Summarizing all the experimental results, we propose the schematic model of the energy band diagrams for LT-GaAs, (Ga,Mn)(Bi,As) and (Ga,Mn)(P,As) layers. For the LT-GaAs the transitions originating from heavy-, light-hole and spin-orbit split off sub-bands (denoted by HH, LH and SO, respectively) to the conduction band at the critical point of the Brillouin zone are indicated. The Fermi level (red dashed line) is located within the band gap due to a large amount of arsenic antisite (As_{Ga}) double donor defects originating from the low-temperature growth conditions. For the disordered-valence-band regime in high-Mn-doped epitaxial layers of (Ga,Mn)(Bi,As) the impurity band and the host valence band merge into one inseparable band, whose tail may still contain localized states (shaded parabolas) depending on the free carrier concentration and disorder. The Fermi levels lie within the strongly disturbed valence band, which, in turn, is extended into the band gap as a result of the carrier-induced many-body effects. For the (Ga,Mn)(P,As) the Fermi level is located in-gap Mn impurity states – possibly hybridized with the valence band.

This research is supported by the IEEE "2025Magnetism in Ukraine Initiative."

Abstract: Using free space setup we observed a remarkable change of the reflection and transmission at frequencies of 4-7 GHz upon the matrix polymerization with embedded magnetic microwire inclusions. Observed dependencies are attributed to the influence of heating and stresses variation on magnetic properties of magnetic microwires during the matrix polymerization.

One of the common problems in the composite materials is the contactless stresses and temperature monitoring. One of the promising solutions addressing the problem of non-destructive fiber reinforced composites, FRC, monitoring is a novel sensing technique involving free space microwave spectroscopy utilizing ferromagnetic microwire inclusions presenting the high frequency impedance quite sensitive to tensile stress and magnetic field [1,2]. Recently several successful attempts for non-destructive FRC monitoring have been reported [2,3].

In this paper, we present our last results on studies of magnetic properties of glass-coated Co-rich microwires and on in-situ polymerization process monitoring of the FRC with Co-rich glass-coated microwires inclusions.

We used inclusions of Co-rich glass-coated $Co_{65.4}Fe_{3.8}Ni_1B_{13.8}Si_{13}Mo_{1.35}C_{1.65}$ (metallic nucleus diameter, d=18.8 μm, total diameter, D=22.2 μm) microwires with low negative magnetostriction coefficients, λ_s, prepared by Taylor-Ulitovsky technique described elsewhere [3].

Studied microwires present good (coercivity of about 10 A/m), high giant magnetoimpedance GMI effect (GMI ratio about 100%).

For the composite matrix we used a vinylester resin (DERAKANE 8084) resin, accelerated with Cobalt Octoate (0,3 pph) and catalyzed with Methyl Ethyl Ketona (MEK 60%, 1,5 pph).

We used the free space measurement system consisting of two broadband horn antennas fixed at the anechoic chamber and a vector network analyzer for the in-situ experiments on polymerization of the composite placed inside the anechoic chamber, as previously described in details in [1]. The reflection (R) and transmission (T) coefficients were measured in free-space. As recently reported [3], the matrix polymerization produces a heating of the composite up to 80 ºC. On the other hand, when a resin polymerizes, it shrinks, since the solid obtained will have a smaller volume than the monomer from which it started. The volume shrinkage is of about 8.2 %. The cured resin presents the following mechanical properties: a tensile strength of 76 MPa, a tensile modulus of 2.9 GPa, and a tensile elongation of 8-10%.

As shown in Figure 1, significant variation in the T parameter is observed in the frequency range, *f*, of 4-7

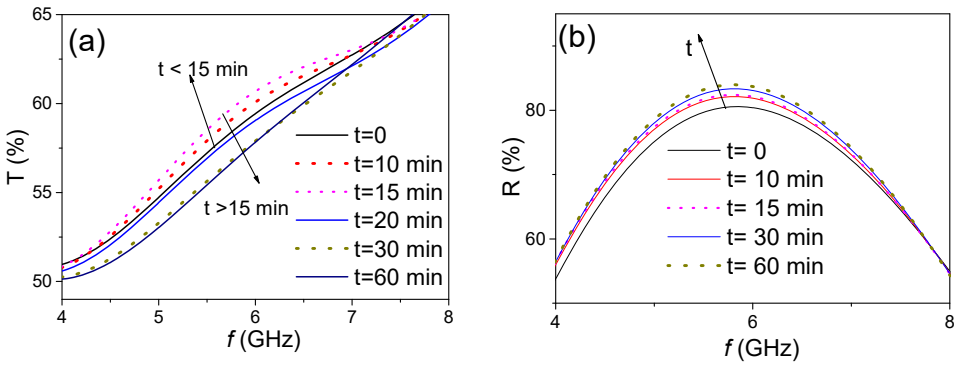

Figure 1. The Transmission, T (a) and reflection, R (b) parameters measured using free-space system during the composite polymerization.

