nanoparticles using CD-PiFM.

We synthesized three-dimensional chiral gold nanoparticles and recorded CD-PiFM images of them on a quartz substrate using CD-PiFM by irradiating left and right circularly polarized light at a wavelength of 785 nm. The chiral gold nanoparticles, as illustrated in the SEM images (insets of Figs. 1a and e), exhibit helicoidal structures, and the D- and L-forms display opposite CD activities in the visible wavelength range.[4] The results for the D-form nanoparticles are presented in Figs. 1a-d. A significant feature, namely the strong attractive and repulsive forces (positive and negative PiFM signals, respectively) around the gold nanoparticles, was observed in the PiFM images (Figs. 1b, c; refer to Fig. 1a for nanoparticle positions). When the probe is positioned below the gold nanoparticles (negative y-direction in the figure), the attractive interaction (positive PiFM signals) increases substantially due to the sharpened tip apex of the cantilever orienting toward the direction of the gold nanoparticles, resulting in a strong attractive interaction. Conversely, when the tip is directly above the gold nanoparticles, where the dipoles of the tip and the nanoparticle are aligned parallel due to illumination from the bottom side of the substrate, a strong repulsive force is observed. The images under left and right circularly polarized illumination (Figs. 1b and c, respectively) appear nearly identical. However, in the differential image (Fig. 1d), differential PiFM signals are observed around a single particle, particularly below (negative y side) the nanoparticles, as indicated by arrows. Similar but inverted image features were observed in the L-form nanoparticles (Figs. 1e-h). This finding demonstrates that the current CD-PiFM technology enables the determination of the handedness of individual particles and the enantio-selective nanoscopy of chiro-optical effects.

It is apparent from the magnified image of a D-form nanoparticle in Figs. 2a-d that a negative signal is present in the lower (negative y) part of the differential image (Fig. 2d). Based on the imaging features

demonstrated, we conclude that enantio-selective chiro-optical force nanoscopy has been achieved with CD-PiFM.

Two-color laser driven novel phenomena in solids: Detection of symmetries and control of photocurrent

Masahiro Sato*, Minoru Kanega, and Mina Udono

[1]Department of Physics, Chiba University, Japan
*corresponding author: sato.phys@chiba-u.jp

Abstract: We theoretically explore novel nonlinear responses of materials to two-color lasers, mixed waves of two different lasers. We show that (a) two-color-laser driven harmonic generation is useful to detect symmetries in quantum magnets and (b) the photocurrent in graphene can be controlled by tuning the laser intensity, ellipticity, and phase.

Two-color lasers, namely, electromagnetic waves consisting of two laser beams with different frequencies, have been studied since the end of the last century [1]. However, its application to material science has been less developed. In recent years, we have predicted novel optical responses that are realized by applying two-color laser to materials. In this conference, we would like to report the following two results (I) and (II) in our recent studies.

(I) Control of photocurrent and high harmonic generation (HHG) in graphene by two-color laser [2]: We theoretically consider the control of two-color-laser driven HHG spectra in graphene. The HHG stands for the laser-driven phenomenon that when a laser pulse with frequency ω is applied to gases or materials, a mixed radiation pulse including multiple lasers with frequencies $n\omega$ $(n = 0, 1, 2, 3, ,,)$ is generated through the nonlinear light-matter interaction. The 0^{th} order harmonic corresponds to the photocurrent (photovoltaic effect). In electron systems in solids, it is known that even-order harmonics are all forbidden if the system is inversion symmetric. Using the quantum master (GKSL) equation approach that takes the inevitable dissipation effect into account, we numerically calculate the two-color-laser driven HHG spectra of inversion-symmetric graphene. We find that the nth order HHGs are drastically changed by tuning frequencies and ellipticities of the laser (as shown

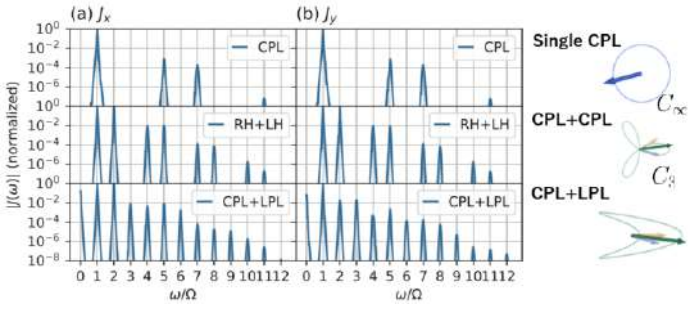

Fig. 1: Two-color-laser driven HHG spectra of graphene; HHG intensity vs radiation-wave frequency. Left and right panels, (a) and (b), respectively correspond to the HHG by the x and y components of current. First, second and third lines are respectively the results of single circularly polarized laser (CPL), two CPLs with different frequencies and combination of a CPL and a linearly polarized laser (LPL). The closed curves denote trajectories of three kinds of laser fields.

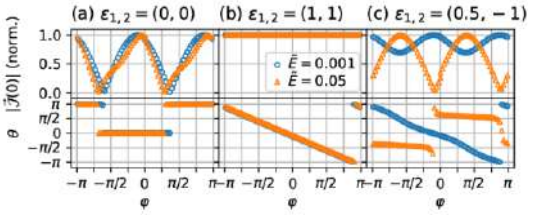

Fig. 2: Relative phase $\varphi = \phi_2 - \phi_1$ dependence of the photocurrent driven by tow-color laser. ϕ_1 and ϕ_2 are respectively the initial phases of first and second beam in the two-color laser. Blue and orange mean the results of weak and strong lasers, respectively. Panels (a), (b) and (c) are the results with different ellipticities of two-color lasers. The first line shows the photocurrent intensity, and the second line is its direction (angle θ).

in Fig. 1) and such features of the HHG spectra can be captured by the dynamical symmetry argument. Moreover, the photocurrent (0^{th} order harmonics) is shown to be controlled by varying the intensity, ellipticities, and relativistic phase of two beams in the two-color laser (see Fig. 2). Remarkably, any single-color laser cannot create photocurrent as graphene is inversion symmetric, while two-color laser enables us to create a finite photocurrent depending on the shape of two-color laser wave. We will report some important results of these two-color laser driven responses in graphene.

(II) Detection of symmetries or symmetry breakings in magnets with two-color laser [3]: Laser is useful to generate new optical phenomena, whereas observing laser-driven optical responses in materials is also efficient to detect new information about them. We theoretically argue what information can be detected from the two-color-laser driven HHG spectra in the Shastry-Sutherland (SS) magnet. This model is a typical two-dimensional (2D) frustrated spin model consisting of orthogonally coupled spin-dimers as shown in Fig. 3. The ground state is in the dimer-singlet phase, where spin-singlet pairs reside on all the strong bonds. As a result, the ground state has no magnetization, and it possesses unusual elementary excitations; spin-1 triply degenerate magnetic modes called triplons and two-triplon bound states (triplon molecules). The SS model with small perturbations can describe the magnetism of the quasi-2D magnet $SrCu_2(BO_3)_2$, which has been actively studied. In frustrated magnets including SS models, disordered or complex equilibrium states often appear, and it is generally difficult to experimentally observe characteristics of such featureless many-spin states. Moreover, if we slightly perturb such a disordered state by changing external parameters (temperature, magnetic field, electric field, pressure, etc.), a phase transition often occurs, i.e., frustrated systems are instable against perturbations and many ordered states are competing each other. Therefore, it is important to propose different methods of measuring various physical quantities to understand such less visible or unstable states. We compute the HHG spectra of the SS model by using an unbiased numerical diagonalization method for finite-size SS models. From the numerical result, we find that the existence or absence of even-order harmonics (i.e., selection rule) strongly depends on the trajectory of the applied two-color laser (see Fig. 4), and this selection rule can be explained by the dynamical symmetry argument. This clearly indicates that one can obtain information about symmetries or symmetry breakings in magnets from the observation of the two-color-laser driven HHG spectra. We will report this symmetry argument in detail.

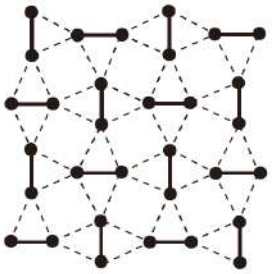

Fig. 3: Crystal structure of the SS model. Black and dotted lines respectively denote strong and weak antiferromagnetic exchange interactions. Spin singlet pair resides on the strong bond.

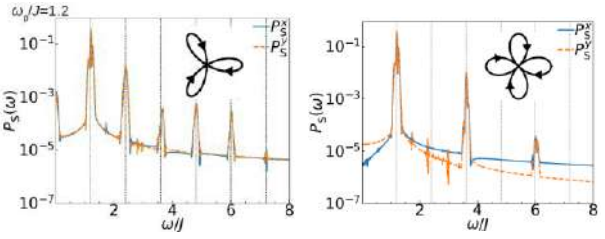

Fig. 4: HHG spectra of the SS model under the applications of three- and four-leaves shaped two-color lasers. Polarization intensity vs frequency.

UV-Plasmonics for Surface-Enhanced Spectroscopies

B. M. Reinhard[1,*]

[1]Department of Chemistry and The Photonics Center, Boston University, Boston, Massachusetts, United States

[*]corresponding author: bmr@bu.edu

Abstract: Aluminum (Al) nanostructures provide tunable plasmon resonances in the UV, which makes Al nanostructures interesting antennas for applications in surface-enhanced chiroptical spectroscopies. In this presentation scalable fabrication strategies for Al nanoparticles are investigated and the wavelength-dependent circular dichroism signal of Al nanostructures embedded in a chiral molecular film is examined.

Al nanostructures provide tunable plasmon resonances in the ultraviolet (UV) where the absorption bands of most biomolecules lie. This energetic overlap makes Al nanostructures interesting antennas for surface-enhanced chiroptical spectroscopies. In this presentation, we will investigate the circular dichroism (CD) signal of different Al nanoantenna geometries embedded in a chiral molecular film and compare with Ag nanoantennas of similar morphology that lack resonances in the UV. We place an emphasis on nanostructures accessible through scalable fabrication strategies. Hole mask colloidal lithography methods were applied to generate nanoparticles whose plasmon resonances could be tuned through variation of the morphology. It is demonstrated that the fabricated Al nanostructures provide distinct plasmon modes in the UV. The fabrication of metal nanoparticles using polystyrene nanoparticles of different diameters as mask is discussed and the fabricated nanoparticles are characterized by optical spectroscopy and scanning electron microscopy (SEM).

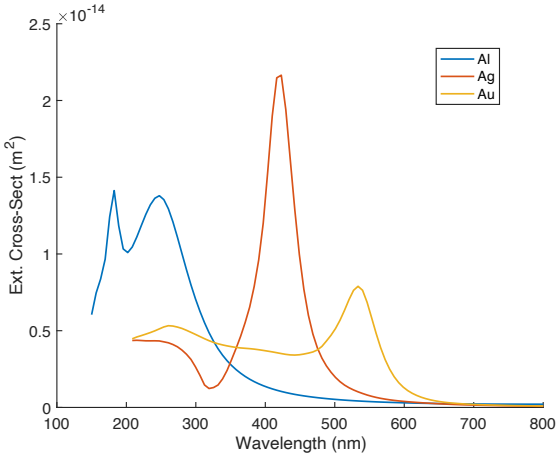

Figure 1: Simulated extinction cross-sections for 50 nm diameter Al, Ag, Au nanospheres in an ambient refractive index of $n_r = 1.333$.

Chiral test analytes with molecular absorption bands in the UV were spincoated on optimized Al nanoparticles and Ag nanoparticle “controls”, and CD spectra were recorded. Collecting CD spectra for the same analyte with achiral Al and Ag nanoparticle substrates facilitated data acquisition in the presence and absence of UV plasmon resonances. The wavelength-dependent CD signal under both conditions is examined and analyzed with a particular focus on the role of the nanoparticles under both conditions.

A second group of UV-resonant substrates to be discussed is that of nanoholes in an Al film generated by scalable bead lithography methods. The spectral properties of the nanoholes are characterized through combination of experimental spectroscopy and electromagnetic simulations. The performance of the substrates is evaluated by characterizing the limit of detection of the CD signal for selected probe molecules.

The spectral properties and performance of nanoparticle and nanohole substrate are compared, and a general

framework for the design of UV-resonant nanoparticles for surface-enhanced spectroscopies in a wavelength range not accessible with conventional Au and Ag plasmonic antennas is developed and presented.

Helicity-dependent optical control of the magnetization emerging from the Zeeman energy

A. Capua[1]

[1]The Hebrew University of Jerusalem, Israel

[*]corresponding author: amir.capua@mail.huji.ac.il

Abstract: Typically, the magnetic component of the optical radiation is neglected when considering light-matter interactions. Here, we show that by simply accounting for the Zeeman energy of the magnetic component of the EM radiation, an optically induced torque emerges, influencing the magnetization state.

The ferromagnetic resonance (FMR) experiment is pivotal for developing Spintronics technology. It occurs on Gigahertz timescales due the relatively slow relaxation time of the spins in ferromagnets. In contrast, optical fields oscillate much faster, at $\sim 400-800$ THz. Therefore, it seems unlikely that such fast-oscillating fields may interact with magnetic moments. However, by combining principles from quantum optics, we have recently [1] realized that the equations governing the FMR experiment are even relevant for magnetic fields that oscillate much faster, at optical frequencies. Namely, the interaction between optical beams and the magnetization is made possible merely by considering the optical magnetic field and its interaction with the magnetization which is determined by the Zeeman energy. We find that the strength of the interaction can be expressed by an elementary efficiency parameter $\eta=\alpha\gamma H/f_{opt}$, where H is the amplitude of the optical magnetic field, α is the dissipation rate of spin angular momentum to the lattice, and f_{opt} and γ are the optical frequency and gyromagnetic ratio. Our results shed light on a variety of highly debated experimental observations on the interaction between optical fields and ferromagnets that have been reported in the last 25 years.

Abstract: We report observation of giant nonreciprocal phase shift (NRPS) and nonreciprocal loss (NRL) effects in magneto-optical(MO) zero-index metawaveguides (MZIMs). One order of magnitude enhancement of NRPS and NRL in MZIMs is observed at both microwave and optical frequencies, which agree well with both effective medium and photonic band theories.

Magneto-optical waveguides are widely used as nonreciprocal phase shifters for wireless communication, optical communication and sensing applications. Thanks to the weak gyromagnetic or gyroelectric property of magnetic materials, such devices are usually much larger compared to other components in the system. A general way to reduce the device footprint is to engineer the magnetic material with large off-diagonal component of its permittivity or permeability tensor by element doping or fabrication process improvement. However, the ratio of the off-diagonal component of μ to its diagonal part is smaller than 1 for microwave frequency. This number is even smaller down to 10^{-2} for optical frequencies. Another method to enhance the magneto-optical effect is to develop magnetic materials or metamaterials with near zero index. Giant magneto-optical Kerr effect(MOKE) and nonreciprocal absorption were observed in semiconductor materials such as indium tin oxide or InAs films at the epsilon near zero frequencies.[1,2] However, such materials are diamagnetic with weak MO effect. Recently, MZIMs emerge as a fascinating playground for the discovery of new MO phenomena. [3,4] However, it is unclear how the nonreciprocal effect is influenced in MZIMs.

In this paper, we report observation of large nonreciprocal phase shift (NRPS) and nonreciprocal loss (NRL) in MZIM metawaveguides. We studied a microwave ferrite phase shifter consisted of a square array of gyromagnetic yttrium iron garnet (YIG) pillars above an Al_2O_3 slab in a parallel-plate aluminum waveguide. (Fig. 1a-c) Under zero applied magnetic field, this metamaterial shows a Dirac-like cone dispersion at the center of the Brillouin zone (Fig. 1d), corresponding to an impedance-matched zero index at 7.45 GHz (Fig. 1e). Due to the gyromagnetic property of YIG, the metamaterial shows distinct band structures for forward and backward propagation of microwave (Figure. 1f). At 7.46 GHz to 7.48 GHz where $n_{eff} \rightarrow 0$, the magnetic field causes a distortion of the flat band, introducing a giant NRPS near the center of the Brillouin zone, as shown by $\Delta\beta$ in Figure 1f. Moreover, the magnetic field tilted and shifted the band between 7.48 GHz to 7.52 GHz, causing distinct bandgap sizes between the forward and backward propagation. A large NRL, that is the imaginary part of $\Delta\beta$, is observed as indicated by the imaginary part of n_{eff} in Fig. 1g. Experimentally, we observed giant NRPS and NRL of this device by measuring the waveguide transmittance as shown in Fig. 1h and 1i. The results agree well with simulations. Analytical calculation of the wave propagation by approximating the device to a MO two-layer slab waveguide with near zero effective index showed good agreement with experiments, indicating

such devices can be also be accurately depicted by the effective medium theory.

Attosecond magnetism: ultrafast control of magnetic phases and novel probes

O. Neufeld[1,*]

[1]Techinon Israel Institute of Technology, Faculty of Chemistry, Haifa, Israel.
[*]corresponding author: ofern@technion.ac.il

Abstract: Magnetism can be coherently controlled by light *via* mechanisms that allow transfer of spin and orbital moments from electric fields to matter at varying timescales, down to femtoseconds. I will present our recent works towards controlling magnetism at even faster attosecond timescales, and developing novel ultrafast spectroscopies for detecting it.

It is commonly established that by irradiating intense laser pulses onto magnets, their magnetization can be manipulated on ultrafast timescales, e.g. causing magnetization flip or demagnetization[1,2]. I will discuss our recent predictions that have established a highly nonlinear optical regime where attosecond magnetization dynamics can occur *via* strong-field driving[3]. Here the solid can be transformed into a magnet within several femtoseconds due to intense circularly-polarized laser driving (see Fig. 1(a)), which is enabled by ultrafast and coherent spin flip processes that build-up from cycle-to-cycle. By driving the system with linearly-polarized lasers that are polarized along non-high-symmetry axes, an oscillating attosecond magnetic response can be generated, forming the prediction for the fastest magnetization dynamics to date (Fig. 1(b)).

In principle, such generation of either persistent magnetic states (i.e. which are long-lived up to several tens to hundreds of femtoseconds), or transient magnetic states that only exist while the laser field is on, both relies on an inherent time-reversal symmetry (TRS) breaking by the laser. This is typically enabled by circularly-polarized light that also carries angular momentum, or in the case of transient magnetism driven by linearly-polarized driving, by a time-local breaking of symmetry that only arises for individual laser half-cycles. I will present our recent work that establishes a new magneto-optical effect by which linearly-polarized driving can generate a persistent magnetic state, which is enabled by few-cycle pulsed driving. In that case, TRS can be broken intrinsically by the carrier envelope phase (CEP)-stable short laser pulse, depending on the value of the CEP (see Fig. 1(c))[4]. This marks the first scheme that allows to coherently turn-on, as well as off, persistent magnetic states, with linearly-polarized lasers.

Besides using light to control magnetism, I will also discuss our recent efforts to measure such extremely fast phenomena. Femtosecond magnetism has been previously measured by circular dichroism (CD) in attosecond transient absorption spectroscopy (ATAS)[2]. However, this approach is very challenging to implement in the attosecond domain, and also leads to XUV light that better probes magnetism in higher energies, far from the Fermi surface. Our recent work proposed to use strong-field induced helical ring currents in order to gate generation of Tesla-scale attosecond magnetic pulses (see Fig. 1(d))[5]. This is the first scheme that can generate attosecond magnetic pulses, which should be usable in down-the-line experiments of ultrafast magnetization. It also permits a tunable control over synthesizing tailored isolated magnetic pulses in the atto- to- femtosecond duration window.

Lastly, I will discuss our recent approach for detecting magnetization based on symmetry-breaking spectroscopy[6] of ultrafast photocurrent measurements[7,8]. By engineering tailored driving fields that break, or exhibit, TRS, and using them to drive photogalvanic currents, we can sense magnetism – photocurrents can only be generated if the sample breaks TRS, which generates a background free signal. We demonstrate this scheme with *ab-initio* simulations and show that it also applies to other phases with broken TRS such as Chern insulators. This is the first scheme capable of probing magnetism in the absence of magnetic or circularly-polarized electric fields.

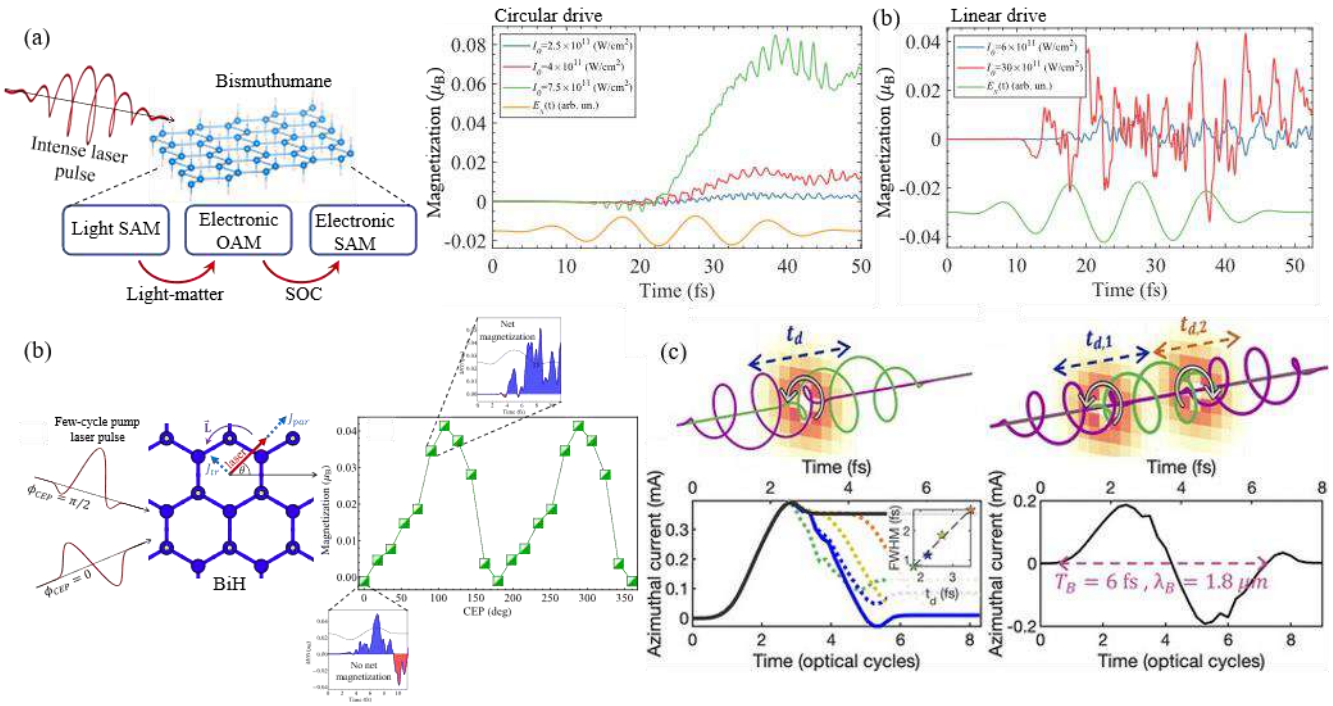

Figure 1. (a) Illustration of ultrafast turn-on of magnetization in monolayer Bismuth – circularly-polarized light transfers angular momentum to the electronic system, which subsequently induces spin-flips through spin-orbit coupling (SOC). The induced magnetic response takes several femtoseconds to build-up (right panel), and is highly-nonlinear and non-perturbative. (b) For linearly-polarized driving magnetism can only be induced transiently while the laser pulse is on (because the laser pulse overall respects TRS, but breaks it locally in time), which allows accessing pure attosecond magnetization dynamics. (c) Few-cycle linearly-polarized pulses can also break TRS if the CEP is properly chosen. Even though such pulses do not carry angular momentum, this is enough to induce a transient magnetic state within few femtoseconds. (d) Sets of counter-rotating circularly-polarized laser pulses irradiate an atomic gas, generating helical ring currents in the medium. By gating the current in time, attosecond magnetic pulses can be generated down to ~800 attosecond durations, and with potentially synthesizable properties such as wavelength and temporal envelope.