GHz during thermoset matrix polymerization. Additionally, some changes in the R-parameter are also observed over a wide frequency range (Figure 1b).

The observed *T(f)* dependencies with are non- monotonic (see Figure 1a): there is an initial increase in T up to t=15 min (at f≈4-7 GHz), followed by a decrease in T for t>15 min. Previously, heating to 80° C and subsequent cooling of FRC during polymerization was experimentally demonstrated. Additionally, the matrix generally shrinks during cooling. Therefore, we can assume that the matrix shrinkage produces compressive stresses in magnetic nucleus of glass-coated microwires.

These experimental findings are crucial for the development of a new sensing technique that enables non-destructive and contactless monitoring of the composites with tunable magnetic permittivity sensitive to applied stress and temperature with ferromagnetic glass-coated microwire inclusions with magnetic properties sensitive to applied stress and temperature variations.

The Generation of Two Distinct Berry Phases on the Surface of a Twisted Triangular Möbius Cavity Resonator

E. C. I. Paterson[1], M. E. Tobar[1*], M. Goryachev[1*] and J. F. Bourhill[2]
[1]Department of Physics, University of Western Australia, Australia
22734222@student.uwa.edu.au (E. C. I. Paterson)

We present the experimental observation of two distinct Berry phases ($\Pi = \pm\frac{2\pi}{3}$) on the surface of a microwave Möbius cavity resonator supporting the TE_{10} mode. These phases arise from self-interference-induced helicity $\mathscr{H}$. This resonator consists of a twisted, hollow equilateral triangular prism with mirror asymmetry, bent around on itself to form a ring.

The Berry phase (Π) is a topologically protected phase factor generated in both quantum and classical systems undergoing cyclical evolution. The accumulation of a π spin-redirection Berry phase has been experimentally observed in optical Möbius strip cavities. This Berry phase is an example of a holonomy, where due to the curved surface of the Möbius resonator the wave vector undergoes a change in it's angular momentum as it travels the closed loop and returns to it's initial position, accumulating a phase shift. Here, we investigate its topological generation on an equilaterial triangular cross-section microwave Möbius resonator.

The Möbius resonator consists of a twisted equilateral triangular hollow prism bent into a ring, as shown in the subplot of Fig. 1(a). If the twist is reversed halfway along its length, the angular momentum of the wave vector returns to its initial orientation after a full circulation. This configuration, along with the homeomorphic torus resonator with zero net twist ($\phi = 0$), as seen in Fig. 1(b), is referred to as the *mirror-symmetric cavity*. In this configuration, the wave vector interferes in phase, accumulating no Berry phase and forming a standing wave pattern with integer azimuthal mode numbers n. In contrast, the Möbius configurations form standing wave patterns with mode numbers of the form $n \pm \frac{1}{3}$, where n is an integer, due to the wave vector requiring three round trips of the cavity before interfering with itself in-phase.

To confirm the expected mode number behavior, we simulated the Möbius resonator with three different twist angles, $\phi = \frac{2\pi}{3}$, $\frac{4\pi}{3}$, and 2π, along with the torus resonator, using the finite element method (FEM). Because the modes in the bulk of the resonator can be fully determined by its surface according to the holographic principle [2], we determined n by counting the number of anti-nodes in the azimuthal tangential surface current density ($\mathbf{K}_{\beta\perp}$) over one loop of the resonator and dividing by the number of windings.

As shown in Fig. 1(a), the TE_{10} mode frequencies in both the Möbius and torus resonators follow the same dispersion relationship, with the fractional ($\mathbb{Z} \pm \frac{1}{3}$) TE_{10} modes in the Möbius resonator lying inbetween the integer TE_{10} modes in the torus resonator.

The Berry phase Π is related to the frequency shift (Δf_i) required to align the fractional modes in the Möbius resonator with the integer modes in the mirror-symmetric resonator. This relationship is given by

$$\Pi = \Delta f_i 4\pi^2 R/c \quad \overline{1 \in \left(\frac{2c}{3v f_i^c}\right)^2} \tag{1}$$

where $\Delta f_i = f^m_{i+\Delta n} \in f^c_i$ is the frequency difference between the $TE_{10(i+\Delta n)}$ mode in the Möbius cavity ($f^m_{i+\Delta n}$) and the TE_{10i} mode in the mirror-symmetric cavity (f^c_i). Here, v is the vertex length of the triangular cross-section, R is the radius of both cavities, and c is the speed of light.