Extreme light manipulation: Hyperbolic Plasmon Polaritons and Subcycle Orbital Angular Momentum Control

A. Ambrosio[1]

[1]Istituto Italiano di Tecnologia, Via Rubattino 81, 20134 – Milano, Italy

[*]corresponding author: antonio.ambrosio@iit.it

Abstract: This research explores two extreme light manipulation phenomena: hyperbolic plasmon polaritons in van der Waals materials and ultrafast modulations with subcycle control of orbital angular momentum. By confining light beyond the diffraction limit and dynamically modulating its properties on femtosecond timescales, we enable new frontiers in nanophotonics.

Extreme light confinement and ultrafast modulation, this research investigates hyperbolic plasmon polaritons in natural van der Waals materials and femtosecond-scale control of structured light. Hyperbolic plasmon polaritons allow for unparalleled spatial confinement of light, breaking the diffraction limit by supporting highly anisotropic wave propagation in the visible and near-infrared range; Novel approaches to orbital angular momentum (OAM) modulation enable subcycle temporal control of light, dynamically shaping its properties at femtosecond speeds. We achieve unprecedented control over light–matter interactions, where tightly confined optical fields can be rapidly modulated to influence ultrafast processes in nanostructures. This dual approach has far-reaching implications for applications such as ultrafast optical switching, next-generation quantum photonics, and high-resolution imaging, unlocking new possibilities at the intersection of extreme spatial and temporal light manipulation.

Abstract: This study presents the fabrication of all-dielectric silicon-based twisted L-shape metamaterials using a two-step electron-beam glancing angle deposition approach. Systematic chiroptical characterization and optimization are performed through Mueller matrix generalized spectroscopic ellipsometry and finite element modeling, demonstrating tunable, broadband chirality response with potential applications in chiral-chemistry, quantum optics, and nanophotonics.

Introduction: Metamaterials with subwavelength-scale periodic structures exhibit unique material properties that are not found in nature, enabling a broad range of advanced functionalities [1-3]. Among these properties, chirality or handedness is particularly intriguing due to its relevance in various disciplines such as physics, chemistry, and biology. Chirality refers to systems where the structure and its mirror image (enantiomer) cannot be superimposed. The optical manifestation of chirality, known as circular dichroism (CD), is the differential absorbance (A) of left (L)- and right(R)-circularly polarized (CP) light and is given as $CD = A_{LCP} - A_{RCP}$. The chiroptical response is quantified using Kuhn's dissymmetry factor (g-factor), given by $g\text{-factor} = 2CD/(A_{LCP} + A_{RCP})$ [1,2]. In this study, we present the fabrication, characterization, and optimization of all-dielectric silicon-based broken L-shape metamaterials using a two-step electron-beam glancing angle deposition (GLAD) approach.

Figure 1 Spectral evolution of g-factor as a function of distortion angle of second columnar segment in broken L-shape metamaterial design. (b) The schematic illustration of conceptual definition of chiral light-proposed metamaterial design interaction. Mueller matrix generalized spectroscopic ellipsometry based experimentally measured (c) circular dichroism (CD) and (d) linear dichroism (LD) as a function of full in plane rotation from 0^{o} to 36^{o} by 15^{o} steps.

During fabrication, the sample stage is rotated before the deposition of the second columnar segment (see the schematic representation in Fig. 1). Depending on the rotation direction, we theoretically verify and experimentally demonstrate both handedness of our proposed metamaterial design (see Fig 1 (a)). By utilizing Mueller matrix generalized spectroscopic ellipsometry, we analyze the chiroptical response of these metamaterials, extracting circular dichroism as well as other optical properties such as linear dichroism, circular birefringence, and linear birefringence (see Fig. 1(c)). We further explore the optical properties of the metamaterials through finite element simulations which employs the structural and optical properties extracted from the anisotropic Bruggeman effective medium model approach-based Mueller matrix generalized spectroscopic ellipsometry data analysis. This enables a more robust understanding of the chiral near- and far- field optical response of proposed metamaterial design. Additionally, we will also discuss that when the structure is dispersed in a liquid environment i.e., the random orientation of the metamaterials eliminates other optical anisotropies, revealing the average chiral response of individual structure design.

In conclusion, this work presents a straightforward yet effective approach to fabricating tunable, broadband chiral metamaterials, offering control over their chiroptical response. These metamaterials have promising applications in areas such as chiral chemistry, quantum optics, and on-chip nanophotonics, with potential for further development in advanced optical devices.

Spin-Charge Dynamics of Topological Magnetic Textures in Kondo-Lattice Magnets

Masahito Mochizuki
Department of Applied Physics, Waseda University, Japan
masa_mochizuki@waseda.jp (corresponding author)

Abstract

Kondo-lattice models describe spin-charge coupled magnets with localized spins and itinerant electrons coupled via exchange interactions. Spin-charge dynamics of topological magnetism in these models are investigated using large-scale spin-dynamics simulations. We will discuss magnetic topology switching and nontrivial spin-wave excitations in skyrmion crystals and hedgehog lattices under microwave irradiation.

The Hamiltonian of the Kondo-lattice model is given by [see also Fig. 1(a)],

$$\mathcal{H}_{\rm KLM} = \sum_{i,j,\sigma} t_{ij} \hat{c}^{\dagger}_{i\sigma} \hat{c}_{j\sigma} - \frac{J_{\rm K}}{2} \sum_{i,\sigma,\sigma'} \hat{c}^{\dagger}_{i\sigma} \boldsymbol{\sigma}_{\sigma\sigma'} \hat{c}_{i\sigma'} \cdot \boldsymbol{S}_i - \sum_i \left[\boldsymbol{H}_{\rm ext} + \boldsymbol{H}(t) \right] \cdot \boldsymbol{S}_i \tag{1}$$

The first term describes kinetic energies of itinerant electrons. The second term describes the Kondo exchange coupling between the itinerant electron spins and the localized classical spins $\boldsymbol{S}_i$ ($|\boldsymbol{S}_i| = 1$). The last term describes the Zeeman coupling where $\boldsymbol{H}_{\rm ext} = (0, 0, H_z)$ is a static magnetic field, and $\boldsymbol{H}(t)$ is a time-dependent magnetic field.

Time evolutions of the localized spins are numerically simulated using the Landau-Lifshitz-Gilbert (LLG) equation,

$$\frac{d\boldsymbol{S}_i}{dt} = -\boldsymbol{S}_i \times \boldsymbol{H}_i^{\rm eff} + \frac{\alpha_{\rm G}}{S} \boldsymbol{S}_i \times \frac{d\boldsymbol{S}_i}{dt}. \tag{2}$$

The equation is composed of two contributions. The first term describes precession of localized spins around the effective local magnetic field $\boldsymbol{H}_i^{\rm eff}$. The second term phenomenologically describes a dissipation effect where $\alpha_{\rm G}$ is the dimensionless Gilbert-damping coefficient. The effective field $\boldsymbol{H}_i^{\rm eff}$ is calculated by,

$$\boldsymbol{H}_i^{\rm eff} = -\frac{\partial \Omega}{\partial \boldsymbol{S}_i} + \boldsymbol{H}_{\rm ext} + \boldsymbol{H}(t). \tag{3}$$

The thermodynamic potential Ω for $\mathcal{H}_{\rm KLM}$ is given by,

$$\Omega = \int \rho(\varepsilon, \{\boldsymbol{S}_i\})\ f(\varepsilon - \mu)\ d\varepsilon, \tag{4}$$

with

$$\rho(\varepsilon, \{\boldsymbol{S}_i\}) = \frac{1}{2N} \sum_{\nu=1}^{2N} \delta(\varepsilon - \varepsilon_\nu(\{\boldsymbol{S}_i\})), \qquad f(\varepsilon - \mu) = -\frac{1}{\beta} \ln \left[1 + e^{-\beta(\varepsilon - \mu)} \right], \tag{5}$$

where $\rho(\varepsilon, \{\boldsymbol{S}_i\})$ is the density of states of the itinerant electrons for a given set of the localized spins $\{\boldsymbol{S}_i\}$, and $f(\varepsilon - \mu)$ is the free energy density of the system. We use the kernel polynomial method based on the Chebyshev polynomial expansion to calculate Ω and the automatic differentiation technique to calculate its magnetization-derivative $\partial\Omega/\partial\boldsymbol{S}_i$ [?, ?]. We solve the LLG

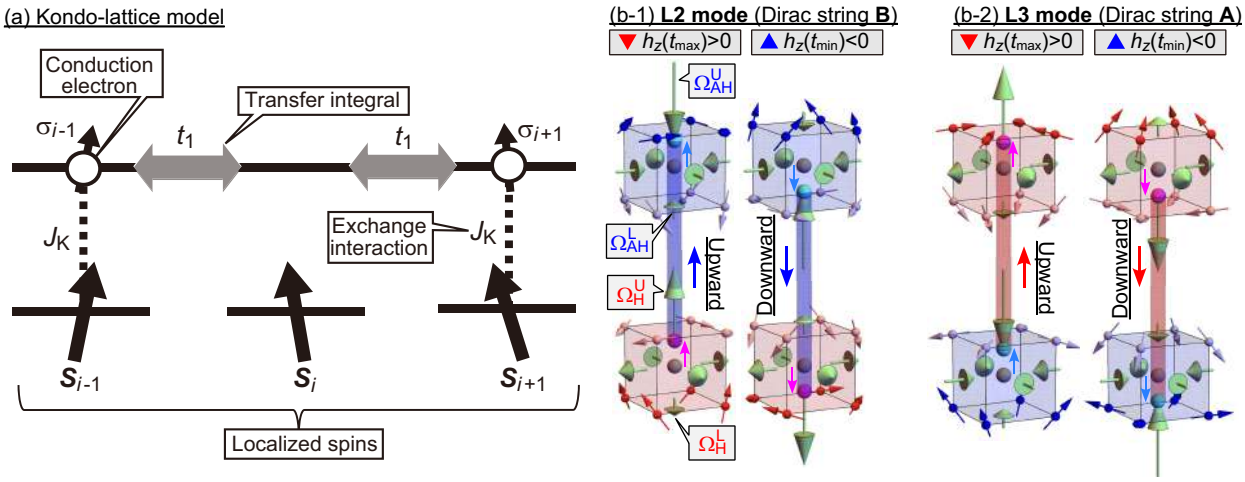

Figure 1: (a) Schematics of the Kondo-lattice model. Itinerant electrons and localized spins are coupled via the Kondo exchange coupling $J_{\rm K}$. The localized spins are not necessarily interacting directly, but indirect interactions mediated by the itinerant electrons exist, which realize long-range ordering of the localized spins. (b) Schematics of the translational oscillations of (b-1) the Dirac string B in the L2 mode and (b-2) the Dirac string A in the L3 mode.

equation using the fourth-order Runge-Kutta method to obtain the spatiotemporal profiles of the dynamics of localized spins.

In this paper, we review the following three topics associated with recent theoretical works studied using the above models and methods.

(1) Microwave-induced magnetic topology switching [1]: It is discovered that application of circularly polarized microwave magnetic field can switch the magnetic topology among three topological magnetic phases characterized by different topological numbers ($|N_{\rm sk}|$=0, 1, and 2) in a triangular Kondo-lattice model.

(2) Low-energy excitation modes and spin-charge segregation [2]: It is discovered that a zero-field skyrmion crystal phase in a triangular Kondo-lattice model has three linearly dispersive Goldstone modes associated with spin excitations and one quadratically dispersive pseudo-Goldstone mode associated with charge excitations. Surprisingly they turn out to be perfectly decoupled in contrast to our naive expectation of strong spin-charge coupling in the Kondo-lattice model.

(3) Spin-wave modes associated in the quadratic hedgehog lattices [3]: It is discovered that quadratic hedgehog lattice phases in the cubic Kondo-lattice model have collective excitation modes associated with translational oscillation of Dirac strings connecting a hedgehog and an antihedgehog [Figs. 1(b-1) and (b-2)]. One of the two modes turn out to vanish upon a field-induced topological phase transition where one of the two types of Dirac-string sublattices undergoes pair annihilations and disappears.

Abstract

We demonstrate the tunable excitation of spin waves using nanoscale a modulated optomagnet. The modulated optomagnet is a plasmonic nanoantenna coupled to a modulated continuous wave (CW) infrared laser source. We experimentally demonstrate the conversion of different sinusoidal microwave signals into monochromatic spin waves belonging to different allowed magnon bands in the GHz frequency regime.

Introduction

Optics has enabled efficient and compact sources of propagating magnons by use of femtosecond optical pulses[1, 2], based on the Inverse Faraday effect (IFE) produced with single or periodic light pulses[3, 4]. However, being diffraction limited, the resulting excitation spots have not allowed for ultracompact magnon emitters. Recently, subwavelength gratings have been successfully used to locally excite spin waves beyond the diffraction limit[5]. However, the tightly confined light spots were obtained through coherent scattering across a large array of subwavelength grooves, and the development of a truly nanometer-scale optical source of spin waves has not yet been presented.

Recent studies on IFE report that illumination with circularly polarized light turns the plasmonic nanoantenna into a nanoscale optomagnet i.e generates a static magnetic field around the disk [6–10]. Our approach is to use these optomagnets to generate spin-waves from a compact tunable nanosource. In this approach a microwave-modulated CW laser beam excites spin-waves trough optomagnet vie resonant IFE. The modulation can be fine tuned which makes optomagnet highly tunable source of spin waves. Here, we report the experimental demonstration of a nanometer-scale optical source of spin waves by coupling a microwave-modulated CW laser to a resonant plasmonic nanoantenna.

Results and discussion

We positioned a 50nm thick gold nanodisk on top of a transparent thin-film yttrium iron garnet (YIG) in a presence of an external static magnetic field ($\mu_0 H$) of 20mT (Fig. 1, (**a**) blue arrow). The diameter of the nanodisk is set to 130 nm to match its electromagnetic resonance with the frequency of the illuminating modulated infrared (IR) laser (λ=808nm). When illuminated with a circularly polarized CW IR laser, the nanodisk generates a static magnetic field around itself, known as the optomagnetic field (Fig. 1, (**a**) black arrows). The idea now is to illuminate

the nanodisk with a microwave-modulated CW laser source, thereby enabling the modulation of the optomagnetic field around the nanodisk as evidenced in [11, 12]. This way we create a microwave-modulated optomagnet on YIG via resonant IFE. The modulated optomagnetic field couples to the spin-waves in YIG (Fig. 1 (**a**) red arrows) which are detected by means of inelastic/Brillouin light scattering (BLS) (Fig. 1 (**a**) green arrows).

Fig. 1 (**b**) shows that when the modulation is removed spin-waves are not excited. Moreover, in Fig. 1 (**c**) one can see that the acquired BLS spectra show the enhancement of spin-wave signals at the frequencies corresponding exactly to the modulation frequencies of the IR CW laser: 3.6 GHz (red), 4.5 GHz (green), and 7.4 GHz (blue). The small peak at 6.2 GHz (indicated with a cross) did not depend on H and was attributed to a parasitic line of the green laser.

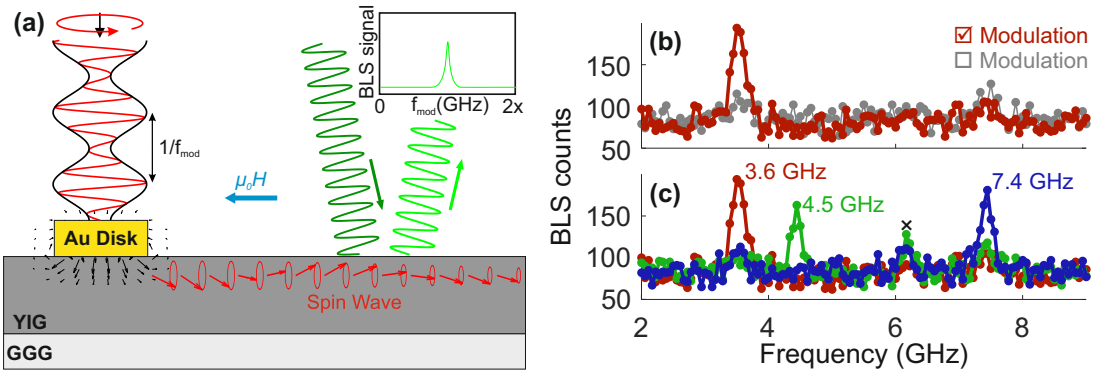

Figure 1: **Excitation of monochromatic spin waves by an optomagnetic nanoemitter.** (**a**) Experiment depiction. (**b**) BLS spectra of the probe beam with/without modulation (3.6 GHz) of the IR laser. (**c**) BLS spectra of the probe beam with different modulations of the IR laser that are indicated in the legend.

Our results show that plasmonic nanoantennas are nanoscale emitters capable of tunably transduce a microwave signal into short-wavelength spin-waves, while avoiding physical and technical constraints inherent to microwave antennas. Particularly, our approach offers a broad spin-wave-frequency bandwidth from MHz to sub-THz depending only on the light-modulation methodology. Spin waves, in turn, serve as a novel probe for investigating plasmon-induced optomagnetic effects a the nanoscale.

Abstract

An inverse design framework optimizes a chiral nanostructure for maximal helical dichroism (HD), achieving 107 % HD at 800 nm for orbital angular momentum beams. This approach significantly enhances differential absorption of the OAM beams with opposite signs of topological charges.

1 Introduction

Chiral light-matter interactions are essential for applications in sensing, imaging, and pharmaceutical development [1]. However, the weak chiroptical response in natural chiral molecules limits practical use. Recent advances have explored the use of light with orbital angular momentum (OAM) [3,4], characterized by a helical phase front and topological charge (l), to probe chirality more effectively. This approach introduces helical dichroism (HD), which measures the difference in absorbance between opposite-helicity OAM beams. This work uses inverse design to create a chiral structure that maximizes HD, achieving a record-breaking response.

The inverse design framework aims to optimize the geometry of a chiral structure to maximize HD, where HD quantifies the differential absorption of opposite OAM beams. Using adjoint-based topology optimization [2], we formulated this as a design problem to maximize HD through iterative adjustments of the material layout. The HD objective function is based on the difference in absorbance between two OAM beams with opposite charges ($\pm l$). The chiral structure is parameterized so that its shape or material distribution can be adjusted during optimization. We used adjoint simulations to compute the gradient of the HD with respect to design parameters, guiding the gradual evolution of the design parameters toward maximizing the differential absorbance between opposite OAM helicities. The design is iterated until the HD reaches a maximum, at which point the geometry is optimized for the largest possible chiroptical effect. This method allows for non-intuitive, complex designs that significantly enhance the HD response, surpassing conventional designs based on heuristic or spiral geometries.

The optimized structure achieves a giant HD of 107% for OAM beams with $l = \pm 3$ at 800 nm. This represents a significant improvement over previous studies, where HD rarely exceeded 20%. The optimized chiral structure exhibits a strong dichroic effect, with a 107% HD response at 800 nm for OAM beams with $l = \pm 3$, far surpassing conventional designs. The structure absorbs the one-handedness of the light more strongly than the opposite, producing a marked difference in reflectance between the two OAM helicities. The HD achieved in our design is an order of magnitude greater than the best previously reported results. The inverse design approach is flexible, allowing for modifications such as different wavelengths or topological

charges (l), making it suitable for various applications. The physical mechanism behind the giant HD response lies in the geometry of the chiral structure, which interacts differently with OAM beams depending on their handedness. The design selectively enhances absorption for one handedness while minimizing it for the other, leading to a large difference in reflectance. This demonstrates the potential for custom-tailored chiroptical responses using inverse design.

We demonstrated that inverse design can be used to create a chiral nanostructure with a giant HD response of 107%, significantly larger than previously reported values. This achievement marks an important step in the development of high-performance chiroptical devices, opening new possibilities for chiral sensing, advanced spectroscopic techniques, and other applications where chirality plays a crucial role.

By combining OAM light with inverse-designed structures, we were able to enhance chiroptical effects to a degree previously unachievable. This work not only advances the field of chiral photonics but also illustrates the power of computational design in unlocking new optical phenomena. Future work may explore extending this framework to 3D structures or broader spectral ranges, further enhancing the versatility and application of such devices.

Magnonic ϕ Josephson junctions and synchronized precession

Kouki Nakata[1], Ji Zou[2], Jelena Klinovaja[2], and Daniel Loss[2]

Abstract

We uncover theoretically that a surprisingly rich dynamics can emerge in magnetic junctions due to intrinsic nonlocal damping, using analytical and numerical methods. In particular, under microwave pumping, we show that coherent spin precession in the right and left insulating ferromagnet of the junction becomes synchronized by nonlocal damping.

1 Introduction

Recently, non-Hermitian physics has been attracting growing interest from both fundamental science and applications such as energy-efficient devices. One of its main themes is to engineer dissipation and to explore the resulting functionality. Since magnons are intrinsically damped in magnetic systems, the goal of non-Hermitian physics aligns well with magnonics, which aims at efficient transmission and processing of information for computing and communication technologies using magnons as its carrier in units of the Bohr magneton μ_B. To this end, establishing methods for the control and manipulation of magnon transport subjected to dissipation is crucial. In magnonics, the effect of dissipation due to local (Gilbert) damping on magnon transport, such as the magnonic analog of the Josephson effect, has been explored, where the macroscopic coherent magnon state, the key ingredient for the magnonic Josephson effect, realizes an oscillating behavior of magnon transport. However, the effect of non-local damping on the magnonic Josephson effect and the resulting functionality remain missing, despite that non-local damping is inevitable and has been playing a central role in non- Hermitian magnonics.

2 Results

We find that the inherent non-local damping leads to rich dynamics, and, interestingly, can be utilized to realize a magnonic analog of the φ Josephson junction [1]. Under microwave pumping, coherent spin precession in each insulating ferromagnet (FM) of the magnetic junction (see Fig. 1) is synchronized by non-local damping as time advances and gives rise of a magnonic φ Josephson junction, where φ stands for the stationary value of the relative precession phase of the left and right FMs. Interestingly, we find that φ decreases monotonically from π to $\pi/2$ as the magnon-magnon interaction, arising from spin anisotropies across the junction, increases. Applying microwaves to each FM continuously, the junction reaches the nonequilibrium steady state where the loss of magnons due to dissipation is precisely balanced by the injection of magnons. Hence, spins in each FM continue to precess coherently, and the synchronized precession of the left and the right magnetization remains stable even at room temperature. Finally, we show that the magnetic junction exhibits rectification and acts as a diode for the magnon current.

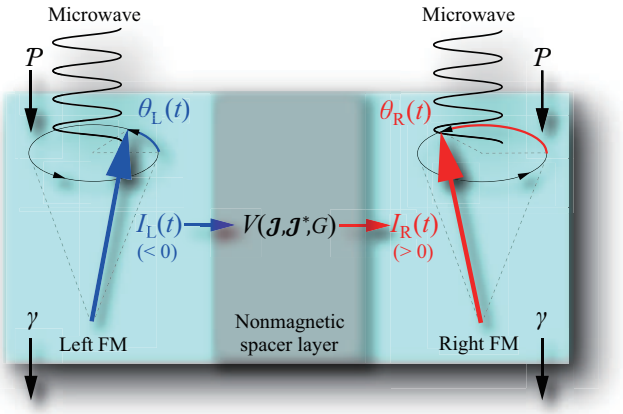

Figure 1: Magnonic φ Josephson junction, formed by a ferromagnetic bilayer coupled by a non-magnetic spacer. Magnons are subjected to local damping at rate $\gamma > 0$. The spacer layer-mediated interaction V between the two FMs consists of coherent coupling ($\mathcal{J}$) and non-local damping (G). Under microwave pumping, the spatially uniform mode of magnons is injected into each FM at rate $\mathcal{P}$, generating coherent spin precessions. The loss of magnons due to dissipation is exactly balanced by the injection of magnons. In the steady state, the spin precessions in each FM get synchronized due to non-local damping and a relative precession angle emerges $\varphi = \lim_{t\to\infty}[\theta_{\rm R}(t) \in \theta_{\rm L}(t)]$ that depends on the magnon-magnon interaction. The associated magnon currents $I_{\rm L/R}$ get rectified when $G = 0$.

Classifying Fragile Topology Using Matrix Homotopy

A. Cerjan[1*]

[1]Center for Integrated Nanotechnologies, Sandia National Laboratories, Albuquerque, New Mexico 87185, USA
[*]corresponding author: awcerja@sandia.gov

Abstract: We develop a Z_2 energy-resolved topological marker for classifying fragile phases using a system's position-space description, enabling the direct classification of finite, disordered, and aperiodic materials, and illustrate this marker's application in both material and photonic crystal systems.

The moiré flat bands in twisted materials have attracted considerable attention not only because of the emergence of correlated phases but also due to their ability to manifest nontrivial topology. Specifically, they can exhibit a new class of topology that can be nullified by the addition of trivial bands, termed fragile topology, which has required an expansion of existing classification schemes. Here, we develop a Z_2 energy-resolved topological marker for classifying fragile phases using a system's position-space description, enabling the direct classification of finite, disordered, and aperiodic materials. Specifically, by translating the physical symmetries protecting the system's fragile topological phase into matrix symmetries of the system's Hamiltonian and position operators, we are to use results from matrix homotopy to construct our topological marker while simultaneously yielding a quantitative measure of topological robustness. We demonstrate our framework's effectiveness using a C_2T-symmetric twisted bilayer graphene model and photonic crystal as a continuum example. Our findings reveal that fragile topology can persist under strong disorder and in heterostructures lacking a bulk spectral gap. Moreover, we find an example of disorder-induced re-entrant topology. Overall, the proposed scheme serves as an effective tool for elucidating aspects of fragile topology, offering guidance for potential applications across a variety of experimental platforms from topological photonics to correlated phases in materials.

Electromagnetic Helicity in Twisted Cavity Resonators

J. Bourhill[1*], E. C. Paterson[1], M. Goryachev[1], and M. E. Tobar[1]
[1]The University of Western Australia, Australia
jeremy.bourhill@uwa.edu.au (corresponding author)

Abstract

Twisting the conducting boundary conditions of an electromagnetic cavity with an equilateral triangle cross-section generates eigenmodes with electromagnetic helicity – a result of the coupling of previously degenerate TE and TM modes. This can be interpreted as an emergence of magnetoelectricity, which produces a confirmable shift in resonant mode frequency.

The unique light-matter interactions exhibited by helical radiation have garnered significant interest across various fields, including material science, nanophotonics, spectroscopy, and quantum information processing. These interactions offer numerous applications, from probing molecular chirality to advancing optical communication technologies and sensitivity to dark matter candidates [1]. Electromagnetic helicity typically only occurs in surface states, at optical frequencies, or due to complex meta-structures.

We present evidence of resonant electromagnetic modes with non-zero helicity produced in vacuo. We investigate a cavity with an equilateral triangular cross-section and electrically conducting boundary conditions at the end faces. The mirror symmetry of this resonator can be broken by introducing an arbitrary twist angle around the central axis of the cavity, resulting in a chiral geometry.

Electromagnetic helicity is intrinsically linked to the dual transformation of the electromagnetic state, effectively rotating the electric and magnetic properties of the medium. This results in the effective mixing of electric and magnetic fields and so electromagnetic helicity will necessarily produce a magnetoelectric coupling. Electromagnetic helicity can be quantified by the following normalised parameter:

$$h_p(\vec{r}) = 2\mathrm{Im}\left[\vec{\mathbf{e}}(\vec{r})\cdot\vec{\mathbf{h}}^*(\vec{r})\right] = \frac{2\mathrm{Im}\left[\vec{\mathbf{E}}_p(\vec{r})\cdot\vec{\mathbf{H}}_p^*(\vec{r})\right]}{\mathcal{E}\mathcal{H}}, \tag{1}$$

where $\mathcal{E}$ and $\mathcal{H}$ are real constants, $\vec{\mathbf{E}}_p(\vec{r}) = \mathcal{E}\vec{\mathbf{e}}(\vec{r})$ and $\vec{\mathbf{H}}_p(\vec{r}) = \mathcal{H}\vec{\mathbf{h}}(\vec{r})$ are the time-dependent electric and magnetic vector fields of some mode p, respectively, and $\vec{\mathbf{e}}(\vec{r})$ and $\vec{\mathbf{h}}(\vec{r})$ are the normalised position dependent eigenvectors such that $\int \vec{\mathbf{e}}(\vec{r})^*\cdot\vec{\mathbf{e}}(\vec{r})dV = \int \vec{\mathbf{h}}(\vec{r})^*\cdot\vec{\mathbf{h}}(\vec{r})dV = 1$. The total helicity for a given mode, $\mathscr{H}_p$ can then be written as the integral of (1) over the cavity volume:

$$\mathscr{H}_p = \int h_p dV. \tag{2}$$

It is observed that the frequency of certain resonant modes in the cavities of interest can be shifted as the boundary conditions are twisted. An eigenmode analysis conducted using finite element modelling (FEM) software reveals that by breaking the mirror symmetry, near degenerate transverse electric (TE) and transverse magnetic (TM) modes are coupled together producing to a non-zero $\mathscr{H}_p$. This effect is detailed in Fig. 1, where the various field components are plotted for the $\phi = 0$ case and the $\phi = 2\pi$ case. We observe a new orthogonality basis generated in the twisted case, appearing as either in-phase mixing of the form TM_{11p}+$\mathrm{TE}_{11(p+1)}$ (labelled ψ^+_{p+1})

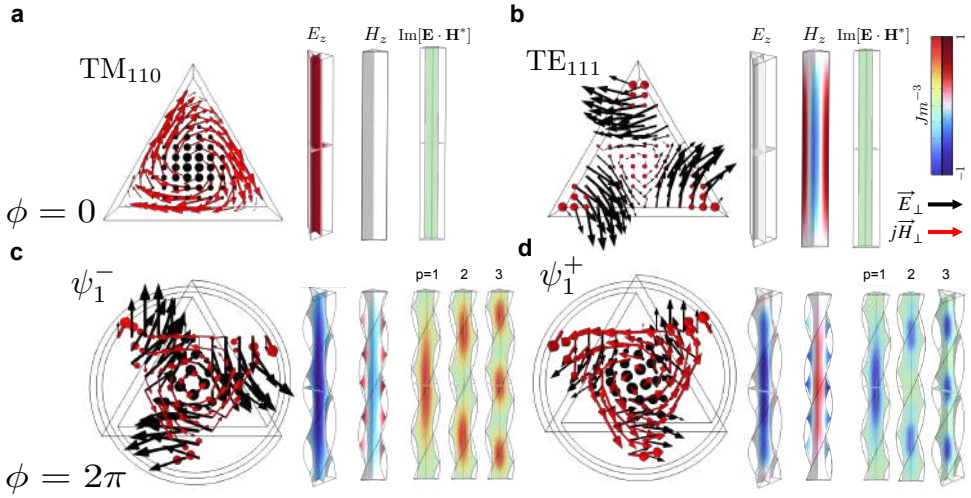

Figure 1: The perpendicular $\vec{E}_\perp$ (black) and imaginary $\vec{H}_\perp$ (red) fields plotted in the cross-section and the normalised densities of the axial fields E_z, H_z & $\mathrm{Im}\,[\mathbf{E}\cdot\mathbf{H}^*]$ for the (a) TM_{110} mode, (b) TE_{111} mode, and the twisted ($\phi = 2\pi$) (c) ψ^- mode, and (d) ψ^+ mode.

or out-of-phase mixing of the form TM_{11p}−$\mathrm{TE}_{11(p+1)}$ (ψ^-_{p+1}). The mixing of previously orthogonal mode solutions can only be explained by a magnetoelectric coupling emerging, resulting in normal mode splitting. Indeed, evaluating the imaginary component of the $\vec{\mathbf{E}}\cdot\vec{\mathbf{H}}$ product in the twisted case reveals the existence of non-zero $\mathscr{H}_p$ which represents the new basis in which mode numbers (such as p) can be counted. From perturbation theory [2], it can be shown that there is a fundamental relationship between $\mathscr{H}_p$ and a resonant mode's frequency shift, $\delta\omega$, given by:

$$\left(\frac{\delta\omega}{\omega_p}\right)_{\kappa\ll 1} = \frac{\delta\kappa\mathscr{H}_p}{2\mu_r\epsilon_r}, \tag{3}$$

where ω_p is the unperturbed cavity frequency, μ_r and ϵ_r the media's relative permeability and permittivity, respectively, and κ is the so-called material "chirality parameter", which acts to mix $\vec{\mathbf{E}}$ and $\vec{\mathbf{H}}$ fields according to:

$$\begin{aligned}\vec{\mathbf{D}} &= \epsilon\vec{\mathbf{E}} - j\kappa\sqrt{\mu_0\epsilon_0}\vec{\mathbf{H}},\\ \vec{\mathbf{B}} &= \mu\vec{\mathbf{H}} + j\kappa\sqrt{\mu_0\epsilon_0}\vec{\mathbf{E}}.\end{aligned} \tag{4}$$

Whilst κ is typically considered a material parameter, it can be shown that there is an empirical equivalence to cavity twist angle ϕ and hence frequency shifts as a function of twist angle can be predicted from (3). Indeed, frequency spectral response measurements of 3D-printed cavities with $\phi = 0$ and $\phi = \pm 10\pi/9$ confirm the predicted frequency shifts from FEM and (3), indicating the generation of electromagnetic helicity in a hollow, free-space volume.

Electrical control of ultrastrong coupling of 2-dimensional electronic systems to single meta-atoms

Abstract: We demonstrate electrical control of ultrastrong light-matter coupling regime in high mobility III-V 2DEG and bilayer graphene at THz and sub-THz frequencies. The meta-atom surface is of the order of 10 μm^2 , allowing the THz (0.05-10 THz) study of exfoliated bilayer graphene devices and other 2D systems.

Strong light-matter coupling has been recently successfully explored in the GHz and THz range with on-chip platforms, where metallic resonators with small cavity volumes are combined with high electron density materials to exploit the collective enhancement of the coupling Ω. New and intriguing quantum optical phenomena have been predicted in the ultrastrong coupling regime, when the coupling strength Ω becomes comparable to the unperturbed frequency of the system ω [1][2]. The use of extremely small cavity volumes ($V/\lambda^3 \simeq 10^{-6}$), attainable with circuit-like resonators, has allowed the study of ultrastrong light-matter coupling at THz frequencies[3][4][5] While sub-wavelength localization of terahertz fields can be efficiently achieved using micro-structured metallic resonators, conventional approaches rely on metamaterials of repeating resonators placed atop the material of interest.[3] [6] This method is incompatible with exfoliated 2D materials, which are usually limited to in-plane dimensions of just a few microns, and with the study of few-electron systems requiring an active mode surface of a few micrometer squared.

We will discuss experimental results where a single strongly subwavelength resonator is coupled to single GaAs/AlGaAs 2 DEG and, in a second experiment, to a dual-gated Bernal stacked bilayer graphene.

In the first experiment, we use the Landau polariton platform that has been extensively exploited to investigate the physics of ultrastrong light-matter coupling both in optical and transport experiments [3][7]. We employ a system of immersion lenses [8](Fig.1(a)) to spectroscopically investigate the single resonator. The resonator features an electrical gate in order to modulate the electron density ρ_{2deg} and, as a consequence, the Rabi frequency Ω. In this case the tuning of the coupling strength happens through the tuning of the dipole that is proportional to the square root of the 2DEG filling factor $\nu = 2\pi\hbar\rho_{2deg}/eB$ [9]. In Fig.1(b) are visible transmission spectra taken for different values of the applied gate voltage. It is evident the closing of the polariton splitting and the progressive disappearance of the diamagnetic shift as the resonator is depleted from electrons and the upper branch at B=0 converges to the empty cavity value of 270 GHz (horizontal dashed line). The gate voltage allows the tuning of the normalized coupling ratio from $\Omega/\omega=0.5$ to $\Omega/\omega= 0.12$, so from ultrastrong coupling to strong coupling.

In the second experiment, we couple a Bernal stacked bilayer graphene (BLG) to a bow-tie antenna resonator (Fig. 1(c)). The presence of a dual gate system allows to independently tune the carrier density and the displacement field, with which we tune the BLG gap in the range 0-6 THz [10]. As visible in Fig.1(d), the measured THz transmission as a function of the displacement field reveals an anticrossing behavior, and the estimated coupling strength, defined by the ratio between the vacuum Rabi (Ω) and the cavity (ω) frequencies, is $\eta= \Omega/\omega \approx 0.43$, which places our system well into the ultrastrong coupling regime.

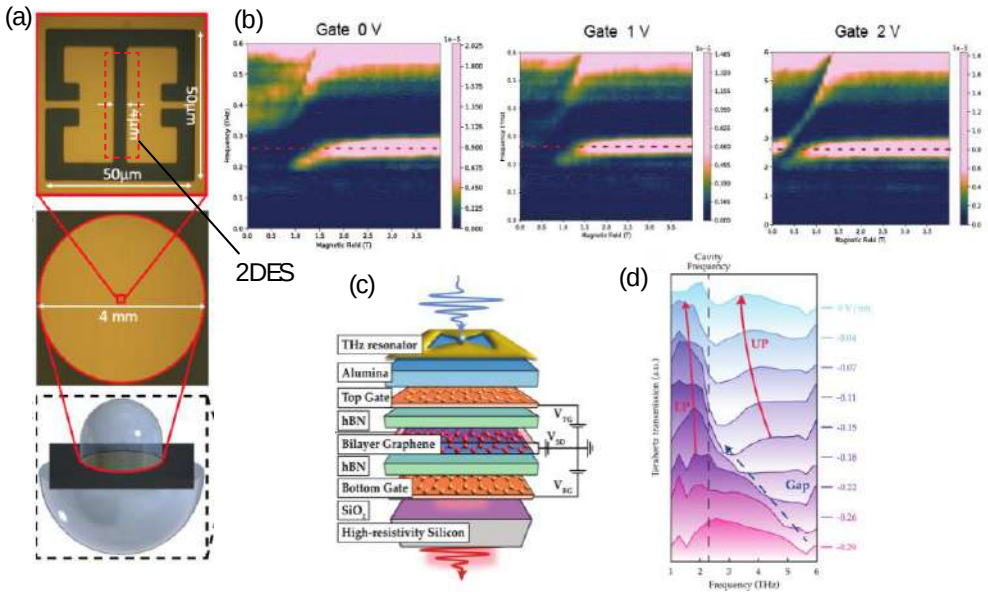

Figure 1. (a): schematic of the immersion lenses arrangement together with the single-meta atom sample. (b):Transmission spectra as a function of gate bias for an electrically-gated, single SRR coupled to a single quantum well. (c): Lateral view of the sample structure. The heterostructure consists of Bernal bilayer graphene, few-layer graphite gates and hbN dielectrics placed on a high-resistivity Si/SiO2 substrate. The heterostructures is insulated from the bow-tie resonator with alumina dielectric. (d): BLG transmission spectra atvarious displacement fields under zero doping (n = 0) measured at 5 K.. The cavity resonance frequency is indicated by a dashed line. A black dashed arrow points to the closing band gap edge, while redarrows highlight the lower and upper polariton branches.

Abstract:
We analyze a maximally chiral metasurface composed of van der Waals (vdW) material within the strong light-matter coupling regime. We demonstrate that, due to specific photonic eigenstates – chiral quasi-bound state in the continuum (quasi-BIC) uncoupled from light of specific circular polarization, chiral self-hybridized exciton-polaritons of certain handedness are formed.

Exciton-polaritons, as eigenstates of systems exhibiting strong light-matter interaction, inherit properties from both massless photons and massive excitons. This makes them promising candidates for novel applications based on polaritonic lasing [1], controlled electronic transport [2] and modified chemical kinetics [3]. Special attention is paid to chiral polaritons, which are crucial for chiral molecular sensing [4] and quantum materials engineering [5].

Metasurfaces with chiral photonic quasi-BICs [6], whose polarization and Q-factor depend on structural asymmetry, offer a convenient platform for creating chiral polaritons. Here we analyze a metasurface composed of dielectric rods of different heights (Fig. 1(a)) arranged to sustain a quasi-BIC uncoupled from normally incident light of right circular polarization (RCP) while resonantly interacting with left circular polarized (LCP) light (Fig. 1(b)). The rods are made of bulk vdW material WS_2, which has stable excitons at room temperature (Fig. 1(c)). As illustrated in Fig. 1(d), the hybridization of the chiral photonic quasi-BIC and achiral excitons results in the formation of two chiral polaritons, resonantly interacting only with LCP light (Fig. 1(e)). To demonstrate chiral polaritonic branches with corresponding Rabi splitting we introduce an in-plane scaling factor S and tune the quasi-BIC resonance wavelength. The resulting transmittance difference between RCP and LCP waves exhibits a characteristic anticrossing pattern around the exciton position at 629 nm (Fig. 1(f)).

To assess the polariton chirality, we perform a multipole decomposition of the coupling coefficients between the metasurface eigenstate displacement current $\mathbf{J}(\mathbf{r})$, which predominantly flows in the *xy*-plane ($J_z(\mathbf{r}) \approx 0$), and free-space plane waves with a wave number $k = \omega/c$ and circular polarizations along the unit vectors $\mathbf{e}_\pm = (\mathbf{e}_x \pm i\mathbf{e}_y)/\sqrt{2}$:

$$m_\pm \propto \int_V \mathbf{J}(\mathbf{r}) \cdot \mathbf{e}_\pm \, e^{i\mathbf{k}\cdot\mathbf{r}} dV \approx \int_V \mathbf{J}(\mathbf{r}) \cdot \mathbf{e}_\pm \, (1 + i\mathbf{k}\cdot\mathbf{r}) dV \approx -i\omega \left(\left[P_x \pm i\frac{2}{c} M_x \right] + i \left[\pm P_y + i\frac{2}{c} M_y \right] \right). \quad (1)$$

The electric and magnetic dipole moments components are given by $P_{x,y} = i/\omega \int_V J_{x,y}(\mathbf{r})\, dV$ and $M_{x,y} = \mp \int_V z J_{y,x}(\mathbf{r})\, dV/2$, respectively. The condition of maximum chirality $m_\pm = 0$ is satisfied when $\mathbf{M} = \pm ic\mathbf{P}/2$, which is analogous to the condition of an ideal chiral point emitter (with an extra factor of 2), where electric $\mathbf{P}$ and magnetic $\mathbf{M}$ dipoles are collinear with a $\pm\pi/2$ phase difference. Next, we numerically analyze the multipole composintion of hybrid eigenstates of metasurfaces with fixed scaling factors (capital letter marks in Fig.1(f)). The calculated dipole moments of polaritons, presented in Fig.1(g), closely match the condition of maximum chirality. To quantify this, we evaluate the dissymmetry factor *g* as the ratio of the rotational strength *R* [7] to the dipole strength *D*:

$$g = 4\frac{R}{D} = 4\frac{\mathrm{Im}(2\mathbf{M}\cdot c\mathbf{P})}{|2\mathbf{M}|^2 + |c\mathbf{P}|^2}. \quad (2)$$

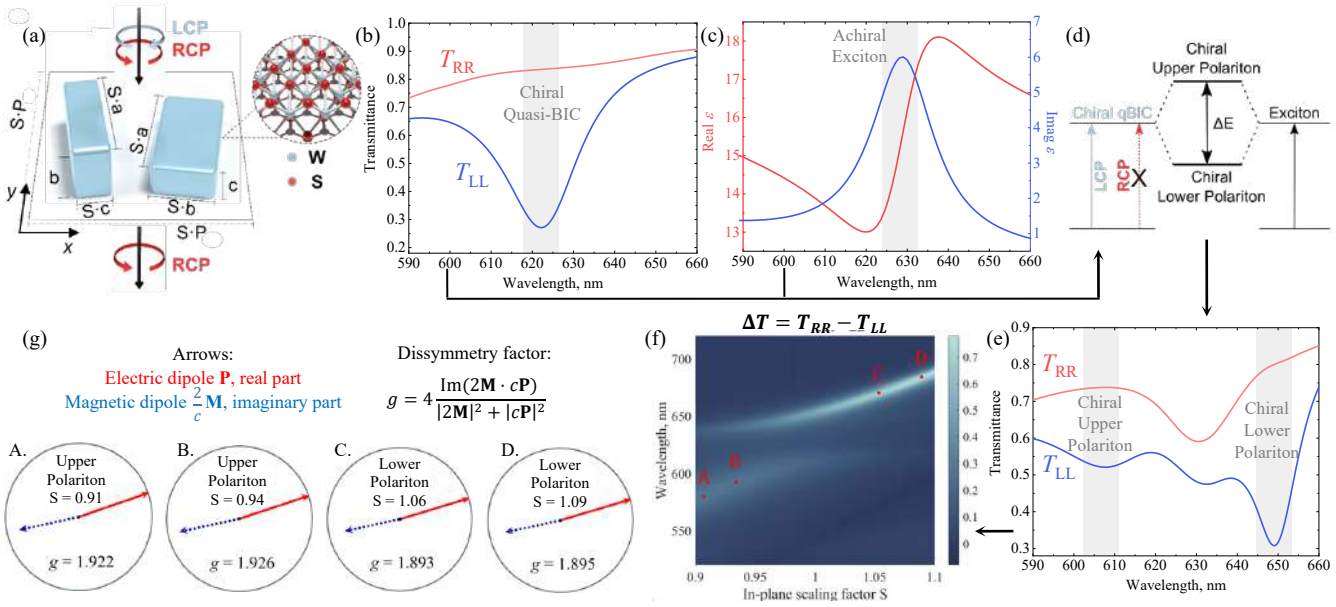

Figure 1. (a) Maximally chiral metasurface made of WS_2 rods with dimensions: a = 225 nm, b = 115 nm, c = 45 nm. The unit cell has a periodicity of P = 375 nm, each rod is rotated in-plane by 12°. (b) Transmittance spectra of the metasurface, showing the photonic chiral quasi-BIC in the absence of excitons. (c) Tabulated dispersion of bulk WS_2. (d) Simplified energy-level diagram of self-hybridization of an exciton and a quasi-BIC into a pair of chiral polaritons. (e) Transmittance spectra of the metasurface with self-hybridized chiral polaritons. (f) Transmittance difference $\Delta T = T_{RR} - T_{LL}$ of the metasurface for different in-plane scaling factors S. Capital letter marks indicate metasurfaces whose eigenstates are analyzed by the multipole decomposition in (g).

The calculated g values approach the theoretical limit of the dissymmetry factor $g = 2$, making our metasurface with polaritons a perspective platform for chiral linear and nonlinear polaritonics [8].

Fluctuation-Driven Phenomena in Chiral and Indefinite-Gain Systems

Daigo Oue[1,2] **Mário G. Silveirinha**[1*]

[1] Instituto Superior Técnico-University of Lisbon and Instituto de Telecomunicacações, Lisbon 1049-001, Portugal

Abstract: We explore fluctuation-induced effects in indefinite-gain systems, where gain and dissipation depend on the polarization or momentum of the wave. We examine their impact on optical forces, quantum friction, and energy flow in steady-state regimes. Additionally, we analyze how quantum fluctuations in such media modify a qubit's ground state, revealing new opportunities for nonreciprocal quantum engineering.

Over the past decade, there has been significant interest in nonreciprocal effects in quantum systems. Nonreciprocity can be achieved through various means, such as preparing the system in a chiral quantum state, utilizing nonlinearities, or using an external magnetic field. When a quantum system is prepared in a state that favors specific circularly polarized (chiral) optical transitions, it exhibits remarkable directional properties [1].

Recently, we investigated the light-matter interactions between an atom with Kramers degeneracy and a reciprocal environment in the absence of any external bias [2]. Our analysis showed that the combined influence of the electron's intrinsic spin magnetic moment and the chiral atomic dipolar transitions could lead to the spontaneous breaking of time-reversal symmetry or the emergence of time-crystal-like states, characterized by notably long relaxation times. These findings present a compelling opportunity to engineer nonreciprocal responses at the nanoscale, driven solely by quantum vacuum fluctuations.

In this talk, we will discuss how material gain can foster more robust nonreciprocal interactions. Specifically, we extend our analysis to environments exhibiting "chiral gain" [3-6]. Such environments can be realized in electrically-biased two-dimensional materials with broken inversion symmetry and significant Berry curvature dipole. It has been demonstrated that these systems facilitate non-Hermitian responses, with the gain dependent on the polarization handedness [3-6].