The TE_{10} modes in the Möbius resonator generate electromagnetic helicity $\mathscr{H}$ [3] due to self-interference as they travel the closed loop of the resonator. For the $\phi = \frac{2\pi}{3}$ twisted Möbius

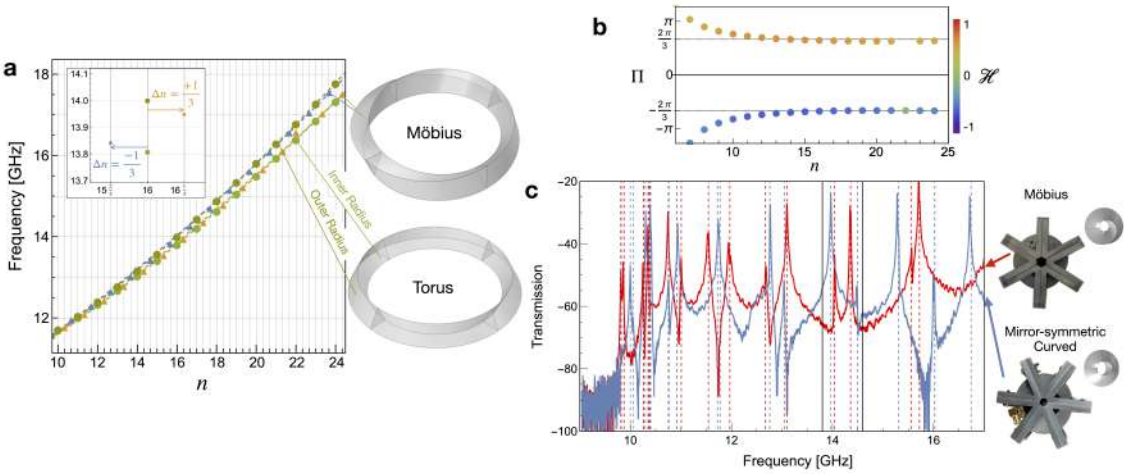

Figure 1: (a) The eigenfrequencies of the TE_{10n} modes as a function of azimuthal mode number n for the trinagular Möbius resonator with a twist of $\phi = \frac{2\pi}{3}$ and torus resonator. (b) Berry phase Π as a function of n with associated $\mathscr{H}$ of the mode depicted by colour, where the asymptotic limits are illustrated as black dashed gridlines. (c) The experimental S_{21} transmission measurements were performed on two resonators: a 3D-printed mirror-symmetric resonator (blue); and a Möbius resonator (red). Both resonators have an absolute twist angle of $\phi = \frac{2\pi}{3}$.

resonator, the positive and negative $\mathscr{H}$ modes have mode numbers adjusted by $\Delta n = +\frac{1}{3}$ or $\Delta n = \in \frac{1}{3}$, respectively, compared to the two radii modes of the mirror-symmetric resonator. Consequently, the sign of the mode's $\mathscr{H}$ corresponds to the sign of the accumulated Π, as demonstrated in Fig. 1(b). In the case of the $\phi = 2\pi$ twisted Möbius resonator, the mode numbers remain constrained to integer values, indicating no Berry phase accumulation, as would be expected.

To validate the expected frequency shift in the mirror-symmetric and Möbius resonators, we 3D-printed aluminum prototypes. The measured transmission spectra are compared with the eigenfrequencies obtained from FEM, as shown by the gridlines in Fig. 1(c). Strong agreement between the transmission peaks and simulation results confirms the presence of two distinct Berry phases ($\Pi = \pm\frac{2\pi}{3}$).

The topologically protected nature of the Berry phase renders it resilient to dynamic perturbations, such as environmental noise, ensuring gauge invariance throughout its evolution and hence the potential to be exploited to encode information via prime factorisation [1] or pack information more densely.

Abstract: By employing customizable anodic aluminum oxide templates, we achieve precise geometrical control of nanostructures, including their sizes, in-plane/out-of-plane shapes, and spatial arrangements. This approach offers a cost-effective, scalable method for fabricating metamaterials.

Structural engineering of metamaterials provides a versatile platform to adjust their macroscopic properties [1]. Controlling the geometrical parameters (i.e., size, shape, and spatial arrangement) of nanostructured metamaterials have been the central aspects of scientific investigations and practical applications. Low-cost high-yield template-guided techniques have been a workhorse for the fabrication of such metamaterials. Here we report designable anodic aluminum oxide templates with well-defined pore features within templates in terms of in-plane and out-of-plane shape, size, spatial configuration, and pore combination [2]. By using designable anodic aluminum oxide template, we realize geometrical controlling of nanostructured metamaterials over their sizes, in-plane/out-of-plane shapes, and spatial arrangements. Integrating geometrically designable metamaterials into optoelectronic devices [3-4] and magnetic devices [5], the resulting performance can be obviously enhanced.