We will examine various fluctuation-induced effects in systems with chiral gain and, more broadly, in indefinite-gain systems. These systems can be characterized by either gain or dissipative interactions, typically governed by wave polarization [3-6] or wave momentum [7-8]. Our discussion will focus on how indefinite gain can be leveraged to tailor optical forces, induce quantum friction and optical instabilities, and control the flow of fluctuation-induced energy in a steady-state regime. Additionally, we will analyze the interaction between a qubit and a chiral-gain medium, demonstrating that it can give rise to unique nonreciprocal responses. These results underscore the vast potential of chiral gain in manipulating quantum system behavior.

Unified Dipolar Interactions in Bispinor Formalism and the Energy Symmetry Sphere

Sebastian Golat[1*], Alex J. Vernon[1], and Francisco J. Rodríguez-Fortuño[1]

Abstract

We present a unified bispinor framework that simplifies dipolar interaction expressions. Our approach leads to the concept of an energy symmetry sphere, which captures how broken parity and time-reversal symmetry give rise to chiroptical and magnetoelectric effects and offers new insights into light-matter interactions.

1 Bispinor Formalism and Dipolar Interactions

Conventionally, the electric field ($\boldsymbol{E}$) and magnetic field ($\boldsymbol{B}$) are treated as separate entities. Nonetheless, according to the theory of relativity, both fields must hold equal significance since an electric phenomenon perceived by one observer could manifest as a magnetic effect to another. This duality symmetry is fundamental to the form of Maxwell's equations in free space. It is only broken in the presence of matter: typically, the dynamics of the electric field are more strongly engaged with by atoms, molecules, and particles, and as a result, it is commonplace in optics to measure only electric quantities like energy, momentum, and angular momentum densities. However, light's more exotic mechanical capabilities and physical significance become obscured without considering the combined behaviour of electric and magnetic fields over space and their interaction with matter. By combining $\boldsymbol{E}$ and $\boldsymbol{B}$ into a single six-component bispinor,

$$\boldsymbol{\psi}(\boldsymbol{r}) = \frac{1}{2\sqrt{\mu_0}} \begin{pmatrix} \boldsymbol{E}(\boldsymbol{r})/c \\ \boldsymbol{B}(\boldsymbol{r}) \end{pmatrix}, \tag{1}$$

we recast the electromagnetic description into a compact form where both fields are treated on equal footing. This bispinor can be understood as a phasor representation of the electromagnetic field tensor up to the prefactor chosen such that the norm squared is the total energy density

$$W(\boldsymbol{r}) = \|\boldsymbol{\psi}\|^2 = \boldsymbol{\psi}^\dagger\boldsymbol{\psi} = \frac{1}{4}\left(\varepsilon_0|\boldsymbol{E}|^2 + |\boldsymbol{B}|^2/\mu_0\right) = W_\mathrm{e}(\boldsymbol{r}) + W_\mathrm{m}(\boldsymbol{r})\,. \tag{2}$$

Instead of considering eq. (1) to be a six-component complex vector ($\mathbb{C}^6$), we can consider it a complex two-component vector ($\mathbb{C}^2$) whose components are three-component vectors ($\mathbb{C}^3$) [1]. A key advantage of this interpretation of bispinor representation is its inherent basis flexibility in the $\mathbb{C}^2$ space. Since the $\mathbb{C}^2$ space is isomorphic to the space of Jones vectors that describe electric field polarisation in a plane wave, it has a very similar mathematical structure. We know that Jones vectors can be expressed not only in a horizontal/vertical basis but also in diagonal/antidiagonal and right/left-handed circular bases. In the case of bispinor, the standard electromagnetic (EM) basis plays the role of horizontal/vertical basis, and we can define alternative bases—such as the parallel–antiparallel (PA) and right–left-handed (RL) bases—which are analogous to the diagonal and circular bases for Jones vectors.

2 The Energy Symmetry Sphere

For Jones vectors, we can define Stokes parameters that describe the polarisation, where S_0 is the sum of squares of the two components in any basis while S_1, S_2, S_3 are their differences in each of the three bases. Any polarisation state can then be mapped to a point (S_1, S_2, S_3) which lies on or inside of the Poincaré sphere of radius S_0. Similarly, for the bispinor the total energy density $W_0 = W_\mathrm{e} + W_\mathrm{m} = W_\mathrm{p} + W_\mathrm{a} = W_\mathrm{R} + W_\mathrm{L}$ (eq. (2)) plays the role of S_0 and then the remaining parameters are analogous to $W_1 = W_\mathrm{e} \in W_\mathrm{m}$ (associated with the reactive power), $W_2 = W_\mathrm{a} \in W_\mathrm{p}$ (linked to the concept of reactive helicity density or magnetoelectric energy), and $W_3 = W_\mathrm{R} \in W_\mathrm{L}$ (proportional to the helicity density) which correspond to energy imbalances in the EM, PA, and RL bases. Any field can then be mapped to a point (W_1, W_2, W_3) which has to be inside the *energy symmetry sphere*. Much like the Poincaré or Bloch sphere visualises polarisation states, the energy symmetry sphere provides a geometric representation of how energy is distributed among various symmetry channels.

Crucially, the coordinates (W_1, W_2, W_3) transform characteristically under symmetry operations. Under parity inversion, components associated with mirror asymmetry (W_2 and W_3) change sign, while time reversal distinctly changes sign of only W_2. The discreet duality transformation changes the sign of reactive quantities (W_1 and W_2), which are only nonzero for non-paraxial light. For symmetric fields such as linearly polarized plane waves, the energy point lies at the centre of the sphere. In contrast, fields exhibiting broken symmetry—whether due to breaking parity, duality, or time-reversal symmetry—result in an off-centre displacement. This displacement can be directly linked to the emergence of chiral, magnetic and magnetoelectric interactions. For example, one can use the bispinor formalism to show that the power absorbed (or similarly scattered and extinguished) by an electromagnetic dipole can be written in terms of the absorption (scattering/extinction) cross-section σ_0 and its asymmetries (σ_1, σ_2, σ_3)—which form their own symmetry sphere—as a simple sum of four terms

$$P = \underbrace{\sigma_0 c W_0}_{\text{active}} + \underbrace{\sigma_1 c W_1}_{\text{reactive}} + \overbrace{\underbrace{\sigma_2 c W_2}_{\text{reactive}} + \underbrace{\sigma_3 c W_3}_{\text{active}}}^{\text{chiral}}, \tag{3}$$

where the first term is well-known as it is the only term that will appear even if no symmetries are broken. The remaining three terms can only appear if both the field and the particle break corresponding symmetries (parity for chiral terms and duality for reactive terms). Similar simplification can be shown for the dipolar force [2] and for the torque by introducing asymmetries in other quantities, such as momentum and angular momentum densities.

Abstract: We analyze the relation between the magnetic state in low-dimensional curvilinear magnets and global characteristics of geometry, such as topology and knotting. It is shown that (i) ferromagnetic wireframes support the topologically-protected high-order negative vorticity states, and (ii) sharp knots in antiferromagnetic spin chains allow tailoring signatures of geometric frustration.

Vector fields defined on a particular manifold necessarily acquire intrinsic characteristics of the manifold, related to its topology [1]. In the particular case of magnetism, the diversity of magnetic responses driven by geometry and distinction from other types of ordered media like nematic crystals is given by the finite out-of-surface component of the order parameter (magnetization m or Néel vector n). Namely, the local values of anisotropy and Dzyaloshinskii–Moriya interaction (DMI) are changed, which leads to the modification of the topologically non-trivial textures like domain walls or skyrmions and their pinning [2, 3]. Still, the relation between the magnetic state and global characteristics of the geometry is under exploration.

Here, we consider magnetic states in 3D nanowires. On the mesoscopic scale, 3D magnetic systems can be designed via additive nanotechologies like focused electron beam deposition (FEBID). Surfaces of magnetically soft ferromagnetic wireframes with segment's diameters of several hundredths of nanometers can be considered as compact manifolds hosting merons (vortices and antivortices). The total vorticity of the manifold allowed by its topology is determined by the Euler characteristic, counting the minimal number of closed cycles formed in the wireframe. While the local geometric shape of the wireframe favors formation of either vortex or antivortex with opposite vorticities, any wireframe homeomorphic to a sphere contains two more vortices than antivortices. Wireframes homeomorphic to N-toruses with $N > 1$ may host the only antivortices being the special case of the geometry with tunable large negative vorticity of magnetic texture [4].

Small enough diameters of the nanowire do not allow the appearance of meron textures in favour of domain walls. There are intensive studies of such effectively 1D systems for plane geometries and high-symmetry space curves like helices with the constant curvature and torsion [5], while lower symmetries haven't been systematically studied with the same details yet. In addition, ultrathin nanowires open a possibility to consider antiferromagnetic systems, where, unlike ferromagnets, the dipolar interaction leads to the hard-axis anisotropy. An exemplary closed curve of a constant torsion (spherical epicycle) can be obtained by the Bäcklund transformation of a spherical curve with M knots [6]. The resulting spin chain possesses the same M-fold symmetry axis of the M-knotted spherical curve, and, as such, its curvature is periodically distributed along the chain. The important signature of this geometry is that the curvature is strongly inhomgeneously distributed along the curve, with sharp peaks near the knots and with almost zero value within the epicycle's segments.

In addition to geometry itself, antiferromagnetic spin chains built along closed space curves provide an additional degree of freedom in the total number of spins because of the presence (absence) of pure geometric frustration for the case of even (odd) spins along the curve. The geometry-driven DMI together with the dominating hard-axis anisotropy lead to the rotation of n by 180° on each segment of the epicycle. For the 4-fold epicycle with an even number of spins, the segment's state fits the periodic boundary conditions on n. This is not the case of the 3-fold epicycle, where fitting of the boundary conditions leads to the dominating weak geometry-induced easy-anisotropy over DMI in one of the segments. These characteristic signatures of the global states in 4- and 3-fold epicycles are opposite in the case of the spin chain with the odd number of spins, where the boundary conditions on n are antiperiodic. The latter opens a possibility to tailor the signature of geometric frustration in antiferromagnetic systems by geometric features [7].

Abstract: We demonstrate a hybrid THz source with pulse shaping capability and chirality control of the emitted radiation without external components. This hybrid THz source integrates a spintronic emitter and a semiconductor photoconductive antenna into one single device in which each of the two emitters respond independently to external parameters.

Terahertz (THz) radiation, spanning from 0.3 - 30 THz, fills the crucial gap between the microwave and infrared spectral range. THz technology has applications in various fields, from imaging and sensing to telecommunication and biosensing. However, the full potential of these applications is often hindered by the need for precise control and manipulation of the frequency and polarization state, which typically requires external THz modulators [1].

Here, we demonstrate a hybrid THz source that overcomes this limitation by integrating two THz emitters into a single device to enable pulse shaping and chirality control of the emitted radiation without external components [2], see Figure. The two sources are a spintronic emitter (SE) [3] and a semiconductor photoconductive antenna (PCA) [4]. The two emitters respond independently to external parameters: the PCA is controlled by the applied bias voltage, while the SE is controlled by the applied magnetic field or the internal magnetic field distribution [5,6]. Moreover, a dual-wavelength excitation scheme at 780 nm and 1560 nm allows for control of the relative time delay between the THz emission from each constituent. These properties of the hybrid emitter enable precise control of the mixing of the two signals to control the frequency, polarization, and chirality of the overall THz radiation. This on-chip hybrid emitter thus provides a powerful platform for engineered THz radiation with wide-ranging potential applications.

Enantioselective molecular sensing by chiral gold helicoid nanoparticles

Jeong Hyun Han[1], and Ki Tae Nam[1*]

[1]Department of Materials Science and Engineering, Seoul National University, Seoul 08826, Republic of Korea
[*]corresponding author: nkitae@snu.ac.kr

Abstract: Colloidally synthesized chiral plasmonic gold nanoparticles, helicoids, offer enhanced and non-vanishing chiral light-matter interaction and thereby great potential for ultrasensitive enantioselective molecular sensing. We demonstrate experimental realization and relevant theory of spectroscopic molecular chirality detection based on circular dichroism and SERS from systematically integrated helicoids platform.

Considering the significance of molecular chirality in various fields including biochemistry, pharmacology, and diagnostics, the ability to accurately detect molecular chirality with ultrahigh sensitivity is of paramount importance. Spectroscopic detection based on the chiral light–matter interactions between circularly polarized light and molecules offers a non-destructive and highly precise approach. In particular, plasmonic metamaterials compress and enhance electromagnetic fields into deep-subwavelength scales, comparable to molecular dimensions, thereby selectively and significantly amplifying chiral interactions in localized nanoscale regions and magnifying the signal from molecular chirality. However, bulk spectroscopic detection from multiple molecules inevitably encounters signal cancellation due to the intrinsic dipolar nature of electromagnetic fields. The counteracting signals originating from oppositely handed local fields near the nanostructure lead to a net signal that, at the ensemble level, is much weaker than that obtainable from single molecules. In this context, helicoid nanoparticles with three-dimensional chiral morphology, synthesized via a seed-mediated colloidal method directed by chiral organothiols, is especially advantageous providing a nearly isotropic, highly chiroptical environment. Their high circular dichroism (g-value upto 0.3) and high symmetry of 432 enhance the chiral interaction between molecules and electromagnetic fields in a consistent handedness. We demonstrate the detection of chiral molecules using helicoid-based platforms in two distinct systems. First, by implanting helicoids in a two-dimensional periodic nanoholes, a photonic crystal is formed that exhibits large-area, strong, and uniform optical helicity density induced by collective resonances of helicoids. In this system, the resonant energy of the helicoid crystal is perturbed by chiral molecules in both its dielectric and chiral energy terms, enabling high-performance, multidimensional sensing that simultaneously captures information on both concentration and chirality via circular dichroism measurement. This approach supports multimodal sensing via transmission, reflection, and conjugation chemistry-based methods. Secondly, the grating-directed self-assembly of helicoids induces extraordinary optical helicity density within their nanogaps, which in turn selectively and dramatically enhances enantioselective molecular excitation. This enhancement facilitates the realization of an enantioselective surface-enhanced Raman scattering (SERS) system. We further envision that the wide synthetic tunability of nanoparticle properties (e.g., shape and size) paves the way for chiroptical molecular detection in a variety of optical systems beyond the two discussed.

Dynamics of softened spin waves in thin films with perpendicular anisotropy at temporal interfaces

K. Sobucki[1], N. Leśniewski[2,1], and P. Gruszecki[1*]

[1] ISIQ, Adam Mickiewicz University in Poznań

Abstract: Spin wave dynamics in thin ferromagnetic films with perpendicular anisotropy and Dzyaloshinskii-Moriya interaction is studied near the phase transition between uniform and stripe-domain phases. Micromagnetic simulations show spin-wave reflection, refraction, and amplification at temporal interfaces introduced by modulating the external magnetic field, offering a novel method for spin-wave control.

Spin waves are propagating precessional disturbances of magnetic moments in magnetic materials, offering promising applications in beyond-CMOS computing, including artificial neural networks [1]. However, efficient methods for spin-wave amplification and control remain critical for their full integration into devices. Time-varying media, along with phenomena such as time reflection and refraction, present new opportunities for magnonics in this regard [2,3].

The dynamics of spin waves and static magnetic configuration strictly result from the mutual competition between various energies present in magnetic systems. For instance, perpendicular Magnetic Anisotropy (PMA) in thin ferromagnetic films at low magnetic fields enables the formation of periodic stripe domain patterns, with well-defined periodicities down to 100 nm [4]. PMA not only modifies the magnetic texture but also significantly influences spin-wave dynamics [4, 5]. This effect arises both from the inhomogeneous magnetic configuration and the intrinsic impact of PMA on spin-wave precession, leading to surprising consequences. Using micromagnetic simulations [6], we show that the effect of PMA on dispersion is most pronounced at low fields near the phase transition to the stripe domain pattern. This leads to novel effects such as bi-reflection and negative reflection of an obliquely incident spin-wave beam at a uniform interface (see Figure. 1(b)) [5].

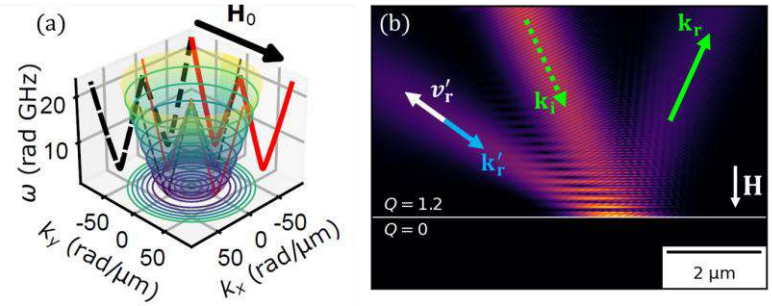

Figure 1. (a) Dispersion relation of spin waves in 2-nm-thick CoFeB film with reduced anisotropy constant Q=1.2. The system is uniformly magnetized by the in-plane applied bias magnetic field of value 220 mT. *(b)* Micromagnetic simulation of the reflection of an SW beam in a 2 nm CoFeB film, incident at a *25°* angle on an interface separating regions with different values of PMA defined a *Q*.

Another important interaction in magnetic systems is the Dzyaloshinskii-Moriya interaction (DMI), which prefers the chiral rotation of neighboring magnetic moments. This causes the dispersion relation in magnetic layers with DMI to be nonreciprocal (different wavelengths for opposite propagation directions). In the next part of the paper, we consider an ultrathin ferromagnetic film with PMA and DMI and we exploit the connection between magnetic texture for fields below the critical field and softened spin wave modes in a uniformly magnetized system, leading to spin wave

freezing[7]. We show how temporal modulations of the magnetic field influence spin-wave propagation near the critical bias field, where a phase transition occurs between high-symmetry (uniform in-plane magnetization) and low-symmetry (aligned stripe domains) phases [7]. Micromagnetic simulations demonstrate phenomena such as spin-wave reflection and refraction at temporal interfaces. Notably, the temporal profile of the bias field modulates time refraction and reflection, leading to spin-wave amplification (Fig. 2). These findings present a practical and easily implementable method for controlling spin waves using external magnetic fields, which can be adjusted via coplanar antennas.

A Multiscale Approach to Molecular Nanoplasmonics: From SERS to Chiroptical Spectroscopies

T. Giovannini[1]

[1]Department of Physics, University of Rome Tor Vergata, Rome, Italy

[*]corresponding author: tommaso.giovannini@uniroma2.it

Abstract: We present a multiscale approach combining a fully atomistic approach to nanoplasmonics and quantum mechanics to model plasmon-enhanced spectroscopies, from SERS to chiroptical response.

The interaction between molecular systems and plasmonic substrates, such as noble metal nanoparticles and graphene, leads to peculiar electromagnetic responses. Among them, Surface-Enhanced Raman Scattering (SERS) has emerged as a widely used analytical technique that exploits the large enhancement of the Raman signal when a target molecule is adsorbed on metallic nanostructures [1]. This enhancement can reach factors up to 10^{10}, even enabling single-molecule detection [1].

In this contribution, we present a novel theoretical framework for surface-enhanced spectroscopies, extending our previous fully atomistic classical electromagnetic models [2-5] to describe the plasmon-mediated chiroptical response [6]. Specifically, we introduce a new methodology for describing Surface-Enhanced Raman Optical Activity (SEROA), which is the chiral analog of Raman signal. Such a mixed electric/magnetic/vibrational spectroscopy provides key insights into chiral molecular responses as modulated by plasmonic environments. Our multiscale method couples an atomistic electrodynamics treatment of the plasmonic nanostructure with a quantum mechanical (QM) description of the adsorbed molecular system. This hybrid integrated strategy is capable of describing metallic nanoparticles [2,3,5] and graphene-based materials [4,7] at the same level of accuracy.

The method is highly scalable, allowing large-scale nanoplasmonic simulations involving more than one million atoms, while also capturing critical quantum effects, such as subnanometer plasmonic junctions [2,5] and geometrical defects [7,8]. The robustness of our approach is demonstrated through selected test cases, including SERS and SEROA spectra [6,9].

Abstract: A key requirement for chiral separation using integrated waveguides and chiral optical forces is the support of a guided chiral mode. We present an experimental method, based on analyzing the spectral response of Mach-Zehnder interferometers, to determine the optimal waveguide width that satisfies this requirement.

Enantiomeric separation, crucial in chemistry and pharmaceuticals, is traditionally performed using techniques like chiral High-Performance Liquid Chromatography. However, these methods are often slow, expensive, and molecule-specific. Optical chiral forces offer a compelling alternative, and while recent research has primarily focused on separating particles with free-space beams [1,2], utilizing guided light in integrated dielectric waveguides presents a promising new avenue. Apart from facilitating large-scale integration, this approach enhances chiroptical interactions, essential for sorting particles of small size and low chirality.

Our recent theoretical work has investigated the chiral forces exerted by guided optical modes on chiral nanoparticles, demonstrating the potential of silicon nitride waveguides for rapid enantiomeric separation within photonic integrated circuits operating at wavelengths of 1310 nm and 633 nm [3,4,5]. A particularly promising configuration leverages the differential chiral pressure force experienced by opposite enantiomers. This results in distinct propulsion speeds along the waveguide, leading to the enantiomeric longitudinal separation [5].

This separation method requires a quasi-circularly polarized mode within the waveguide, created by superimposing the quasi-TE_0 and the quasi-TM_0 modes with a $\pi/2$ phase difference. Crucially, these modes must share the same effective index to maintain the phase delay and prevent polarization oscillation, i.e. to preserve the helicity (or chirality) of the mode. This degeneracy of the TE and TM modes is achieved at a specific waveguide width (given a fixed wafer layer thickness) [5].

In this work, we present an experimental method for determining the effective indices of the quasi-TE_0 and quasi-TM_0 waveguide modes. We fabricated an array of integrated asymmetric Mach-Zehnder Interferometers with varying waveguide widths. Analyzing their transmitted optical power across a spectral range allowed us to calculate the effective indices and pinpoint the waveguide width at which degeneracy occurs.

The authors acknowledge funding from the European Commission under the CHIRALFORCE Pathfinder project (grant no. 101046961).

Magneto nanophotonics platform based on monocrystalline yttrium iron garnets

Y. Ota[1*], S. Gao[1], K. Taniguchi[1], T. Yambe[1] Y. Tanimura[1] and S. Iwamoto[2]

[1]Department of Applied Physics and Physico-Informatics, Keio University, Japan

Abstract: Monocrystalline yttrium iron garnets (YIGs) are an outstanding material for magneto-optics. However, their application to nanophotonics has been limited due to the difficulty of fine nanopatterning. Here, we report a platform of magneto-nanophotonics based on YIG realized by the development of high-quality YIG membranes and their nanopatterning using dry etching.

Magneto optical (MO) effects are essential to break the reciprocity of light traveling through an unmodulated transparent optical structure with a linear response, which is vital to realize handy nonreciprocal photonic devices. In general, MO responses in any natural materials are weak in the optical regime and hence the devices tend to be bulky, hindering many applications in particular in integrated photonics. To enhance MO effects, optical confinement is promising as it effectively increases MO interactions. In this context, high quality photonic structures based on high quality MO materials will be a key development to realize compact but functional MO devices. In the telecom band wavelengths at room temperature, the choice of transparent MO material is not many and is virtually limited to the family of yttrium iron garnets (YIGs) in particular in the form of monocrystal. However, there has been no monocrystalline YIG thin film detachable from the mother substrate and furthermore the nanopatterning of YIG is notoriously difficult due to e.g. the chemical inactivity of the material. These obvious obstacles have hampered the progress of YIG-based magneto nanophotonics in the telecom wavelength band.