Acoustic lattice resonances and generalised Rayleigh–Bloch waves

Abstract: Rayleigh–Bloch waves are modes localised to periodic arrays of scatterers with unbounded unit cells. We study them for line arrays of sound-hard scatterers embedded in an acoustic medium above the cut-off, both theoretically and experimentally, in which we observe the first generalised Rayleigh–Bloch waves in the radiative regime.

One-dimensionally periodic lattices (with appropriate boundary conditions on the scatterers) support surface waves that propagate along and exponentially decay away from the lattice. These exist under many guises for both scalar and vector wave regimes from acoustics and electromagnetism to linear water waves and elasticity. Distinct from naturally occurring interfacial surface waves (e.g. Rayleigh, Stonely and Scholte waves, or surface plasmon polaritons), the waves we allude to owe their existence to the underlying embedded periodic lattice and are thus commonly termed Rayleigh–Bloch (RB) waves; they exist on infinite lattices, with the criterion for their existence having been analysed in the context of functional analysis for some time [1]. In particular, they differ from pure Bloch waves that exist in cells which are bounded (e.g. an infinite 2D phononic crystal), as RB waves exist in 1D lattices with an unbounded unit cell, resembling a strip or ribbon, and they are known to have a large influence on the response of the corresponding semi-infinite or finite structures with equally spaced bodies.

Here, we study RB waves for line arrays of sound-hard circular scatterers embedded in a two-dimensional acoustic medium, for which it has recently been shown that they exist for higher frequencies than previously thought. Moreover, it was shown that RB waves can cut off (disappear) and cut on (reappear), and additional Rayleigh–Bloch waves can cut on and interact with the existing ones [2]. These complicated behaviours are reconsidered using a family of quasi-periodic Green's functions that allow particular plane-wave components to become unbounded away from the array so as to trace the trajectories of the Rayleigh–Bloch wavenumbers as they swap between Riemann sheets that are categorized according to the unbounded plane wave(s) and provide new understanding of RB waves around the critical frequency intervals where they cut on/cut off/interact [3].

More specifically, to find acoustic RB waves, we seek solutions ϕ of the 2D Helmholtz equation

$$(\Delta + k^2)\,\phi = 0, \tag{1}$$

in the (x,y)-plane with sound-hard (Neumann) boundary conditions applied on periodically spaced circular scatterers with boundary Γ and separation a, that satisfy both radiation and Bloch conditions, i.e.

$$\partial_{\boldsymbol{n}}\phi = 0 \qquad \text{on } \Gamma, \tag{2a}$$

$$\phi \to 0 \qquad \text{as } |y| \to \infty, \tag{2b}$$

$$\phi_R = \mathrm{e}^{\mathrm{i}R\beta}\,\phi_0, \tag{2c}$$

$$\partial_x\phi_R = \mathrm{e}^{\mathrm{i}R\beta}\,\partial_x\phi_0, \tag{2d}$$

where $\boldsymbol{n}$ is the outward surface normal, ϕ_0 is the solution in the fundamental cell and ϕ_R is the solution in the R^{th} cell at a distance $R = n\,a$ for $n \in Z$. Solutions to this problem are known as pure RB surface waves [1] with the prescribed values of k^2, at which they occur, being eigenvalues of the operator $-\Delta$ subject to (2). As is often the case, a non-dimensional form is adopted and, as such, k is a wavenumber that acts as a proxy for a prescribed angular frequency. With this, β represents the RB wavenumber, i.e. the component of the wavevector parallel to the array.

The unboundedness of the periodicity cell and the associated existence of a continuous spectrum make it difficult to compute RB wavenumbers above the first cut-off induced by the Bloch conditions (2c–d). We present a method for solving this problem by introducing a family of quasi-periodic Green's functions that allow particular plane-wave components to become unbounded away from the array [3]. The Green's function formulation is combined with the block Sakurai–Sugiura method to trace the trajectories of the RB wavenumbers as they swap between Riemann sheets that are categorized according to the unbounded plane wave(s). The Green's function approach allows the point spectrum to be calculated separately from the continuous spectrum, which facilitates analysis of critical points where RB waves cut on or cut off. The Green's function solution method also gives a convenient ansatz for the far-field of the eigenmodes, which allows the modes to be identified as decaying away from the grating (thus, in the point spectrum, and embedded if the eigenvalue lies on a branch cut) or bounded but non-decaying (thus, in the continuous spectrum). Moreover, the Green's function approach allows the eigenpairs to be generalised to unbounded solutions that grow away from the array, which allows RB waves to be tracked in frequency space after they cut off or before they cut on.