In this contribution, we report our effort to develop a magneto nanophotonics platform based on monocrystalline YIG. We are developing YIG thin films on glass using a bonding-and-grinding approach. The large refractive index difference between YIG and glass will enable tight light confinement in the YIG layer, facilitating the design of high confinement photonic structures. Furthermore, the glass layer can be selectively etched out to form a freestanding YIG membrane, which will provide an extra refractive index difference between YIG and the cladding material. We are also working on nanopatterning of YIG using dry etching. Perforating airholes in the YIG membranes with diameters of a few hundreds will be required to realize photonic crystals and metasurfaces operating in the telecom wavelength bands. The key requirements will be the faithful patterning of the designed structures and the realization of vertical etched sidewalls. Such a technology for fine nanopatterning of the monocrystalline YIG thin films will entail a variety of magneto nanophotonic devices including MO metasurfaces for giant Faraday rotation[1], hybrid metasurfaces[2] and nonreciprocal slow light waveguides based on the bound states in the continuum[3]. Figure 1 illustrates how the development of the YIG-based nanophotonic platform will lead to the realization of various magneto nanophotonic devices. Such a platform will also advance magnonics since YIG is also known as one of the best magnetic materials with the lowest magnon damping.

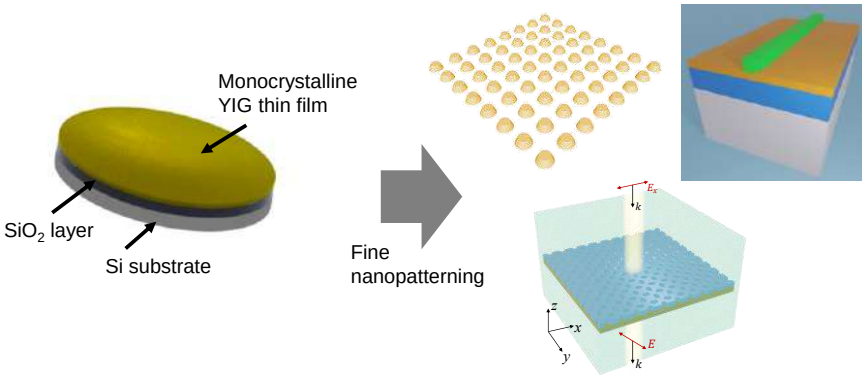

Figure 1. High quality monocrystalline YIG thin films will lead to a variety of magneto nanophotonic devices

Microwave-to-Optical Quantum Transduction Mediated by Antiferromagnetic Magnons in Antiferromagnets

Akihiko Sekine*, **Ryo Murakami, and Yoshiyasu Doi**
Fujitsu Research, Fujitsu Limited, Kawasaki 211-8588, Japan
akihiko.sekine@fujitsu.com (corresponding author)

Abstract

While earlier studies regarding the magnon-mediated quantum transduction have so far utilized ferromagnetic magnons in ferromagnets, here we formulate a theory for the microwave-to-optical quantum transduction mediated by antiferromagnetic magnons in antiferromagnets. We find that the quantum transduction can occur even in the absence of an external static magnetic field.

The quantum transduction, or equivalently quantum frequency conversion, between microwave and optical photons is a quantum technology that enables the interconnects between quantum devices such as quantum memories and quantum processors. It is also essential for realizing large-scale quantum computers with superconducting qubits. Due to the large frequency difference between microwave and optical ranges, the quantum transduction needs to be done via the interactions between photons and intermediate bosonic modes or via the nonlinear interaction between photons [1].

In this study, we focus on the quantum transduction mediated by magnons. Such a quantum transduction mediated by magnons can have a wide bandwidth and can be operated even at room temperature. While earlier studies have so far utilized ferromagnetic magnons in ferromagnets [2, 3], here we formulate a theory for the microwave-to-optical quantum transduction mediated by antiferromagnetic magnons in antiferromagnets. We derive analytical expressions for the transduction efficiency in the cases with and without an optical cavity (where a microwave cavity is used in both cases) [4]. In contrast to the case of ferromagnets, we find that the quantum transduction can occur even in the absence of an external static magnetic field. We also find that, in the case with an optical cavity, there exists an optimal value of the thickness d_{AFM} of the antiferromagnets at which the transduction efficiency takes a maximum value. This results from a competitive behavior between the microwave-magnon interaction $\propto \sqrt{d_{\mathrm{AFM}}}$ and the light-magnon interaction $\propto 1/\sqrt{d_{\mathrm{AFM}}}$. On the other hand, in the case without an optical cavity, the transduction efficiency is an monotonically increasing function of the thickness d_{AFM}, which comes from a cooperative behavior between the microwave-magnon interaction $\propto \sqrt{d_{\mathrm{AFM}}}$ and the light-magnon interaction $\propto d_{\mathrm{AFM}}$.

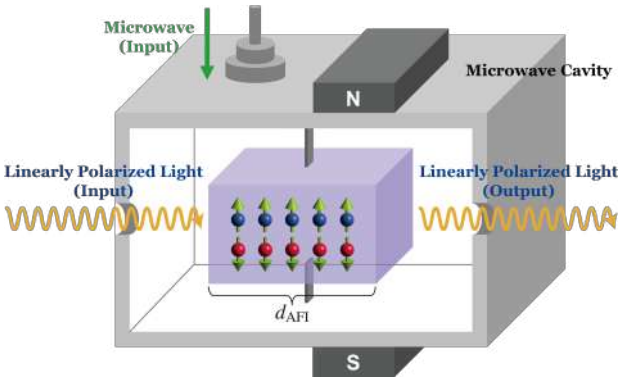

Figure 1: Schematic illustration of our experimental setup for the microwave-to-optical quantum transduction without an optical cavity.

Excitations and light-matter interactions in polar topologies

S. Rijal, Y. Nahas[1], S. Prokhorenko[1*], and L. Bellaiche[2]

[1]Smart Ferroic Materials Center, Physics Department and Institute for Nanoscience and Engineering, University of Arkansas, Fayetteville, Arkansas, USA

Abstract: Polar topological textures such as polar vortices, bubbles and skyrmions, are swirling patterns of electric polarization spontaneously emerging in ultra-thin ferroelectrics. Here, we explore lattice excitations giving rise to polar textures and novel phenomena entailed by non-linear interactions of such excitations with IR light in ultra-thin $Pb(Zr,Ti)O_3$ films.

Polar topological textures are swirling patterns of electric polarization that can spontaneously form in ultra-thin ferroelectrics due to strong depolarizing fields[1]. A prototypical example of polar topologies is given by the so-called vortex crystals[2]. These structures can be described as vortex tubes formed by local electric dipoles that are periodically arranged within the plane of an ultra-thin ferroelectric film such as $Pb(Zr_{0.4},Ti_{0.6})O_3$ (Fig. 1a). In some cases, polar vortex tubes are also known to develop spontaneous polarization along their axis rendering the structure chiral on the local scale[1] (Fig. 1b).

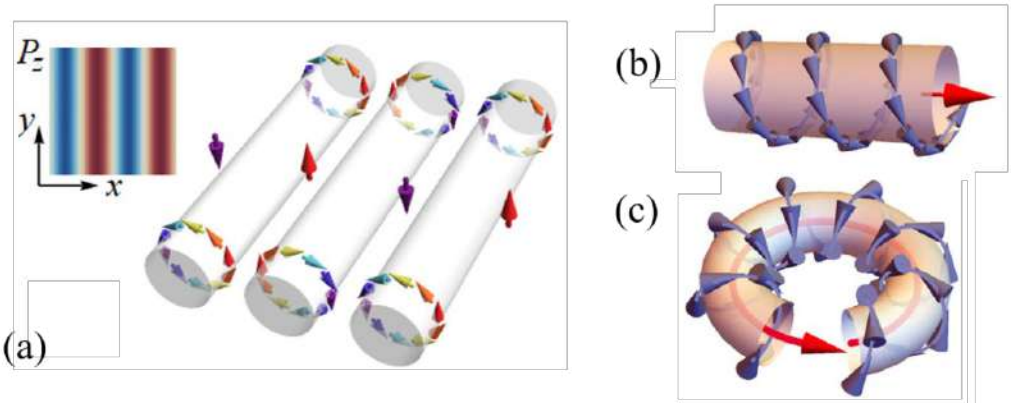

Figure 1. (a) Schematical structure of polar vortex crystals consisting of alternating clockwise/anti-clockwise vortex tubes formed by local electric dipoles and periodically arranged within the plane of an ultra-thin ferroelectric film. Inset shows the distribution of out-of-plane polarization in the mid-point horizontal cross-section of the film. (from Ref. 4) (b) Structure of a vhiral vortex tube with non-zero polarization component along the vortex tube axis. (from Ref. 5) (c) Structure of a chiral electric bubble obtained by closing a chiral vortex tube into a vortex ring. (from Ref. 5)

Here, we use first principles based effective Hamiltonian simulations to show that the formation of polar vortex patterns in ultra-thin $Pb(Zr_{0.4},Ti_{0.6})O_3$ is intrinsically linked to vortex-like lattice excitations that soften upon cooling[2] and, depending on external conditions, can give rise to ordered vortex crystals[2], glass-like vortex labyrinth[3] or arrays of electric bubbles[3,4] (Fig. 1c). By analyzing the calculated finite-temperature phonon dispersions and mode eigenvectors, we show that the vortex modes induce precession of local electric dipoles and discuss possible implications of such dynamics for magnetoelectric coupling. Additionally, we show that changing

PZT composition can lead to emergent chirality on the local scale and identify lattice excitation responsible for the transition from non-chiral (Fig. 1a) to locally chiral structures (Figs. 1b-c).

Finally, we will discuss non-linear interactions of the vortex modes in ultra-thin ferroelectrics and the dynamical phenomena it entails2. Based on the analysis of the effective Hamiltonian model and symmetry arguments, we show that the finite wave-vector vortex modes (γ) are non-linearly coupled to zone-center phonons (ϕ). The corresponding fourth-order interactions $\phi\,\gamma^3$ and $\phi^2\,\gamma^2$ induce non-trivial dynamical phenomena that can be used to operate e.g. resonant switching of the vortex tube orientation with far-infrared light.

Our results provide insight into the dynamics of the formation of polar topologies and open new routes for functionalizing ultrathin ferroelectrics.

Abstract: We derive a formula for the polarization in a crystal induced by a perturbation linear in the coordinates. We use the linear response theory, and found that there appears an additional correction term to the previous work on the semiclassical theory. We confirm this result in a model calculation.

In crystals with certain symmetries such as inversion or *PT* symmetries, the polarization is identically zero in the bulk. If we introduce some perturbation linear in the coordinates, the symmetry that prohibits polarization will be broken, and the polarization is expected to appear. In Refs. 1 and 2, this problem is studied by the semiclassical theory, and a polarization formula has been obtained for an arbitrary perturbation linear in the coordinates. This class of perturbations includes the uniform electric field and the uniform orbital magnetic field, and the results reproduce the known formulae for the dielectric constant and the magnetoelectric tensor.

In the present talk, we study this problem by the linear response theory. We add a general perturbation linear in the spatial coordinates to the system, and calculate the induced polarization[3]. To calculate the polarization, we need a special treatment; we first make the perturbation to have a wavenumber q and a frequency ω, and calculate the current response. By dividing the response by $q\omega$ and take the limits of q and ω going to zero, we obtain the formula for the polarization[3]. The result is almost the same as that in the semiclassical theory[1,2], but we find an additional correction term to the polarization. We show the validity of our result by numerical calculation on a two-dimensional tight-binding model[3].

Abstract: We study the optical properties of periodic arrays of graphene nanostructures under static magnetic fields. We demonstrate the magnetic-field-controlled activation and deactivation of collective modes, offering new possibilities for tunable graphene-based photonic devices. Furthermore, our findings reveal magneto-optic phenomena such as chiral response and Faraday rotation.

Doped graphene nanostructures support electromagnetic resonances known as plasmons, which exhibit strong optical responses in the infrared and terahertz regimes [1]. When subjected to a static magnetic field, the conductivity tensor of graphene acquires a Hall component, leading to the emergence of magnetoplasmons—hybrid modes that retain the strong confinement and tunability of plasmons while introducing novel magneto-optic effects. These effects include nonreciprocal wave propagation, circular dichroism, and polarization rotation, making magnetoplasmons highly attractive for a plethora of applications.

To fully exploit the unique properties of graphene nanostructures, they are often arranged in periodic arrays. This approach has been leveraged to achieve giant Faraday rotation in metasurfaces composed of graphene ribbons under a static magnetic field [2]. Furthermore, periodic arrays of graphene disks can sustain collective modes driven by coherent interactions among their constituents [3]. Due to their collective nature, these resonances exhibit exceptionally high quality factors and a strong electric field enhancement across a significant area of the unit cell. However, previous studies on collective resonances have primarily focused on scenarios without an external magnetic field. The interplay between coherent interactions and magneto-optic effects remains unexplored and holds the potential to unlock new avenues to control light-matter interactions.

In this work, we investigate the optical properties of periodic graphene nanostructures subjected to static magnetic fields. We show that the external magnetic field provides a powerful means of modulating collective modes, effectively allowing for their selective activation and deactivation [4]. Moreover, we explore the magneto-optic phenomena induced by the magnetoplasmons, including perfect chiral absorption and perfect chiral emission [5]. These findings underscore the potential of graphene-based photonic systems for the active manipulation of the optical response and the development of tunable magneto-optic devices.

Nonlinear response of truly chiral phonons: light-induced phonon angular momentum and Peltier effect

Hiroaki Ishizuka[1] **and Masahiro Sato**[2]
[1]Institute of Science Tokyo, Japan
[2]Chiba University, Japan
Corresponding author: ishizuka@phys.sci.isct.ac.jp

Abstract: The nonlinear response of chiral phonons to electromagnetic waves is theoretically studied. We show that chiral phonons give rise to large angular momentum compared to ordinary phonons. In addition, we show that the Peltier effect by chiral phonons occurs from a mechanism distinct from those proposed recently.

The chiral phonon is a phonon mode whose angular momentum and the wavenumber couple, $\mathbf{L}\cdot\mathbf{k}\neq 0$, where $\mathbf{L}$ is the crystal angular momentum and $\mathbf{k}$ is the phonon momentum, respectively. In centrosymmetric materials, these phonons appear in a pair of right-handed and left-handed modes, which are degenerate. In contrast, in chiral crystals [Fig. 1(a)], non-degenerate chiral phonons emerge, which are called truly chiral phonons; such phonon modes have recently been observed in α-HgS [1]. These truly chiral phonons are characterized by a non-zero group velocity at the symmetric points in the Brillouin zone, and hence, they may possess unique properties such as the efficient energy and angular momentum transport. However, the functionality arising from the truly chiral phonons has not been fully explored.

In this work, we theoretically studied the nonlinear responses of truly chiral phonons to electromagnetic waves. We consider a general phonon model whose Hamiltonian reads,

$$\hat{H}=\sum_{ia\mu}\frac{\hat{p}_{ia\mu}^2}{2m_a}+\frac{1}{2}\sum_{ia\mu,jb\nu}(\hat{u}_{ia\mu}-\hat{u}_{jb\mu})D_{ia\mu,jb\nu}(\hat{u}_{ia\nu}-\hat{u}_{jb\nu}), \tag{1}$$

where $D_{ia\mu,jb\nu}$ is the dynamical matrix, $\hat{u}_{ia\mu}$ is the displacement along the μ axis of $a\,(=1,2,3)$ sublattice atom in ith unit cell, and $p_{ia\mu}$ is the conjugate momentum of $\hat{u}_{ia\mu}$ satisfying $[\hat{u}_{ia\mu},\hat{p}_{jb\nu}]=\mathrm{i}\delta_{ij}\delta_{ab}\delta_{\mu\nu}$. The second-order nonlinear response of $\hat{H}$ to electromagnetic waves is studied using the nonlinear response theory [2, 3]. Using this theory, we show that a series of nonlinear responses reflects the unique properties of truly chiral phonons, such as phonon angular-momentum generation, the Peltier effect of phonons, and the photo-induced phonon orbital current. In addition, we consider a three-ion model of the chiral crystal in Fig. 1(a) as a demonstration.

Firstly, we studied the generation of angular momentum of phonons. We find that the angular momentum of the phonon is generated by both chiral and non-chiral phonons. However, a unique feature of chiral phonons is that there is a polarization-dependent contribution with τ^2 dependence on the lifetime of the phonon τ. This behavior is in contrast to the contribution of non-chiral phonons whose nonlinear conductivity increases as τ^1. This result implies that a significantly larger angular momentum may be induced by chiral phonons, especially in a clean system with a long phonon lifetime.

In addition to selectively exciting phonons, such as in the case of angular-momentum generation, recent theoretical studies pointed out that a nonlinear response of phonons can be

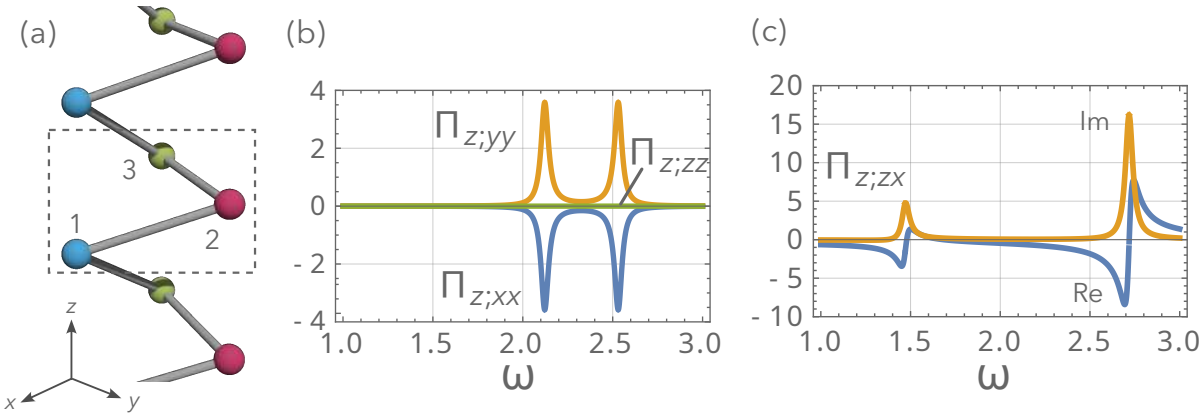

Figure 1: (a) A schematic of a chiral crystal with truly chiral phonon modes. The fequency dependence of nonlinear Peltier coefficient for (b) the linearly polarized electromagnetic wave and (c) circularily polarized electromagnetic wave. The results are for phonon current along the z axis.

used to control the flow of phonons and other charge-neutral excitations through a mechanism similar to the bulk photovoltaic effect [4–7]. One such phenomenon is the Peltier effect of phonons, in which a steady current of phonons is generated by the electromagnetic wave [2]. By analyzing the Peltier effect of chiral phonons, we find that, in addition to the shift-current-like effect studied in a previous work [2], the energy current of phonons occurs through a mechanism similar to the injection current. Moreover, for chiral phonons whose bands are doubly degenerate at $\mathbf{k} = \mathbf{0}$, we show that the phonon current is related to the asymmetric excitation of phonons with opposite angular momentum.

Nano-Squeezing of Optical Chirality via Topology-Optimized 3D Nanogap Antennas

A. Taguchi[1*]
[1]Research Institute for Electronic Science, Hokkaido University, Japan
taguchi@es.hokudai.ac.jp (corresponding author)

Abstract

We numerically investigated optical chirality flowing in a topology-optimized 3D chiral dielectric nanostructure. From the near-field analysis, we observed that chirality flux concentrates and eventually leads to a local enhancement of chirality density at the nanogap. This finding has important implications for better controlling chiral light-matter interactions at the nanoscale.

1 Introduction

Circularly polarized light (CPL) not only carries energy but also transports a physical quantity known as optical chirality, which is vital for the enantioselective excitation of chiral molecules. Despite its importance, enhancing optical chirality at the nanoscale remains challenging. This difficulty partly arises from the inherently complex behavior of near-fields involving the spin angular momentum (SAM) of light. In this work, we demonstrate that rationally designed nanostructures can guide the flow of optical chirality, enabling its confinement into subwavelength spaces while simultaneously enhancing its density. These findings provide novel insights into controlling optical chirality using nanostructures, paving the way for enhanced chiral light-matter interactions at the nanoscale.

2 Chiral Structure Design using Topology Optimization

To design a 3D chiral nanostructure for enhancing optical chirality at the nanoscale, we employ topology optimization (TO), a machine-aided design methodology that enables the creation of complex nanostructures with desired physical properties constrained by Maxwell's equations. As shown in Fig. 1(a), our optimization model comprises an antenna region made of TiO_2, which receives counter-propagating right-handed CPL (r-CPL) with a wavelength of 532 nm. The counter-propagating CPL creates a polarization standing wave, where the electric and magnetic

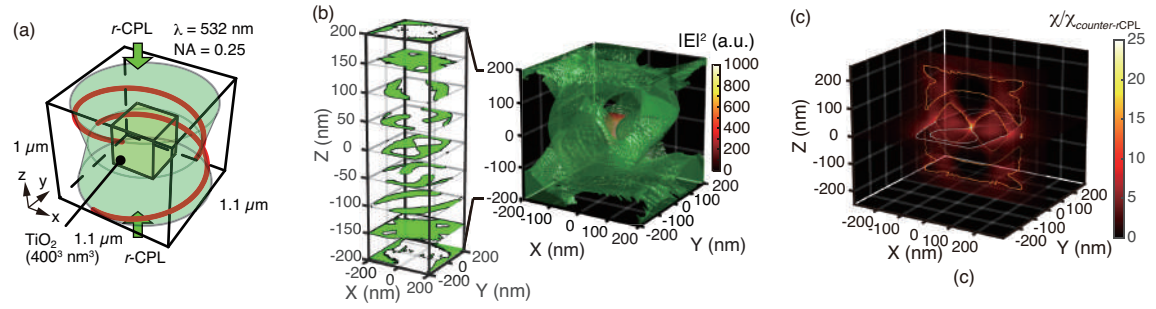

Figure 1: Topology-designed gap antenna for counter-propagating r-CPL. (a) Schematic of boundary conditions. (b) 3D model of the antenna with Z-sliced sections, overlaid with electric field intensity distribution. (c) Optical chirality density, χ, normalized to structure-free, displayed at planes $Z = 0$ nm and $Y = 0$ nm under counter-propagating r-CPL excitation.

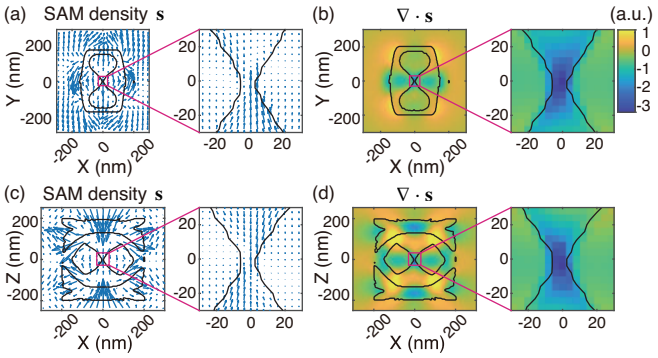

Figure 2: (a) SAM density vector in X-Y plane at $Z = 0$ nm and (b) the corresponding SAM divergence. (c,d) Same as (a,d) but X-Z plane at $Y = 0$ nm.

fields are aligned in parallel and $\pi/2$ out of phase, with the azimuthal orientation spiraling along the propagation axis. This configuration establishes the optimal conditions for maximizing optical chirality. TO is then applied to determine the optimal material distribution, maximizing the field intensity at the center while preserving the conditions for chirality enhancement.

Figure 1(b) shows the resulting structure, which features a nanogap as narrow as 8 nm at the center ($Z = 0$ nm), where the electric field intensity is significantly enhanced. We observe an enhancement factor of 1,250 for counter-propagating r-CPL. Figure 1(c) illustrates the distribution of optical chirality, which peaks within the gap with an enhancement factor of 24.5. The spatial width of the chiral field at full width at half maximum (FWHM) is 10.4 nm, indicating subwavelength confinement.

3 Chirality Flux within the Chiral Nanostructure

Figure 2 illustrates how the spin angular momentum (SAM) density, or equivalently, the chirality flux of the incident CPL, flows into the nanogap. The SAM converges into the nanogap and cancels out, creating a distinct negative divergence of SAM. This leads to an increase in the local optical chirality density, as dictated by the conservation laws of optical chirality. This illustration demonstrates how the optimized 3D chiral structure "squeezes" the optical chirality inherent in the incoming CPL into the nanoscale region.

4 Conclusion

This work demonstrates that topology-optimized 3D dielectric nanogap antennas can effectively enhance and confine optical chirality within a subwavelength mode volume, representing a valuable step toward chiral light control at the nanoscale. These findings pave the way for applications in chiral light-based technologies, including chiral molecular sensing, quantum spin optics, and other nanoscale photonic systems exhibiting chirality.