These theoretical investigations are complemented by experimental results in airborne acoustics, in which we experimentally observe the first generalised RB waves above the first cut-off, i.e., in the radiative regime. We consider radiative acoustic lattice resonances along a diffraction grating and connect them to generalised RB waves by considering both short and long arrays of non-resonant 2D cylindrical Neumann scatterers embedded in air, forming both small and large-scale acoustic gratings for airborne sound in the audible frequency range. On short arrays, we observe finite-lattice resonances under continuous wave excitation, and on long arrays, we observe propagating Rayleigh–Bloch waves under pulsed excitation [3]. The first generalised RB mode is shown to exist over a range of frequencies for an example aspect ratio predicted by [2]. In airborne acoustics, we are able to achieve both continuous wave and pulsed excitations that permit the excitation of collective acoustic lattice resonances on short arrays and propagating generalised RB waves on long arrays, respectively. In doing so, we demonstrate that they are one and the same and that their interpretation is unified through the analogue of polarisability of the scatterers and the gaps between them.

Reconfigurable Topological Insulators and Acoustic Devices Based on an Electroacoustic Material Platform

M. J. Leamy[1*]

[1]Woodruff Endowed Professor, George W. Woodruff School of Mechanical Engineering, Georgia Tech, USA
[*]corresponding author: michael.leamy@me.gatech.edu

Abstract: We present recent work on reconfigurable, electroacoustic topological insulators as a platform for enabling acoustic devices such as multiplexers/demultiplexers, transistors, logic gates, and single-bit memory. The theoretical underpinnings of the reconfigurable topological insulator will be discussed together with experimental results confirming multiple device operation.

Topological insulators (TIs), exhibiting topologically-protected edge and interface waves, have recently emerged in phononic systems [1]. Reconfigurabilty is essential for enabling TI-based applications [2]. To address this need, we employ shunted piezoelectric (PZT) disks with negative capacitance circuits to dynamically alter a unit cell's mechanical impedance [3-5], thus breaking inversion symmetry and realizing topological states. Dynamic reconfigurability and programmability of such material platforms can then be obtained through simple on/off switching.

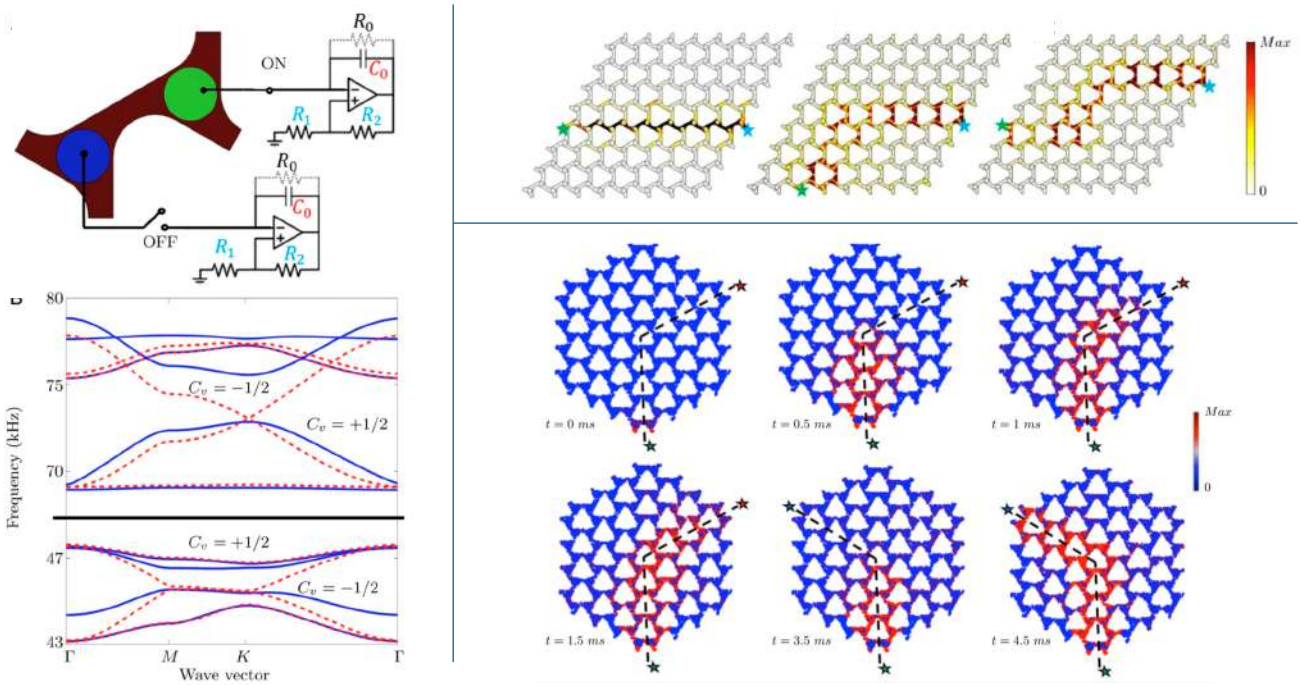

Figure 1: (left) Electroacoustic unit cell depicting two PZT disks, shunted circuits, and associated band structure where red dashed curves correspond to all shunted circuits open, while blue solid curves correspond to one open and one closed shunted circuit. (top-right) Numerically-computed interface waves along reconfigurable domain walls. (bottom-right) Experimentally characterized operation of an electroacoustic demultiplexer.

Figure 1 documents an electroacoustic unit cell (left subfigure) exhibiting programmable topologically protected interface states useful for acoustic multiplexers, demultiplexers, transistors, and single-bit memory [6-8]. The reconfigurable structure is composed of an elastic hexagonal lattice whose unit cell contains two shunted PZT disks, each connected to a negative capacitance circuit by an on/off switch. Closing one or the other circuit results in the breaking of mirror symmetry and yields mechanical behavior analogous to the quantum valley Hall effect. By interfacing two topologically-distinct materials (i.e., differing switches closed), a reconfigurable domain wall is introduced exhibiting a localized interface state topologically-protected from backscattering at defects and sharp edges (top-right subfigure). Through the use of programmable time-division, in which topological domain walls appear and disappear in time, we have experimentally demonstrated multiplexing and demultiplexing (bottom-right subfigure). Specifically, for demultiplexing, two channels of information enter at the input located at the bottom of the lattice spaced in time with a known period. When Channel A is present at the input, a topological domain wall connects the input to Channel A's output at the top-right of the lattice; similarly, when Channel B is present at the input, a topological domain wall connects the input to Channel B's output at the top-left of the lattice. Multiplexing is achieved using reverse operation. We have also demonstrated an acoustic transistor using the same programmable platform, and a memory device for storing a single bit using a single electroacoustic unit cell with a shunted defect. Details will be provided during the talk.

We would like to acknowledge the U.S. National Science Foundation for support of this research under grant numbers 1929849 and 2424345.

Abstract: Elastic spin angular momentum is reported for all three basic modes in continuum rods. Elastic spin controlled unidirectional wave routing is observed in experiment. Similar phenomena are observed for guided modes in rods made of metameterials.

Bosonic-like waves in topological metamaterials and/or phononic crystals have raised wide interest owing to their exotic features. The chirality of topological edge states (TES), known as pseudo-spin, is an important feature for performing robust wave manipulation. Unlike the mathematical concept of pseudo-spin, the spin angular momentum (SAM) of elastic waves describes their local but intrinsic chirality. The SAM of some guided modes locks to the wave direction, which leads to unidirectional routing in both metamaterials and classical structures.