Magnetoelectric effect in antiferromagnetic Chern insulators

T. Hirosawa, D. Komine, and N. Furukawa

Aoyama Gakuin University, Japan
*corresponding author: hirosawa@phys.aoyama.ac.jp

Abstract: The magnetoelectric effect is a cross-correlation phenomenon between electric and magnetic dipole moments, which occurs when both the time-reversal and inversion symmetries are broken. In this work, we discuss the magnetoelectric effect in antiferromagnetic Chern insulators, which support spin-polarized chiral edge states.

The magnetoelectric effect occurs when the electric and magnetic dipole moments are strongly coupled. It is characterized by a higher-order multipole moment, such as the magnetic toroidal moment [1]. Since the magnetic toroidal moment is induced by a pair of localized spins with opposite polarization, antiferromagnetic materials provide an ideal platform for the magnetoelectric effect. However, the linear magnetoelectric effect is generally very small in antiferromagnetic materials.

Here, we investigate the magnetoelectric effect in antiferromagnetic Chern insulators. Chern insulators are time-reversal-symmetry broken topological phases of matter. When they are in proximity to the antiferromagnetic order, both the time-reversal and inversion symmetries are broken, allowing the magnetoelectric effect. Furthermore, the bulk-boundary correspondence guarantees the emergence of chiral edge states, partially spin-polarized due to the coupling with the antiferromagnetic order. We discuss the magnetoelectric effect of spin-polarized chiral edge modes and propose tight-binding models for their realization.

Enhanced chiral sensing and unambiguous enantiomer differentiation with achiral anisotropic photonic metasurfaces

S. Droulias

Department of Digital Systems, University of Piraeus, Piraeus 18534, Greece

corresponding author: sdroulias@unipi.gr

Abstract: Achiral anisotropic photonic metasurfaces can provide enhanced sensing and unambiguous enantiomer differentiation of weak chiralities at the nanoscale. In this work it is demonstrated how the additional degrees of freedom offered by anisotropic metasurfaces with respect to their isotropic counterparts can enable chiroptical signals with unprecedented enhancement.

Sensing molecular chirality at the nanoscale has been a long-standing challenge, due to the inherently weak nature of the associated chiroptical signals. Recently, circular dichroism (CD) measurements of chiral media embedded in nanophotonic platforms have granted access to weak chiralities at the nanoscale [1,2]. However, because in such measurements the incident wave probes the chiral medium together with the metasurface, chiroptical signals result from the dispersion of both. As a result, although CD measurements are intuitively expected to be sensitive only to the imaginary part of the chirality parameter κ, Im(κ), they are sensitive to both Re(κ) and Im(κ) [3]. Therefore, it is crucial to be able to isolate the metasurface's contribution from the total chiroptical signal, in order to deconvolve and unambiguously determine the unknown chirality. While several chiral sensing schemes based on CD measurements have been proposed for the detection and differentiation of enantiomers, a scheme that is able to distinguish Re(κ), Im(κ) is still missing.

Recently it was shown how, with the aid of achiral isotropic metasurfaces, it is possible to deconvolve the unknown chirality from the background dispersion of the metasurface [3]. The idea is based on probing the metasurface, in which the chiral inclusion is embedded, with linearly polarized waves, and measuring changes in the transmitted polarization, which is characterized in terms of the rotation θ and ellipticity η of the polarization vector. Because the metasurface is achiral, any changes in the transmitted polarization are solely due to the embedded chirality. In this scheme, the unknown κ_A is expressed in terms of the reference κ_B, as

$$\kappa_A = \kappa_B \frac{\theta_A + i\eta_A}{\theta_B + i\eta_B} \tag{1}$$

where θ_A, η_A and θ_B, η_B are the chiroptical signals from simulations or experiments with chiral inclusions A and B, respectively.

In this work, achiral anisotropic metasurfaces are studied as a vehicle for the detection of a chiral inclusion and the unambiguous retrieval of its unknown chirality parameter κ with unprecedented enhancement. Anisotropic metasurfaces offer additional degrees of freedom with respect to their isotropic counterparts and can thus enable detection schemes, beyond probing with linearly polarized beams [4,5]. An example is shown in Fig. 1, in which a realistic anisotropic metasurface is used. The metasurface supports resonant conductivities along the y-axis, similar to the one examined in [4] for chiral sensing in the near infrared. In this example, the metasurface is composed of a 100 nm thin dielectric slab on which a 50 nm chiral layer with refractive index $n = 1.5 - 0.001i$ and chirality parameter κ is placed.

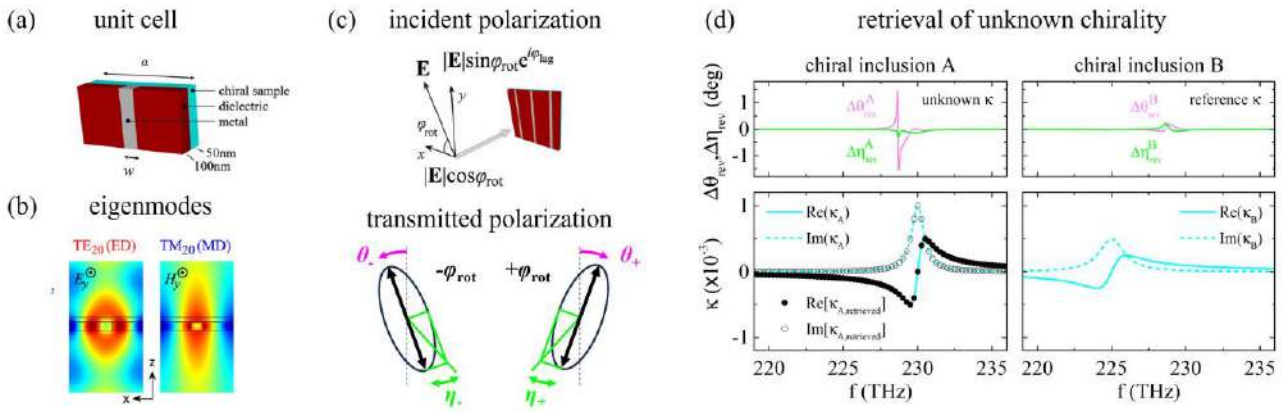

Figure 1. Achiral anisotropic photonic metasurface for enhanced chiral sensing and unambiguous enantiomer differentiation. (a) Schematic illustration of unit cell. The periodicity is α = 840 nm and the silver wire has thickness w = 140 nm. (b) Field distribution of the electric type (TE_{20}) and magnetic type (TM_{20}) modes that are utilized for sensing. (c) Excitation with elliptically polarized wave, and polarization state of the transmitted wave, analyzed in terms of its rotation θ and ellipticity η, for excitation with $\pm\varphi_{rot}$ orientation. (d) Retrieval of the unknown chirality parameter κ_A of inclusion A, with reference chirality parameter κ_B of inclusion B, using the averaged chiroptical signals $2\Delta\theta_{rev} = \theta_+ + \theta_-$, $2\Delta\eta_{rev} = \eta_+ + \eta_-$ in transmission. *Top row*: numerically calculated chiroptical signals of the transmitted wave. *Bottom row:* chirality parameters κ_A, κ_B of the two inclusions (cyan lines) and retrieved κ_A (black lines) of inclusion A.

The dielectric slab has refractive index n = 3.4 and supports TE (components H_x, E_y, H_z) and TM (components E_x, H_y, E_z) waveguide modes, which are used to implement the electric/magnetic moment pair. The slab is periodically interrupted by silver wires with periodicity α = 840 nm and the whole system is placed on a glass substrate of refractive index n = 1.5. The space on the opposite side (adjacent to the chiral layer) is index-matched with the substrate.

It is demonstrated how anisotropic metasurfaces, like the one presented in the above example, can be used to (i) achieve enhanced chiroptical signals by more than two orders of magnitude, (ii) perform complete measurements of the total chirality (magnitude and sign of both its real and imaginary parts) and (iii) enable chirality measurements in an absolute manner, i.e. without the need for sample removal, using a crucial signal reversal (excitation with reversed polarization). Analytical formulas that provide insight into the sensing mechanism are derived and numerically verified, generalizing Eq.(1) to detection with elliptically polarized beams.

What is and what is not a good measure for enhanced chiroptical response?

T.Weiss[1*]

[1]University of Graz and NAWI Graz, Universitätsplatz 5, 8010 Graz, Austria

Corresponding author: thomas.weiss@uni-graz.at

Abstract: Enhancing chiral light-matter interaction by nanophotonic resonators has attracted a lot of interest in recent years. However, various theories and measures exist to understand and quantify this enhancement. We are going to compare these approaches and discuss their advantages and disadvantages.

Detecting the handedness of chiral molecules is of utmost importance for chemical, biological, and pharmaceutical applications, since the handedness of a molecule determines its interaction with the environment. This includes chemical interactions as well as the interaction with light. Hence, it is possible to determine the handedness of chiral molecules by optical measurements, but the chiroptical response of such molecules is usually rather weak. Therefore, conventional approaches require using large numbers of chiral molecules.

Nanophotonic resonators such as plasmonic and dielectric nanoantennas can enhance the chiroptical response. However, two questions naturally arise: What are the dominant mechanisms of this enhancement and how can we actually quantify it?

A widespread approach to address these questions is to consider the local optical chirality $C \quad \mathbf{E}^* \cdot \mathbf{H}$ (prefactor depends on unit system), which has been shown to quantify the absorption difference between left- and right-handed circularly polarized light by single molecules [1]. This quantity can be easily calculated and optimized for arbitrarily complex electromagnetic environments [2], see figure 1. However, it does not account for the backaction of chiral molecules on the nanophotonic resonator, thus excluding possible effects such as resonant shifts.

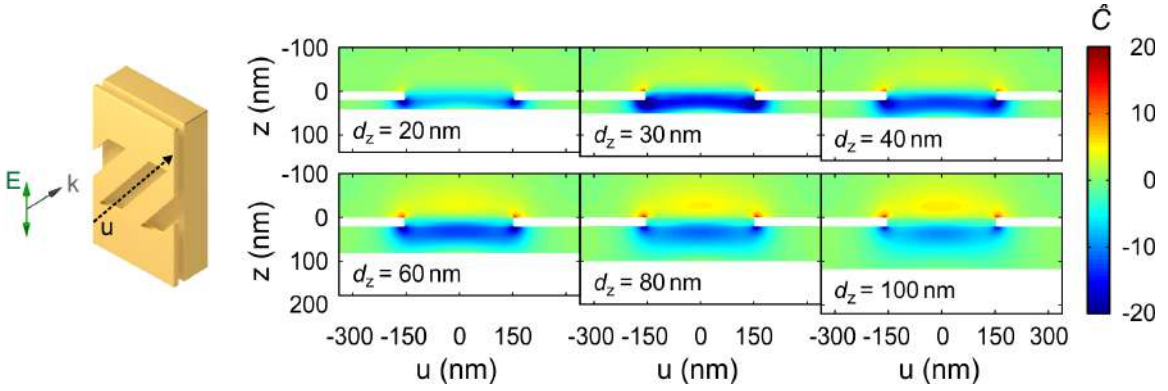

Figure 1: Local optical chirality C for inclined two-dimensional periodic arrays of slits in a gold film that is located at a distance d_z on top of a gold mirror. Figure taken from reference [2]

While full-wave simulations account for such backaction [3], they provide little insight into the underlying physics, and one needs to somehow quantify the enhanced chiral light-matter interaction. Regarding the physical insight, we have developed a first-order perturbation

theory [4] that allows us to approximate the near- and far-field response and indentify several contributions to enhance chiral light-matter interaction by nanophotonic resonators. The first one is a change in the excitation and emission efficiencies of the resonant states, which requires a coplanarity of the incident field and the dominant field components at the location of the chiral medium. The second one is a chirality-induced resonance shift, which surprisingly only occurs in chiral spatial arrangements of the resonator and the chiral medium. The third contribution is based on an interplay of nearly degenerate resonant states.

Playing with these contributions provides different strategies to enhance chiral light-matter interaction. Yet, we might ask what is the connection to the local optical chirality. Indeed, it turns out that the resonance shift can be brought into a form of an integral with the integrand being proportional to the local optical chirality for high-quality resonant states [4]. However, this intgrand is calculated for the resonant contributions alone, while the local optical chirality is usually derived by accounting for resonant and incident field. Thus, the local optical chirality is not a universal quanitity of the nanophononic resonator, since it depends on the underlying experimental conditions, while the resonant contributions are universal. We will analyze the connections and differences in detail.

Finally, we are going to address the question of measures for the enhancement of chiroptical response. Here, we focus on the far-field response. Experimentally accessible quantities are the transmission, reflection, and possible diffraction. From those, it is possible to calculate the circular dichroism as the absorption difference between left- and right-handed circularly polarized incident light. Since not all necessary terms to calculate circular dicroism are experimentally accessible, often only the difference in reflection or transmission is considered. Finally, a normalization or a conversion from intensities to degrees can be carried out. To quanitify the enhancement, these measures are then often normalized by expressions attributed to the system in the absence of resonant contributions. We are going to compare these various approaches and discuss under which circumstances they are equivalent and what are potential pitfalls, particularly when postprocessing experimentally accessible quantities and renormalizing them by some reference value. As it turns out, not all claims of huge enhancement factors actually rely on enormous resonant enhancement but are partially a consequence of how this enhancement is quanitified.

Emergent chirality, antiskyrmions and Bloch skyrmions in ferroelectrics

J. Hlinka[1]

[1]Institute of Physics, Czech Acad. Sci, Prauge, Czech Republic
*corresponding author: hlinka@fzu.cz

Abstract: The talk is summarizing symmetry aspects of magnetic and structural skyrmion defects and phases in ferroelectric crystals and relationships to the species of macroscopic chiral symmetry breaking.

In this talk, I would like to provide summary of our recent results and open questions related to magnetic and structural skyrmion and antiskyrmion topological defects, and ordered skyrmion and antiskyrmion phases in ferroelectric crystals. It concerns both chiral and nonchiral structures, and we shall discuss the relationships to the concept Aizu species of macroscopic chiral symmetry breaking[1-3]. Potentially, I would also like to discuss some unresolved challenges related to the interaction of crystals with skyrmion textures with the light as well as with the exotic light beams carrying a nonzero orbital angular momentum.

Abstract: We bring together the advantages of terahertz and optical spectroscopies to introduce TACOS (Terahertz-Assisted Chiro-Optical Spectroscopy), a novel approach for ultrafast and highly efficient imaging of molecular chirality. TACOS relies on driving nonlinear electronic dynamics with terahertz and few-cycle optical pulses, but it does not require optical carrier-envelope phase stability.

Like our hands, opposite versions of the same chiral molecule (enantiomers) behave identically unless they interact with another chiral entity. Telling them apart is vital, but also challenging. Traditional optical methods rely on the weak magnetic coupling between light and matter, yielding weak enantiosensitivity. The electric-dipole "revolution" [1] is transforming the landscape of molecular chiral discrimination with a new generation of chiro-optical methods offering orders-of-magnitude greater enantiosensitivity. Different "streams" of this revolution rely on analyzing different observables, but share one common ingredient: the chiro-optical response is driven by purely electric-dipole interactions – weak magnetic effects are not needed.

Locally chiral light [2-4], where the tip of the electric-field vector draws a chiral 3D Lissajous figure in time, can drive highly enantiosensitive *electronic* dynamics within the electric-dipole response. Such light can be created by overlapping two laser beams that propagate in different directions and carry several frequencies. However, non-collinear configurations lead to spatial modulations of the field's properties, such as amplitude, phase or polarization gratings, with spatial periodicities on the order of the wavelengths. In the case of optical frequencies, these are significantly smaller than typical interaction regions. Thus, one needs to carefully design the optical setup so that such gratings do not wash out enantiosensitive effects in the macroscopic response of the medium.

Locally chiral fields are not limited to optical frequencies. As shown by S. Eibenberger [5-7] and co-workers, one can drive highly enantiosensitive *rotational* dynamics by combining microwave fields with different frequencies propagating in different directions. Thanks to their longer wavelengths, these arrangements of microwave fields maintain their properties over spatial regions that can cover the size of typical molecular samples. This means that, in contrast with the optical domain, here one does not need to worry about a potential cancelation of the enantiosensitive response in the macroscopic response of the medium. However, microwaves are not well suited for *attochemistry*, an emerging field which aims to image and control chemical reactions by manipulating *electronic* motion in molecules on the attosecond timescale.

TACOS [8] brings the advantages of both approaches together and creates an opportunity for imaging and controlling molecular chirality at the level of electrons over large spatial regions. Our approach involves cross-polarized and cross-propagating THz and optical pulses interacting with a medium of randomly oriented chiral molecules, see Fig 1. Without the THz field, the local response of the medium to the optical pulse would be linearly polarised and insensitive to its handedness. The linear response to the THz field breaks this symmetry by transiently orienting the electronic clouds of the molecules. As a result, the non-linear response to the optical pulse acquires an enantiosensitive polarization component that is orthogonal to both driving fields and enables efficient chiral recognition: it leads to emission of harmonic light which has opposite polarizations in opposite enantiomers.

The multiphoton pathways giving rise to the enantiosensitive response are depicted in Fig. 1. Because both pathways involve absorption of the same number of optical photons, their relative amplitude and phase are not sensitive to the intensity and phase of the optical field. As a result, the polarization of the nonlinear optical response is not sensitive to the carrier-envelope phase of the optical pulse. In contrast, only the chiral pathway is sensitive to the THz field, and thus we can control the enantiosensitive response by adjusting the properties of the THz pulse.

Using the linear response to a THz pulse to electronically orient the molecules ensures that they maintain the same orientation over a spatial region on the order of half the THz wavelength and that the orientation persists during half the THz period. Thus, if the optical beam, the medium, or a substantial part of them is smaller than half the THz wavelength, the enantiosensitive response can be maintained across the interaction region, creating exciting opportunities for chiral attochemistry.

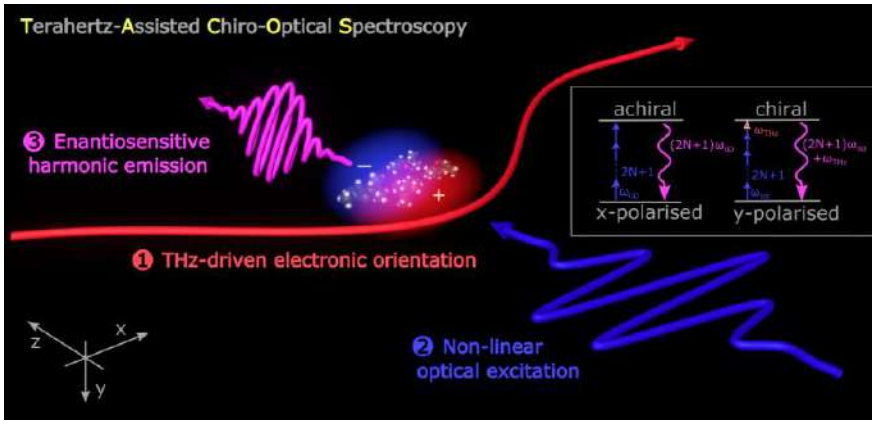

Figure 1. Step 1: a linearly polarized THz field (red) orients the electronic density of the medium via linear response, inducing anisotropy. **Step 2:** the non-linear response to an ultrashort optical pulse (blue) becomes twisted. **Step 3:** the medium radiates at new optical frequencies (magenta) with enantiosensitive elliptical polarization. The relevant multiphoton pathways are depicted in the inset (achiral and chiral).

Coherent dynamics of a magnon Bose–Einstein condensate – temporal coherence and correlation characteristics

A. A. Serha[1*]

[1]Fachbereich Physik and Landesforschungszentrum OPTIMAS,
Rheinland-Pfälzische Technische Universität Kaiserslautern-Landau, 67663 Kaiserslautern, Germany
[*]corresponding author: serha@rptu.de

Abstract: Nonlinear interactions in externally excited magnetic media can lead to Bose–Einstein condensation of spin-wave quanta—magnons. Using frequency- and time-resolved microwave detection techniques, we have observed the spontaneous formation of a coherent magnon BEC phase at the ferromagnetic resonance frequency in a perpendicularly magnetized magnetic film.

Bose–Einstein condensation (BEC) is the spontaneous accumulation of bosonic particles or quasiparticles at the minimum frequency of their spectrum. This can be achieved by a reduction in temperature or an increase in particle density. The second method is also relevant for systems with a temperature-dependent population, such as magnons, photons, polaritons, and excitons [1-3]. In an artificially overpopulated magnon gas in single-crystal ferromagnetic samples of yttrium iron garnet (YIG), BEC of magnons can be observed even at room temperature [4]. The spontaneous appearance of coherence is a key feature of BEC [5, 6] and determines effects such as supercurrents and Josephson oscillations [7]. Here, I present direct measurements of a magnon condensate's time and phase coherence by detecting microwave radiation from a parametrically pumped perpendicularly magnetized YIG film. In particular, I report the spontaneous narrowing of the spectrum line associated with this magnon state and demonstrate the appearance of a randomly coherent BEC phase in every single measurement.

This study was funded by the Deutsche Forschungsgemeinschaft (DFG, German Research Foundation) – TRR 173 – Grant No. 268565370 Spin+X.

Electron-phonon interaction in chiral crystal: Angular momentum and phonon chirality

J. Kishine,[1] T. Tateishi,[1] A. Kato[2]

[1]The Open University of Japan, Japan

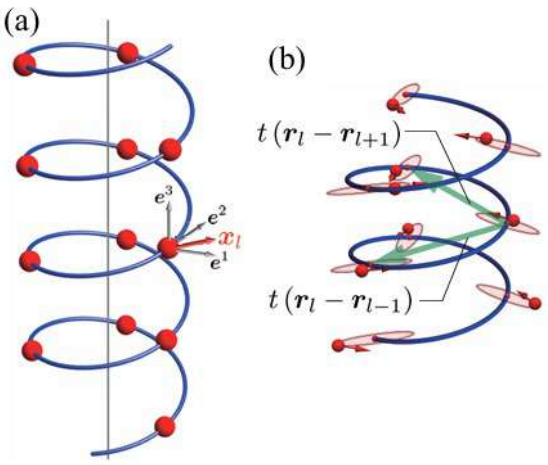
[2]Osaka Metropolitan University, Japan

Abstract: Chiral phonons in helical crystals enable angular momentum transfer in quantum materials. We establish a framework incorporating conserved crystal momentum and crystal angular momentum, deriving electron-phonon interactions. Examining Lipkin's Zilch and macroscopic angular momentum, we reveal insights into chiral systems, impacting optoelectronic, thermoelectric, and spintronic material design.

Chiral phonons in crystals with helical symmetry [Fig. (a)] play a crucial role in angular momentum transfer in quantum materials. In this work, we construct the wavefunction of chiral phonons in a chiral helical crystal, establishing a theoretical framework that rigorously incorporates both the crystal momentum (CM) and the crystal angular momentum (CAM) as conserved quantities. Based on this formulation, we derive the electron-chiral phonon interaction using the tight-binding scheme [Fig. (b)], ensuring explicit conservation of these quantities. A hallmark of chiral phonons is the mixing of longitudinal and transverse modes, which distinguishes them from conventional phonons. Unlike conventional electron-phonon interactions, where electrons couple only to longitudinal phonons, chiral helical crystals permit coupling to left- and right-handed chiral rotational modes, with the interaction vertex carrying CAM.

Furthermore, we analyze the phononic analogue of Lipkin's Zilch, a time-even pseudoscalar originally introduced in electromagnetism as

$$Z^{\mu} = \epsilon^{\mu\nu\rho\sigma}\partial_{\nu}\left(F_{\rho\lambda}\tilde{F}^{\lambda}{}_{\sigma}\right)$$



where $F_{\mu\nu}$ is the electromagnetic field tensor and $\tilde{F}_{\mu\nu}$ is its dual. In the context of chiral phonons, we extend this concept to phononic fields, providing a chirality measure analogous to circularly polarized light. By examining the interrelations between macroscopic angular momentum (MAM) and Zilch, we offer complementary perspectives on angular momentum dynamics in chiral materials. Our analysis shows that while CAM governs the interactions of chiral phonons with electrons, Zilch provides a global measure of phononic chirality, revealing novel conservation laws in vibrational dynamics.