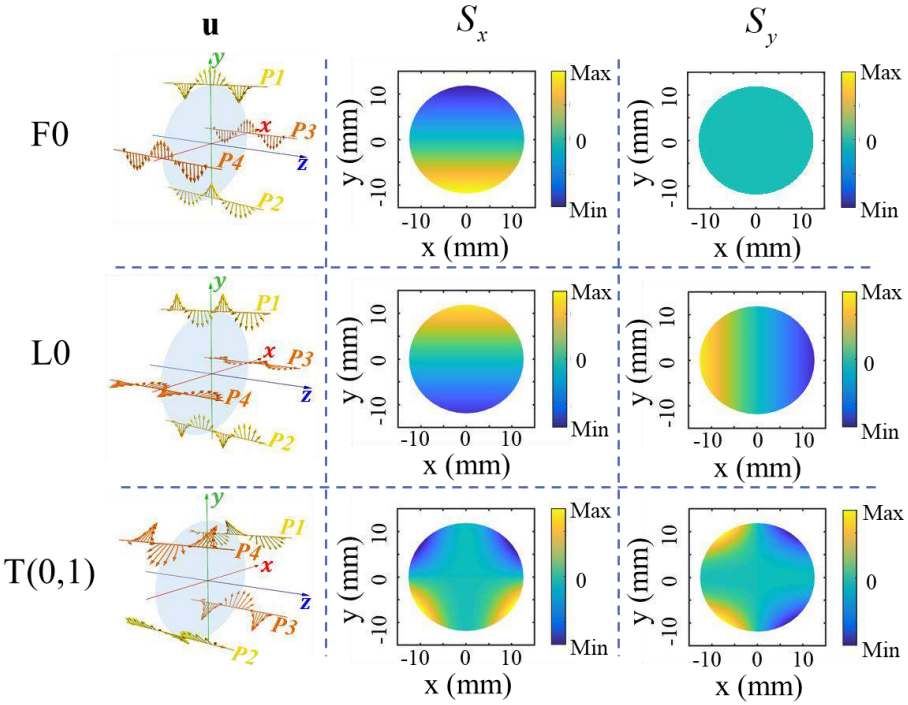

Fig. 1. Displacement field and SAM distribution [5]. First column shows the real part of displacements for F0, L0 and T(0,1) modes at 25 kHz, second and third columns present the relevant distribution of S_x and S_y.

For example, the elastic spin has been charactered for in Lamb-Rayleigh waves along different directions, and demonstrate spin-wavenumber locking over a broad frequency range [1, 2]. Interestingly, we extend elastic SAM to topological metamaterials. We observe the previously overlooked elastic spin-valley locking mechanism [3] and the elastic SAM texture in topological metamaterials based on *p*/*d* symmetry inversion [4]. The chiral,

spatial, and frequency controlling of wave routing is shown in phononic circuits.

In this work, we report the elastic spin for guided modes in continuum rods, including the zero-order flexural (F0) mode, zero-order longitudinal (L0) mode, and zero-order tortional (T(0,1)) mode [5]. Figure 1 shows the displacement polarization and spin component S_x and S_y, for all three guided modes in continuum rods with ellipse cross section. Basically, F0 and L0 modes show some similarity with Lamb modes, i.e. the zero-order antisymmetric plate (A0) mode and zero-order symmetric plate (S0) modes. Yet, F0 and L0 modes demonstrate more elastic spin, along other spatial direction, due to their three-dimensional polarized displacement field. A further study is shown for guided modes in rod structures composed by metamaterials.

Abstract

This paper designed periodic infilled trench barriers for attenuating Rayleigh waves with frequencies between 10 to 30 Hz. The saturated soil model is adopted and the waste rubber tire is used as filling material. Both the dispersion curves and the performance of some periodic infilled trench barriers are obtained.

1 Introduction

Ambient vibration results in an adverse impact on the surrounding sensitive buildings and people's daily live. To reduce these undesirable vibrations, the suppression of Rayleigh wave propagation plays a key role due to Rayleigh wave carries a major amount of energy. Till now, a variety of vibration mitigating methods have been developed, among which periodic wave barriers have been received much attention by many researches[1,2]. However, there are a lot of issues still need to be considered in studying periodic wave barriers. First, some ambient vibrations concentrate in the low-frequency range between 10 to 30 Hz[3]. How to design a periodic surface wave barrier to attenuate this vibration is still open. Second, most of the achievements related to periodic surface wave barriers are under the assumption of single-phase soil. The results suitable to the scenario of saturated soil can be countable[4,5]. Third, there is few study on the performance of periodic wave barriers using waste rubber tire as fillers.

In the present study, some combined periodic infilled trenches as wave barriers for Rayleigh wave attenuation in saturated soil are developed. The dispersion curves and the performance of the combined periodic infilled trenches are obtained. The numerical simulation results show that the barriers proposed by the present study could effectively manipulate the propagation of Rayleigh waves with frequencies between 10 to 30 Hz.

2 Equations

The wave equations of saturated soil in **u**-***p*** form can be expressed as follows[6]:

$$\begin{cases} -\omega^2(\rho-\dfrac{\rho_f}{\rho_c})\mathbf{u}-\nabla(\sigma(\mathbf{u})-\alpha\mathbf{p}\mathbf{I})=\dfrac{\rho_f}{\rho_c}\nabla\mathbf{p} \\ -\dfrac{\omega^2}{M}\mathbf{p}-\nabla\bullet\dfrac{1}{\rho_c}(\nabla\mathbf{p}-\omega^2\rho_f\mathbf{u})=\omega^2\alpha\zeta_{vol} \end{cases} \tag{1}$$

In addition, the criterion based on strain energy is introduced in order to distinguish the surface wave modes, which is expressed as[7]:

$$\xi=\frac{1}{H}\frac{\int_0^H z\cdot E_p dV}{\int_0^H E_p dV} \tag{2}$$

The symbols shown in Eq.(1) and Eq.(2) have the same meanings as those as in the papers [6,7], respectively.