These findings uncover intricate interactions between electronic and vibrational degrees of freedom, offering deeper insight into chiral quantum systems. The proposed framework, when combined with realistic electronic band structures incorporating spin-orbit coupling and first-principles phonon calculations, provides a powerful approach to elucidating angular momentum transfer mediated by phonons in chiral crystals. These insights hold significant implications for the understanding and design of chiral quantum materials with novel optoelectronic, thermoelectric, and spintronic functionalities, paving the way for advanced applications in quantum technologies.

Spin polarization induced by nonequilibrium fluctuation near the surface in chiral metals

Y. Kato[1,2*]
[1]Department of Basic Science, The University of Tokyo, Japan
[2]QuaRC, Institute of Molecular Science, Japan
Corresponding author: yusuke@phys.c.u-tokyo.ac.jp

Abstract: We theoretically address spin polarization induced by the fluctuating electric fields, i.e., noises in chiral metals, with the Boltzmann transport theory. Based on these results, we discuss chirality-induced spin selectivity (CISS) without biased inputs and the enantio-selective interaction between chiral materials and a magnetic substrate.

Recently, magnetic properties inherent to nonmagnetic chiral molecules [1,2], chiral metals [3,4] and chiral superconductors [5], which have been dubbed chirality-induced spin selectivity (CISS), have attracted much attention from chemists and physicists [6]. The term CISS now describes a general correlation between electron spin polarization and handedness of chiral materials [6]. Among various phenomena related CISS, the spin polarization near the edges in chiral molecules without intentional inputs is one of the issues to be addressed. This phenomenon has been inferred in experiments of enantio-specific adsorption of chiral molecules by a magnetic substrate [2].

In this presentation, we argue spin polarization near the surface in chiral metals subject to the fluctuating electric fields [7], as a theoretical basis for an analogous phenomenon observed in [2]. We consider the simplest model for chiral metals. The Hamiltonian is given by

$$\mathcal{H} = \frac{k^2}{2m} + \alpha \boldsymbol{\sigma} \cdot \boldsymbol{k}, \tag{1}$$

with $k = |\boldsymbol{k}|$ and a coupling constant α of the hedge-hog type antisymmetric spin-orbit interaction. The sign of α represents the chirality of the system and determines whether the wave vector $\boldsymbol{k}$ and the spin are parallel or antiparallel for a given spin-splitting band. We solve the Boltzmann equation for the chiral metal within the relaxation time approximation in the presence of fluctuating electric fields

$$E_\mu(t, \boldsymbol{r}) = \int_{-\infty}^{\infty} \frac{\mathrm{d}\omega}{2\pi} E_\mu(\omega, \boldsymbol{r}) e^{-\mathrm{i}\omega t} \tag{2}$$

that satisfies

$$\langle E_\mu(\omega, \boldsymbol{r}) \rangle = 0, \quad \langle E_\mu(\omega, \boldsymbol{r}) E_\nu(\omega', \boldsymbol{r}') \rangle = 2\pi \delta_{\mu\nu} S_E^{\mathrm{w}} \delta(\omega + \omega') g(|\boldsymbol{r} - \boldsymbol{r}'|), \tag{3a}$$

with a power spectrum S_E^{w} of the white noise and the spatial correlation of the fluctuating electric field as $g(|\boldsymbol{r} - \boldsymbol{r'}|) = \frac{e^{-|\boldsymbol{r}-\boldsymbol{r}'|/\lambda_E}}{8\pi\lambda_E^3}$,with a correlation length λ_E.

Figure 1 (a) shows the profile of the spin polarization in the presence of fluctuating electric fields (2) obeying Eq. (3) , near the surface in the chiral metal occupying a semi-infinite region with $z > 0$. The boundary $z = 0$ with the vacuum $z < 0$ is perfectly rough. This result is schematically drawn in Fig. 1(b), where the red arrows represent spin polarization when $\alpha > 0$. The sign of spin is the opposite when $\alpha < 0$

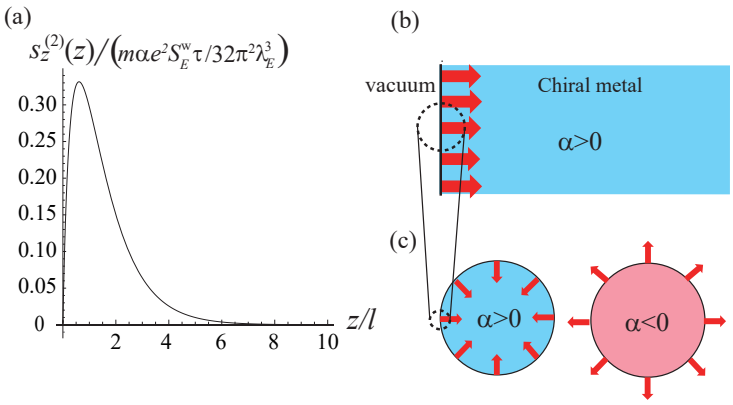

Figure 1: (a) Spin density induced by the fluctuating electric field. m, α, e, τ denote electron mass, the coupling constant of the spin-orbit interaction, and the relaxation time. The coordinate z is scaled by the mean free path ell. (b) Schematics of the spin polarization represented by the red arrows in the chiral metal with $\alpha > 0$. (c) The hedge-hog type spin polarization at the surface of the chiral metal with a spherical shape.

Our results also imply the hedge-hog type spin polarization in the sphere of the chiral metals, as shown in Fig. 1(c), where the radius of the nano-particle is assumed to be much larger than the mean free path. By Fig. 1(c), we emphasize that the spin polarization is chirality-dependent (enantio-selective in the terminology of chemistry [2]). This result is analogous to the antiparallel spin polarization at the edges in chiral molecules discussed in [2]

As an implication to experiments, the radial spin polarization shown in Fig. 1(c) in chiral metals could be used to separate the nanoparticle of chiral metals by a magnetic substrate, similarly to enantio-separation of chiral molecules [2].

Abstract: Advances in photonics enable precise control of structured light for imaging, sensing, and quantum applications. While bulky optics limit scalability, photonic integrated circuits (PICs) offer compact solutions. Here we present a reconfigurable PIC to measure and generate structured and twisted light, enhancing applications in imaging, sensing, and manipulation.

Advances in optics and photonics have led to unprecedented control of the spatial and temporal properties of light fields, with applications ranging from optical imaging and sensing to communication and quantum technologies [1]. Central to these developments is the strong demand for precise and scalable tools to measure, manipulate, and generate structured light. Traditional approaches often rely on bulky free-space optics, which limit integration and scalability in real-world applications. Photonic integrated circuits (PICs) offer a promising solution, enabling compact, robust, and highly flexible platforms for structured light applications [2–4].

In this paper we present a PIC designed for the measurement and generation of structured and twisted modes of light, implemented on a silicon-on-insulator platform [2, 3]. Our photonic chip consists of a mesh of Mach-Zehnder interferometers in combination with carefully arranged grating couplers acting as a free-space interface (see Fig. 1). By actively controlling the interferometers, we guide light across the photonic circuit, enabling the characterization and generation of various structured light fields sampled by an application-tailored array of grating couplers.

We analyze the sampled light using a theoretical framework based on transmission matrices to obtain information about intensity, phase, and polarization. We discuss the basic physical principles underlying our measurement scheme [4] and demonstrate its applicability as a photonic sensor by processing fundamental Gaussian modes and higher-order light modes such as Laguerre-Gaussian (LG) and Hermite-Gaussian modes, as well as combinations thereof. We demonstrate on the example of LG modes the distinction and sensing of orbital angular momentum (OAM) states of light as well as the handedness of their twisted phase fronts [2].

By operating the chip in reverse, with a single injection waveguide (see Fig. 2) combined with the interferometric on-chip control, this configuration also enables the fast and precise generation of complex structured light fields in free space with well-defined amplitude and phase distributions [3]. Our results prove that the presented photonic chip provides a flexible workbench for numerous applications as well as developments towards future applications in imaging, sensing, or manipulation in nanooptics [5].

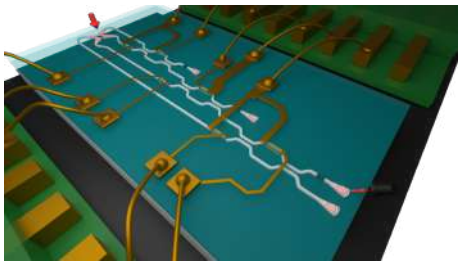

Figure 1: Simplified schematics of the photonic integrated circuit for light processing. Light is coupled into the chip through an application-tailored array of grating couplers, serving as a free-space interface. On-chip processing of the incoming light is performed by a mesh of actively controlled Mach-Zehnder interferometers, ultimately allowing for the extraction of information about its intensity, phase, and polarization through intensity measurements at the terminating waveguides through a correspondingly developed theoretical model.

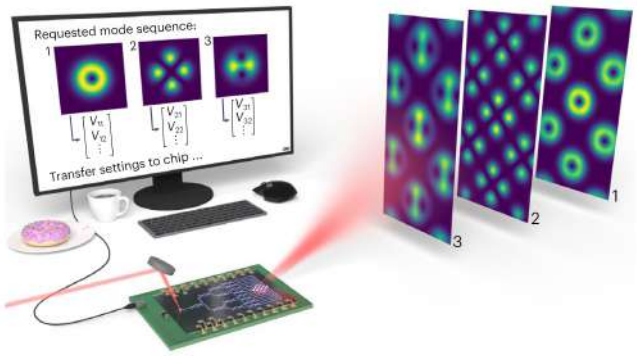

Figure 2: Overview of the light generation process using the photonic chip. A desired target field distribution or sequence is defined on a computer, upon which the required mesh configuration is calculated based on a corresponding theoretical model and transferred onto the chip. This allows distributing light from an injection waveguide in such a way that the chip re-emits it at terminating waveguides with tailored amplitude and phase, resulting in the desired far-field patterns, as exemplarily shown on the right. Reproduced with permission from Ref. [3].

Abstract: We show that textured spintronic emitters can be used as THz metamaterials for molding the vectorial distribution and the topological properties of the emitted fields. The proposed metastructures are shown to control the sub-wavelength characteristics of propagating modes with the possibility for novel applications, as demonstrated for the non-destructive supercurrent generation in Type-II superconductors.

In layered heterostructures hosting a ferromagnetic layer interfaced with a normal metal with strong spin-orbit coupling, heating with an infrared laser leads to a buildup of a spin-polarized current emanating from the magnetic layer. The current diffuses into the normal layer where it is converted into a swiftly decaying charge current pulse due to spin-orbital scattering. The resulting coherent broadband THz radiation [1] can be well enhanced by material compositions. This element for producing THz radiation is called spintronic THz emitter (STE) [2].

Here, we propose to exploit intrinsic interactions in the magnetic/normal metal system for generating metastructures of such spintronic THz emitters [3,4,5]. By performing analytical and numerical micromagnetic/electromagnetic simulations, we demonstrate that appropriately engineered STE metastructures are capable of producing broadband, strong THz radiation with a predefined polarization, orbital, chiral, and topological properties. An example is shown in Fig.1. To demonstrate the usefulness of the emitted fields we quantified the action of these fields on the order parameter of a Type-II superconducting micron-size Niobium disc (Fig.1). Using time-dependent Landau-Ginzburg equations, we show how the topology of the THz fields results in a texturing of the superconducting phase while the superconducting density remains almost constant leading to a superconducting current only (Fig.1). Further numerical simulations evidence that the structured THz fields are utilizable for generating and steering on the nanoscale Abrikosov vortices, which can be useful for a *ps*-control of the transport properties of nanoscale superconductors. Further examples including driving non-collinear magnetic texture will be discussed.

The results point to a new way for the generation of structured broadband THz fields with possible applications in the fields of optoelectronics, ultrafast magnetism, and superconductivity.

Tunable of Universal Quantum States at Weyl Semimetal Interstitial Interfaces with Magnetic Textures

E. Thareja[1], G. Pantano[1], I. Vekhter[2], and J. Gayles[1*]

[1]Department of Physics, University of South Florida, Tampa, FL 33620

[*]corresponding author: gayles@usf.edu

Abstract: Magnetic multilayers combining Weyl and skyrmionic topologies enable tunable electronic states with novel functionalities. We model Fermi-arc-like bound states at interfaces, demonstrating tunability via magnetic and electrostatic potentials. Using CoGe/FeGe interfaces, we show enhanced spin-orbit coupling and transport phenomena, optimizing Weyl-skyrmion interactions for next-generation spintronic devices.

Magnetic multilayers of alternating Weyl and Skyrmionic topologies are highly sought for novel device technology due to the possibility of efficiently manipulating magnetic textures and realizing phenomena such as the quantum anomalous Hall effect. In magnetic Weyl semimetals, the electronic band structure features pairs of Weyl nodes with opposite chirality charges, and the momentum space position of these nodes can reverse across a planar interface, giving rise to Fermi-arc-like bound states. We use a low-energy approximation to show that a magnetic interstitial layer can tune these states in three distinct ways: the electrostatic potential and in-plane magnetic potential components control the shape of the bound-state Fermi-arcs, with moderate in-plane magnetic potentials spin-filtering electrons a chirality-reversed planar interface (CRPI)[1].

$$H_{CRPI}(\boldsymbol{q}, x) = \mathrm{sgn}(x) ta(n\tau_z q_z \sin k_0 a) + (U_0\tau_0 + \boldsymbol{U}\cdot\boldsymbol{\tau})\delta(x) + \tau_y q_y + \tau_x \hat{q}_x \quad (1)$$

Additionally, both in-plane magnetic components and electrostatic potentials regulate electron transmission, while the ratio of in-plane to out-of-plane magnetic components modulates magnetic potential effects. This tunability stems from spin-momentum locking and chirality reversal at the interface, allowing for a material-dependent interchange of states. Some of our seminal results are summarized in Figure 1. Our model can be universally extended to investigate 2D planar twinning interfaces in B20 compounds using first-principles calculations, focusing on the Weyl semimetal CoGe[2] with a FeGe[3] interstitial. By employing supercell calculations that restrict the interface to the primitive cell, we demonstrate that the spin and anomalous Hall effects are significantly enhanced due to increased spin-orbit coupling and atomic potential variations at the interface. We explore the interplay between nonmagnetic Weyl semimetals and magnetic skyrmion-hosting systems in heterostructures across two thickness regimes: one with a semi-infinite Weyl system and a thin skyrmion-hosting film and the other with a semi-infinite skyrmion system and a thin Weyl film. This work defines the physical bounds of skyrmion-Weyl interactions and determines methods to maximize the synergy of these two systems

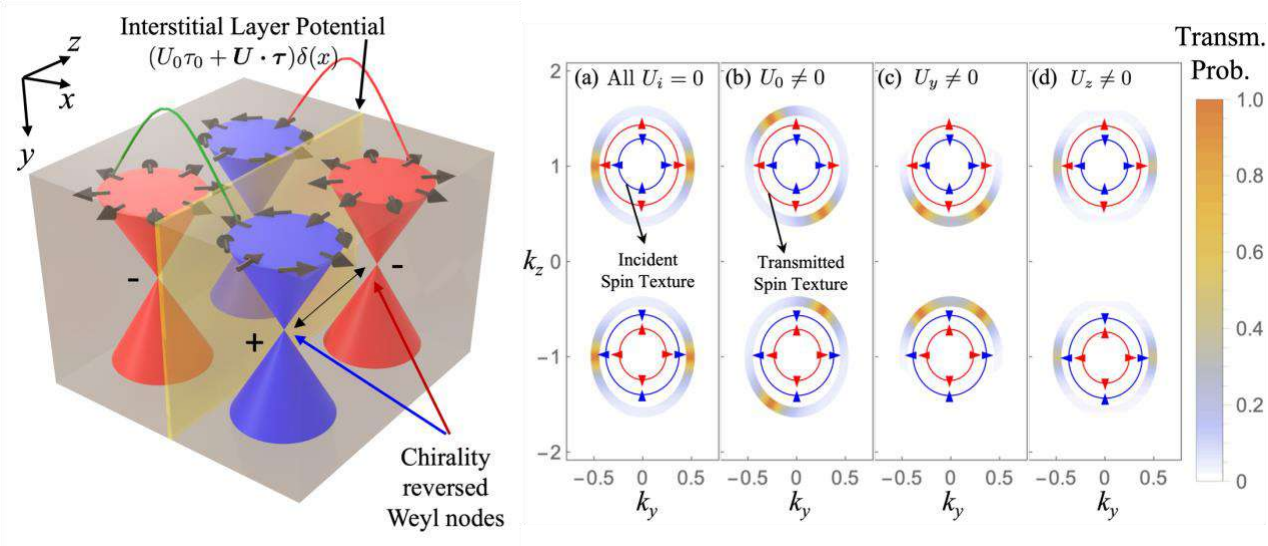

Figure 1. On the left is a schematic of the chirality-reversed planar interface (CRPI) which Weyl chirality denoted by red and blue. The interface is detailed by the yellow plane which consist of a δ electrostatic and magnetic potential. On the right are transport results of the transmission probability of electrons through the CRPI with variation of the inplane momenta. Inner (outer) circle arrows represent spin texture of the incident (transmitted) electron. The incident momentum component perpendicular to the interface kx = 0.1, energy E = 0.5t, and interface potentials (b) U_0 = t, (c) Uy = t and (d) Uz = t.

Nonlinear chiral quantum photonics

N. Rotenberg[1]

[1] Centre for Nanophotonics, Department of Physics, Engineering Physics & Astronomy, Queen's University, Kingston, Canada

[*]corresponding author: nir.rotenberg@queensu.ca

Abstract: This talk explores the physics that emerge when different coloured photons simultaneously and coherently interact with a chirally-coupled single quantum emitter. We focus on the strength with which these interactions can be used to control the phase and amplitude of the scattered photons, showing that surprising trends emerge when compared to the more standard symmetric (i.e., not chiral) or single-beam configurations.

Two fundamental aspects of quantum optics that have benefited tremendously from the maturation of nanophotonic platforms are chiral and coherent nonlinear optics. This is due to the ability of nanophotonic systems to control the flow and structure of light at the same nanoscale dimensions that characterize quantum emitters such as atoms or quantum dots. For chiral quantum optics, the ability to shape complex vector light-fields results in directional interactions, where photons only interact with an emitter if they flow in one direction down a waveguide [1]. In this ideal case, the presence of the quantum emitter is imprinted only on the phase of the scattered photons, and not their amplitude (as is more usual). For nonlinear quantum optics, nanophotonic structures can enhance the efficiency of light-matter interactions to the point where strong coherent nonlinearities can be observed at the few-photon level. For a single molecule and two colors of photons, for example, this has enabled the observation of efficient nonlinearities originally predicted by Mollow for atomic clouds, including the AC Stark shift (a tuning of the emitter resonance) an energy exchange between the photon beams, and even a coherent amplification [2].

Here, I discuss our recent work to understand the physics that emerges at the union of these two aspects: that is, the coherent optical nonlinearities that emerge in chiral quantum systems. I show how such a system may be modeled, and then use this model to explore the nonlinear signatures on the spectra of the scattered photons. Although this (chiral) system is very similar to the more symmetric scenario considered by Mollow, surprising differences emerge. These will be highlighted, as will the way in which they could enable all-optical control of quantum optical states. Finally, I will touch on the structures that support and enable few-photon chiral nonlinear optics.

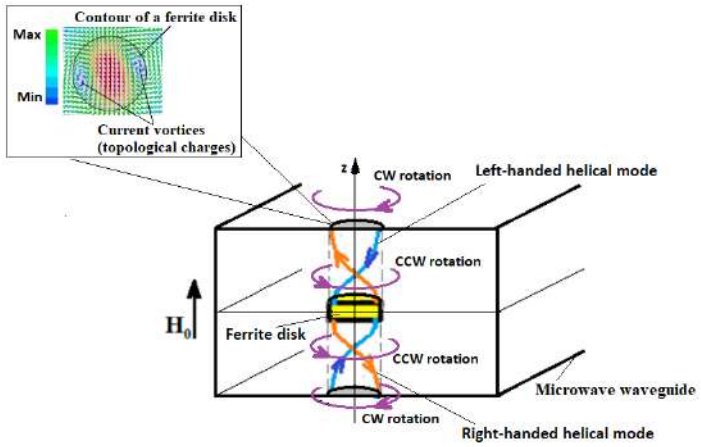
Symmetry in magnetoelectric electromagnetism

E. O. Kamenetskii *

Ben Gurion University of the Negev, Israel
*corresponding author: kmntsk@bgu.ac.il

Abstract: When studying the relationship between electromagnetism and magnetoelectricity, one of the main questions is how to unite these two entities of different symmetry properties. There are claims that quantum vacuum can asymmetrically transfer momentum to ME structures. Conversely, dynamic processes in ME structures cause asymmetric transfer of momentum to vacuum.



When studying the relationship between electromagnetism and magnetoelectricity, one of the main questions whether is it even possible to unite these two entities. This seems to be the cornerstone of magnetoelectric (ME) QED. While in electromagnetism we have space-time symmetry, ME processes are characterized by space-time symmetry breakings. The propagation of an EM wave is considered as a process of coupling between polar (e.g., E-field) and axial (e.g., H-field) vectors in a region the size of a wavelength. In the ME meta-atom, we observe the coupling between polar and axial vectors in the subwavelength region. There are claims that the vacuum can impart momentum asymmetrically on ME structures. Asymmetric momentum transfer arises from the ME structure since it breaks the temporal and spatial symmetries of electromagnetic modes.

In a 3D-confined structure of a magnetic insulator with magnetodipolar mode (MDM) oscillations, an orbital angular momentum (OAM) as well as a spin angular momentum (SAM) can be observed along a static magnetic field. In such a confined structure as quasi-2D ferrite disk, energy levels of MDM oscillations are quantized. Quantum confinement is characterized by a half-integer internal OAM, which is also associated with a circulating energy flow. The ME effect can be realized through magnetic modes that break both space-inversion and time-reversal symmetries. We consider ME magnon-photon coupling in cavities hosting ferrite ME meta-atoms. In this structure, quantum vacuum field fluctuations of the photons confined in the cavity are ME fields.

In the Figure, we show a structure in which a small ferrite disk is placed in a rectangular waveguide in close proximity to the waveguide walls. There are quasistatic solutions for helical modes. Rotation of the electric field in a ferrite disk is in the angular momentum balance with the rotation of electric currents and topological charges induced on the metal walls. We can observe *braided fields in vacuum* cylinders above and below a ferrite disk. The insertion shows the topology of surface electric currents on the upper wall of a waveguide. The whole picture of this topological structure rotates clockwise.

Inside a ferrite disk, the total angular momenta of CW and CCW modes do not eliminate each other. The CW – CCW asymmetry in a ferrite disk would give the vacuum an angular momentum in one azimuth direction, and the metal wall of the cavity would have to gain momentum in the opposite direction to compensate. The spin and orbital angular momentum of vacuum zero fluctuations contribute to the motion of electrons on the metal walls of the cavity. The possibility of extracting momentum from vacuum was discussed by Feigel [1]. Feigel argued that the momentum of vacuum zero fluctuations can occur only in a structure with PT-symmetry breakings. The main idea is to suggest a new quantum mechanical effect, namely the extraction of momentum from the electromagnetic vacuum oscillations. In the proposed effect, momentum is extracted from a vacuum field. This is different from the case of the Casimir

effect, in which energy is extracted from a vacuum field [2]. In Ref. [3], Feigel argued that rotating ME particles can generate changes in momentum of zero-point fluctuations, which result in the self-propulsion in quantum vacuum. The self-propulsion requires mechanical back-action from ME particle. To provide this ME particle should be a propellor-like device. In our case, we see that, while keeping the solid body motionless, the rotating fields of ME particles modify the momentum of quantum vacuum

One-way transparency at custom wavelengths via a layered magnetoelectric window

Abstract: We demonstrate one-way transparency in a tunable artificial structure of split-ring metamaterial and magnetic substrate, overcoming the temperature and resonance frequency limitations of multiferroic crystals. This dynamic interaction enables controllable non-reciprocal light propagation, paving the way for practical applications.

The study of controllable non-reciprocal light propagation is driven by both fundamental interest and telecommunication applications. So far, polarization-independent, switchable one-way transparency has only been achieved in multiferroic crystals under cryogenic temperatures and high magnetic fields, limiting its practical use. Here [1], we present an alternative approach using an artificial layered structure composed of split-ring metamaterial and magnetic substrate layers interacting in the dynamic regime. Our quasi-optical experiments in the GHz range show that this system breaks both time-reversal and spatial inversion symmetries under a moderate external magnetic field. The ability to tune its dynamic response and achieve controllable one-way transparency makes this method highly promising for real-world applications.

The proposed one-way transparent structure consists of a paramagnetic gadolinium gallium garnet ($Gd_3Ga_5O_{12}$, GGG) layer coupled to a two-dimensional periodic array of split-ring resonators. [**?**] In contrast to most of the experimental studies of non-reciprocity in multiferroics (e.g. [2, 3]), our sample possesses no spontaneous magnetic or ferroelectric ordering, and the magnetoelectric interaction is manifested only in the dynamic regime. The presence of both the paramagnetic and the split-ring layers and their electromagnetic coupling by the close vicinity are essential to the realization of the non-reciprocal propagation of light.

The physical mechanism behind the proposed effect can be understood through a simple argument. A linearly polarized electromagnetic wave propagating along the z-axis, with oscillating (ac) field components e_x and h_y, excites the split rings lying in the xy-plane via the electric channel when their gaps are aligned along the x-axis. Due to induction, currents in the rings generate a secondary ac magnetic field along the z-direction. When combined with the wave's h_y component, this results in an elliptically polarized magnetic field with a rotational axis along x. This field interacts with the paramagnetic moments in the GGG layer, which are aligned by the static external magnetic field.

The precession direction of the magnetic moments is dictated by the external field's sign, while the rotation sense of the ac-field h_{yz} is determined by the experimental geometry. Consequently, the two can either rotate in the same direction or in opposite directions. Ideally, in the first case, strong magnetic absorption occurs, whereas in the latter, absorption is suppressed.

In a our experiments, we observed a strongly asymmetric transmission of the structure with respect to the applied field direction. In a similar structure, where centrosymmetry is restored,

the light propagation was reciprocal. The results are interpreted in a phenomenological model consisting of coupled magnetic and electric oscillators.

Abstract: It is widely believed that the skyrmion Hall effect is absent in antiferromagnets because of the vanishing topological charge. However, the Aharonov-Casher theory indicates the possibility of topological effects for neutral particles. Here, we predict the skyrmion Hall effect in emerging altermagnets with zero net magnetization and zero skyrmion charge.

We first show that the neutral skyrmion manifests as a magnetic quadrupole in altermagnets.We reveal a hidden gauge field from the magnetic quadrupole, which induces the skyrmion Hall effect when driven by spin transfer torque. Interestingly, we identify a sign change of the Hall angle when one swaps the anisotropic exchange couplings in altermagnets. Furthermore, we demonstrate that both the velocity and Hall angle of altermagnetic skyrmions sensitively depend on the current direction. Our findings real the critical role of magnetic quadrupole in driving the skyrmion Hall effect with vanishing charge, and pave theway to discovering new Hall effect of neutral quasiparticles beyond magnetic skyrmions.

Abstract: Nanoparticles, with their ability to integrate multiple biomedical modalities, are among the most promising candidates for developing electromagnetically-responsive theranostic carriers. We present the concept of a metamaterial drug delivery capsule based on golden and magnetized vaterite, highlighting its distinct advantages in the emerging field of light-activated theranostics.

The presentation is based on our recent works [1], [2], [3], [4], [5], [6], [7], [8] and on a large set of new data. On top of our published results, we will demonstrate novel light-driven functions, including release, uptake acceleration, and cell treatment, underlying 'golden', 'gilded', and magnetized' vaterite advantages.

The fast-changing and evolving landscape of biomedical challenges motivates the continuous development of new functional platforms. Implantable devices made from biocompatible materials, capable of responding to optical signals and tailoring propagation of light waves, can be employed in health monitoring applications and therapeutics. The incorporation of such elements into living organisms can boost light-tissue interactions and shift conventional approaches toward precision medicine by opening new opportunities in sensing, photothermal therapy, photoacoustic tomography, and bioimaging. One of the grand challenges on those pathways is the miniaturization of biocompatible photonic structures along with providing multiple functionalities, such as monitoring of vital biological processes, light-responsive drug release, or local heating of a nanoscale area with the simultaneous measurement of its temperature.

The vaterite polymorph of calcium carbonate ($CaCO_3$) has a wide scope of potential applications in biology and medicine due to its outstanding combination of chemical, morphological, and physical properties. Being a fully biocompatible, FDA-approved material, it possesses a sponge-like morphology that effectively entraps a variety of functional materials. In addition, vaterite synthesis is a cheap, simple yet flexible process, yielding particles of different shapes depending on the chemicals used. As cargo release from vaterite particles is associated with structural transformations, an understanding of particle−fluid interactions is required for the future advancement of this material platform toward targeted drug delivery needs. Furthermore, the propulsion and diffusion of capsules are also dependent on interaction with a fluid environment, further motivating the performance of detailed studies with full control over parameters. Figure 1 is our executive summary. The panels on the left demonstrate the different shapes of fabricated particles. The shapes are not only responsible for optical properties but have a crucial impact on particle-cell interaction dynamics, as we will demonstrate. The right panel is 'golden' vaterite' – small 3nm size gold nanoparticles are diffused into the mesoporous matrix, thus creating a new metamaterial – this structure possesses an artificial localized plasmon resonance at the infrared spectral range, matching the biological transparency window. The bottom part is the imaging.

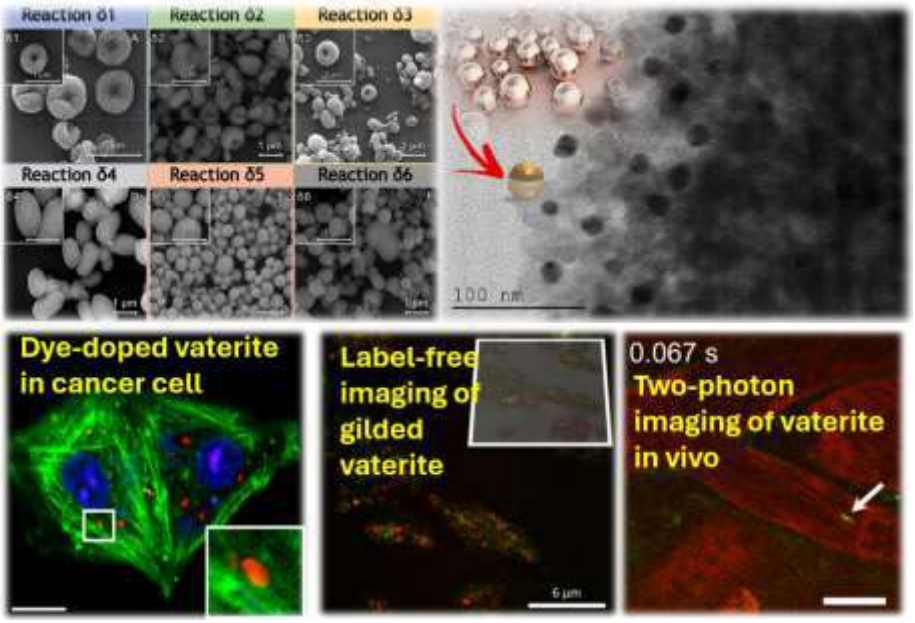

Fig. 1: Vaterite. (Left) Particles of different shapes to tailor both optical properties and particle-cell interaction dynamics. (Right) 'Golden' Vaterite – TEM image of CaCO3 matrix, loaded with gold nanoparticles. Bottom: Imaging of capsules in vitro and in vivo.

We demonstrated a new mesoscopic approach to on-demand engineering of electric and magnetic resonances in submicron low-index vaterite spherulites by filling them with gold nano inclusions. This makes it possible to increase the effective permittivity of the structure and provide efficient light trapping. The controllable variations in the volumetric gold filling factor allow tuning the spectral positions of both Mie resonances from the dipole to octupole order within the visible and near-infrared ranges. As an example of a potential thermal therapy application, we demonstrate an efficient laser heating of golden spherulites. Both water suspensions and individual spherulites, being illuminated with near-infrared light were investigated via time-resolved fluorometry and fluorescence-lifetime imaging microscopy (FLIM) and demonstrated an efficient local temperature elevation. The combination of various Mie resonances, high payload capacity for drugs, and the submicron size offer golden vaterite as a unique platform for multifunctional biomedical nanophotonic devices. The fabrication of the samples is made with the aid of colloidal chemistry.

Microwave coherent storage based on the long lifetime cavity electromechanical system

Tiefu Li[1*]

[1]Tsinghua University, China
[*]corresponding author: litf@tsinghua.edu.cn

Abstract: We demonstrate coherent microwave signal storage in a cavity electromechanical system. 55ms storage time has been experimentally realized. This result shows potential of cavity electromechanical systems with high-quality factors for the application in quantum storage devices for quantum computers.

Cavity optomechanical system holds potential for applications in ultrasensitive detection and serves as a fundamental element in the development of general quantum networks. Here we demonstrate the coherent storage of microwave signals in the gigahertz range using a cavity electromechanical system consisting of a high-quality SiN membrane resonator and a superconducting cavity. The membrane resonator was first cooled to its quantum ground state, where the phonon occupation number is 0.79. Subsequently, through the operations of writing, storing, and restoring, we demonstrate the coherent storage of microwave signals, which is manifested in the precise reproduction of the amplitude and phase of the written signal. The experimental results show a coherent storage time of 55 milliseconds, which means that less one thermal noise phonon is thermalized during this interval. This suggests that cavity electromechanical systems with high-quality factors hold significant potential for application in quantum storage devices for quantum computers.

Abstract:
The CISS effect, where chiral materials cause magnetic like behavior has different manifestations, including in electron transport, photoelectric effect, magnetic switching, and others. But can these effects be understood from one underlying theory? We show our spinterface model explains many of the effects. However, there is still work to be done.

The chirality-induced spin selectivity (CISS) effect was reported a quarter of a century ago and relates to a number of different observational findings that reveal that chiral layers (usually of molecules) can preferentially transmit electrons with specific spin orientations. This can influence transport properties, optical properties, enantioselectivity and more. The effect is clearly rising from the chirality of the layers, since the preferred spin orientation is reversed when the chirality is reversed.

Interest in the CISS effect has increased in the past decade due to being potentially useful for a variety of applications, including spintronic devices (chiral-based magnetic memory devices and non-magnetic efficient spin sources for spin logic devices), chiral semiconductors and semimetals for displays, spintronics and sensors, and even quantum technologies (quantum spin-state preparation and manipulation, and chiral-based qubits and quantum gates).

Interestingly, there is still no agreement on the origin of this effect. W number of theoretical explanations have been put forward to explain the CISS effect, yet to date, there is no agreement to the underlying physical mechanism. Moreover, it is not clear if the same mechanism is common to all the various experimental observation that were all clumped under the CISS umbrella, and even on what constitutes the CISS effect and its signatures.

In this talk we will show our approach, referred to as the spinterface model, as a plausible explanation for the CISS effect. We will present its strong suits in capturing quantitatively many of the experimental observations, but also critically discuss where it (and other theories) is still lacking. We will also describe a series of old and new predictions which arise from the spinterface model, which we invite the experimental CISS community to test and the theory community to challenge.

In this figure we exemplify the spinterface predication for the thermoelectric effect, showing current as a function of temperature-difference for different electrode magnetizations (parallel and antiparallel to the current flow, blue and orange lines respectively). For the relevant junction parameters (which will be discussed), the current can change direction when the electrode magnetization is reversed (or equivalently the molecular chirality), a signature of the spinterface mechanism. Inset: schematic of the thermo-electric CISS effect.

Plasmonic Nanocrystals for Hot Electron Generation and Chiral Photochemistry

Alexander Govorov

Ohio University, Athens, USA
govorov@ohio.edu

Abstract: Plasmonic nanostructures with hot spots exhibit significantly amplified optical and energy-related effects, including the hot-electron generation via plasmonic hot spots for photochemistry and photodetection, chiro-optical plasmonic phenomena for sensing chiral biomolecules and asymmetric photochemistry, and more.

Plasmonic nanostructures with hot spots exhibit significantly amplified optical and energy-related effects. This talk will cover the following phenomena:

(1) Plasmonic hot spots efficiently generate energetic electrons, which can be applied in photochemistry and photodetection.

(2) Nanostructures with small interparticle gaps enhance optical heat generation and confine high photo-temperatures to small volumes.

(3) Colloidal nanocrystal assemblies and metastructures with plasmon resonances significantly amplify biomolecules' chiral optical responses (circular dichroism) and induce chiral photochemical effects.

Manipulating Light-Driven Nanoscale Vectorial Currents

Hou-Tong Chen[1*]

[1]Los Alamos National Laboratory, USA

Abstract: By breaking the inversion symmetry in a class of optoelectronic metasurfaces, nanoscale vectorial photocurrents and terahertz cylindrical vector beams have been successfully demonstrated through integrating raindrop-shaped plasmonic nanoantennas on graphene as a model system. Appropriate symmetry designs further enable the control of the photocurrent direction utilizing the incident light polarization.

The generation directional photocurrent generally requires breaking the spatial inversion symmetry or time reverse symmetry. This could be accomplished by applying electric and/or magnetic fields, using materials without a centrosymmetric crystal structure, or extrinsically by nanostructure patterning. Here we show that in a class of optoelectronic metasurfaces, the inversion symmetry-broken plasmonic nanoantennas can lead to a preference of direction for the flow of the excited hot electron near the plasmonic hotspot, and generation of ultrafast terahertz radiation and vector beams when excited by femtosecond lasers.

More specifically, we integrate arrays of teardrop-shaped gold nanoantennas designed to resonate at near-infrared wavelengths (800 nm and 1550 nm) on top of large-area CVD graphene. The plasmonic hotspot concentrates the incident light and enhances the light absorption in graphene near the sharp tip of the nanoantenna. The excited hot electrons see a broken inversion symmetry environment: a fixed Fermi energy level for graphene underneath the gold nanoantenna and a tunable and different Fermi energy level for the bare graphene outside the gold nanoantenna. This leads to a difference in graphene Seebeck coefficient when hot electrons look toward left (i.e., gold nanoantenna) and right (i.e., bare graphene) directions, resulting in a net directional flow of charge carriers. We investigated such a light-driven directional current generation by varying the nanoantenna size, excitation fluence, wavelength and polarization, nanoantenna orientation patterning, and graphene Fermi energy level (by back gating).

We further investigated the generation of ultrafast terahertz radiation and cylindrical vector beams arising from the transient nanoscale vectorial photocurrents upon femtosecond laser excitations. We found that appropriate designs of nanoantenna symmetry allow us to control the direction of the nanoscale current by tuning the polarization direction of the linearly polarized incident light. The demonstrated optoelectronic metasurface platform can impact many research fields such as ultrafast terahertz generation, photodetection, microscopic magnetism, ultrafast spintronics, etc.

Abstract: Planar dielectric structures with mirror symmetry broken by substrate exhibit strong circular dichroism for normally and obliquely incident light. We demonstrate that these structures implemented on different material platforms, such as perovskites or noncentrosymmetric semiconductors, perform as efficient luminescent and second harmonic sources of circularly polarized light.

Chiral metasurfaces are capable of maximum optical chirality – selective interaction with light of particular helicity. The fundamental requirement for this is the absence of mirror symmetry planes. In practice, fabrication of structures with such symmetry demands complicated technological capabilities, as it involves assembling meta-atoms with different tilts or heights [1, 2]. The most straightforward method to break the mirror symmetry is to use a substrate [3]. Apart from applying such chiral metasurfaces as chiral mirrors or polarization filters, they can be used as efficient sources of chiral light. In this study, we demonstrate that a planar dielectric structure with mirror symmetry broken by a substrate can perform strongly chiral luminescence and second harmonic generation (SHG).

We consider a C_{4h}-symmetric photonic crystal slab (PCS), see Figure 1a), which does not convert polarization of normally incident waves. Without substrate, the PCS is optically non-chiral. Upon a substrate, the PCS exhibits a pair of near-maximum chiral transmission resonances for left circularly polarized (LCP) and right circularly polarized (RCP) light, Figure 1b). Note that the transmission chirality is maintained when the light is incident at a small angle from the normal [3]. To analyze chiral luminescence capabilities of such PCS made of perovskite semiconductor $MAPbBr_3$, we model the spectra and the degree of circular polarization (DCP) of emitted light in COMSOL Multiphysics using the reciprocity principle. We obtain that the metasurface emits into a narrow cone between $\pm 5^\circ$ along the side and $\pm 2^\circ$ along the diagonal of the PCS unit cell. The DCP achieves the values of ± 0.8 within this directions, see Figure 1c).

We also model in COMSOL Multiphysics SHG by a metasurface of similar design with the PCS made of noncentrosymmetric semiconductor AlGaAs with the normal directed along the [101] crystallographic axis. Pumping wavelength is varied in order to generate second harmonic (SH) in the range covering the chiral linear transmission resonances, see Figure 1b). If the metasurface is pumped by RCP or LCP light, the SH intensity spectra manifest Fano-type resonances, see Figure 1d). Almost full conversion of circular polarization during SHG is observed, similarly to the performance of a homogeneous layer of AlGaAs of the same crystal orientation. In the case of linearly polarized pumping, strong dependence on the pumping polarization direction relatively to the AlGaAs crystal axis is observed. When the direction of the pumping polarization coincides with the crystal axis, i.e., $\alpha = 0^\circ$ on Figure 1e), Lorentz-type resonances are observed. When the direction of the pumping polarization is perpendicular to the crystal axis, i.e., $\alpha = \pm 90^\circ$ on Figure 1e), Fano-type resonances are observed.

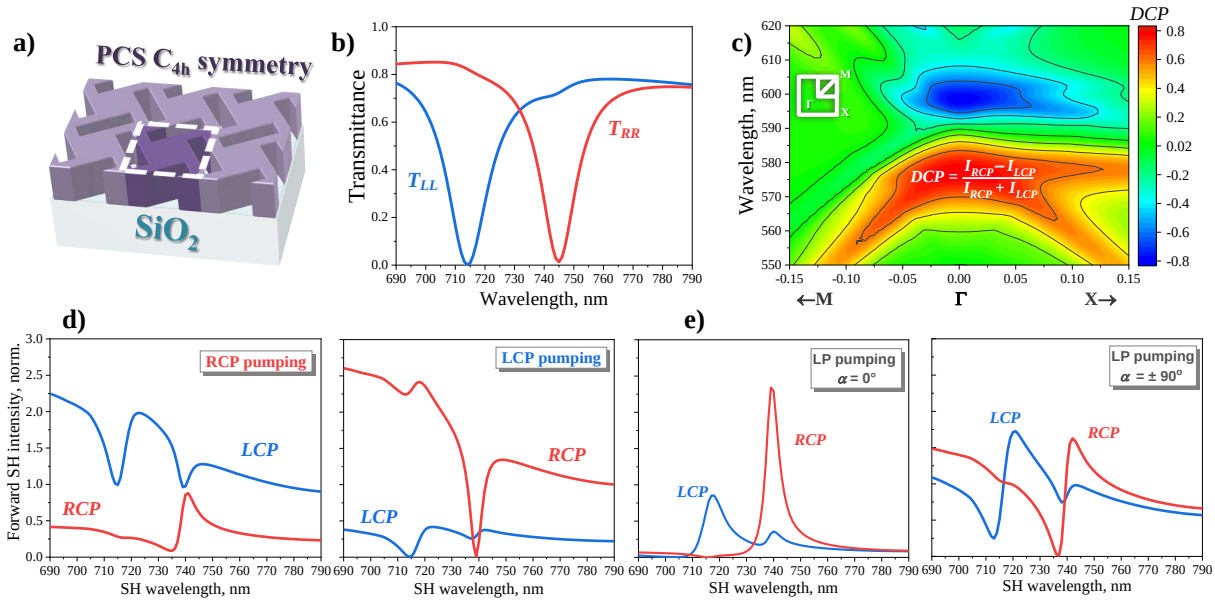

Figure 1: a) Scheme of the planar chiral structure: C_{4h}-symmetric PCS on a SiO_2 substrate with the unit cell marked by white dashed square. b) Simulated transmission spectra of LCP and RCP light of an AlGaAs PCS on glass. c) Colormap of luminescence DCP of a $MAPbBr_3$ PCS on glass in the axes of the in-plane wavenumber and wavelength. Spectra of SH intensity generated by circularly polarized (d) and linearly polarized (e) pumping of an AlGaAs PCS on glass. Different angles α between the pumping polarization and the AlGaAs crystal axis are shown in e).

In this study, we consider rotational symmetric PCSs on substrates that exhibit maximum optical chirality in linear transmission. We demonstrate the versatility of such structures for applications in chiral optics as luminescent emitters of circularly polarized light of either handedness at very close wavelengths. We also show that they can perform as nonlinear sources of chiral light of either handedness depending on the pumping field polarization and wavelength.

Abstract: Impact of Bi, P and Mn incorporation into GaAs layers on their electronic and band structures as well as magnetic and structural properties has been studied. A set of the homogenous (Ga,Mn)(P,As) layers with 8% of Mn and 32% of P contents and (Ga,Mn)(Bi,As) layers with 4% of Mn and 0.3% of Bi contents of high structural perfection have been grown by low-temperature molecular-beam epitaxy. Embedding P ions into the GaAs crystal lattice leads to an increase in the band gap, while Bi and Mn impurities lead to its decrease. A significant impact of Mn interstitial impurities on the structural and magnetic properties of the films was observed. We observe an enhancement of charge density in the presence of Mn. The schematic energy band diagrams for the LT-GaAs, (Ga,Mn)(Bi,As) and (Ga,Mn) (P,As) were proposed.

Dilute quaternary III-V semiconductors such as (Ga,Mn)(Bi,As) and (Ga,Mn)(P,As) offer a unique platform to explore spintronic functionalities by combining semiconducting behavior with ferromagnetism [1]. In these materials, Mn atoms act as acceptors, increasing hole concentration and mediating ferromagnetic exchange, while Bi and P substitute for As, modifying the band structure and spin–orbit interactions [2–4]. Bi narrows the band gap and enhances spin–orbit coupling, enabling phenomena such as anisotropic magnetoresistance and spin–orbit torque [5]. P doping, on the other hand, introduces tensile strain and promotes perpendicular magnetic anisotropy and anomalous Hall effect [6]. In this study, we investigate the structural, magnetic, and optical properties of (Ga,Mn)(Bi,As) and (Ga,Mn)(P,As) nanofilms using HRXRD, micro-Raman spectroscopy, FTIR, spectroscopic ellipsometry, and SQUID magnetometry [5–7]. Our results provide critical insights into band structure evolution, magnetic anisotropy, Curie temperature, and spin-related effects, contributing to the development of next-generation spintronic devices.

HRXRD confirmed high crystalline quality, pseudomorphic growth, and strain variations due to Bi (compressive) and P (tensile) incorporation [8, 9]. Annealing led to partial strain relaxation in all samples. SQUID magnetometry revealed ferromagnetic ordering at low temperatures in all systems. (Ga,Mn)(Bi,As) films exhibited easy-plane magnetic anisotropy with in-plane 〈100〉 axes, while tensile-strained (Ga,Mn)(P,As)

showed perpendicular magnetic anisotropy. Micro-Raman data also confirmed enhanced and more uniform hole distribution after annealing, leading to increased Curie temperatures (Tc), consistent with SQUID results.

The optical properties of the epitaxial films were investigated using spectroscopic ellipsometry (SE) [10, 11]. From SE measurements the spectral dependences of the ellipsometric angles $\Psi(\lambda)$ and $\Delta(\lambda)$ are obtained, allowing us to calculate the effective complex dielectric function $\varepsilon(E) = \varepsilon_1(E) + i\varepsilon_2(E)$. The analysis of the optical transition energies enables elucidation of the behavior of the Fermi level in *p*-type samples depending on the acceptor-doping level.