3 Figures and Tables

For the saturated soil[8], we designed a periodic infilled trench barrier. The periodic constant and the width of the trench are chosen as 2 m and 0.6 m, respectively. The trench is filled with foam and waste rubber with the same thickness 0.3 m. The Young modulus, Poisson ratio and the density of the two filling materials are 37 and 4.5 MPa, 0.32 and 0.48, 60 and 1480 kg/m^3, respectively. The depth of the barrier is 4 m. Figure 1 gives the dispersion curves of the combined periodic trenches for Rayleigh waves. It is found that the barrier has the first two attenuations 13.8 ~21.1 Hz and 21.2 ~27.7 Hz. Figure 2 shows the vibration models of points A and B in the dispersion curves. The surface wave models of the two points are obvious.

Simulation of Acoustic Metamaterial Lens Imaging under Complex-Frequency Excitation in a Real-Frequency Solver

Tuo Liu[1*]

[1]Institute of Acoustics, Chinese Academy of Sciences, China
[*]corresponding author: liutuo@mail.ioa.ac.cn

Abstract: This summary presents a method for complex-frequency acoustic simulation implementable in real-frequency solvers based on a conversion of the imaginary frequency component into effective material properties. The method is subsequently applied to evaluating the complex-frequency subwavelength imaging of an acoustic holey-structured metamaterial lens with inherent thermal-viscous loss.

Complex frequency excitation (CFE) corresponds to temporally decaying or growing oscillatory signals that supply virtual gain or loss in space, under which wave systems can exhibit interesting response behaviors or propagation properties. Recent works have shown that the inherent material loss, which has long been a problem that superlensing systems suffer from, can be overcome via CFE so that the overall imaging performance is recovered as if in an ideal lossless scenario [1,2]. While the theoretical analyses in those works are straightforward together with readily available experimental realizations, the associated full-wave simulations are rather resource-consuming and indirect, commonly performed by utilizing truncated transient signals either in the time domain or synthesized at a series of discrete frequencies since most numerical solvers do not support computations at complex-valued frequencies. This summary reports on a simple and general method compatible with real-frequency solvers for complex-frequency calculation [3] and shows its effectiveness in the simulation of an acoustic holey-structured metamaterial lens under CFE with realistic thermo-viscous effect included.

To implement the full-wave simulation at a complex angular frequency, $\omega^* = \omega_r + i\omega_i$, the inhomogeneous acoustic Helmholtz equation with time dependence $e^{i\omega^* t}$ is re-written into the form of

$$\nabla \cdot \left(-\frac{1}{-\rho} (\nabla p - \mathbf{q}_d) \right) - \frac{\omega_r^2 p}{\rho c_{\mathrm{eq}}^2} = Q_m, \tag{1}$$

where $c_{\mathrm{eq}} = \omega_r c / \omega^*$ is a mathematical treatment to the original equation [3]. Here p, ρ, c, and $\mathbf{q}_d$ and Q_m are the acoustic pressure, density, speed of sound, and dipole and monopole domain sources, respectively. They are generally all functions of the position vector $\mathbf{r}$ and real-valued angular frequency ω_r, *viz.*, $p = p(\mathbf{r}, \omega_r)$, etc. After a conversion of the imaginary part, ω_i, into the equivalent speed of sound, c_{eq}, as an additional background parameter variation, Eq. (1) only contains real frequency, ω_r, and can thus be solved by any real-frequency numerical solvers to mimic the response under CFE at ω^*, as depicted in Fig. 1(a).

Next the above method is applied to the frequency-domain finite-element simulation of the super-resolution imaging of a lossy acoustic superlens under CFE [2] in the commercial software COMSOL Multiphysics. As presented in Fig. 1(b), the acoustic superlens is a holey-structured metamaterial [4] immersed in air with thermo-viscous effect considered through the acoustic boundary layer impedance boundaries (no slip, isothermal) inside the narrow holes, and the object to be imaged is a letter "A" of deep subwavelength dimensions. The simulation results at the image plane are given by Figs. 1(c) and 1(d). The metamaterial lens produces sub-diffraction-limited

image at its Fabry-Perot resonance (~1705 Hz) in the ideal lossless case. The presence of thermo-viscous effect leads to not only a red shift of the resonance frequency (~1614 Hz) but also non-negligible dissipative losses that attenuate the evanescent waves and consequently result in degraded performance under real-frequency excitation. As expected, CFE provides virtual gain effect to compensate the loss, and the image is almost fully recovered at $1614 + i88$ Hz. The results therefore confirm the effectiveness of the proposed method in performing complex-frequency simulations in a more straightforward and efficient way as compared to existing methods [1,2].

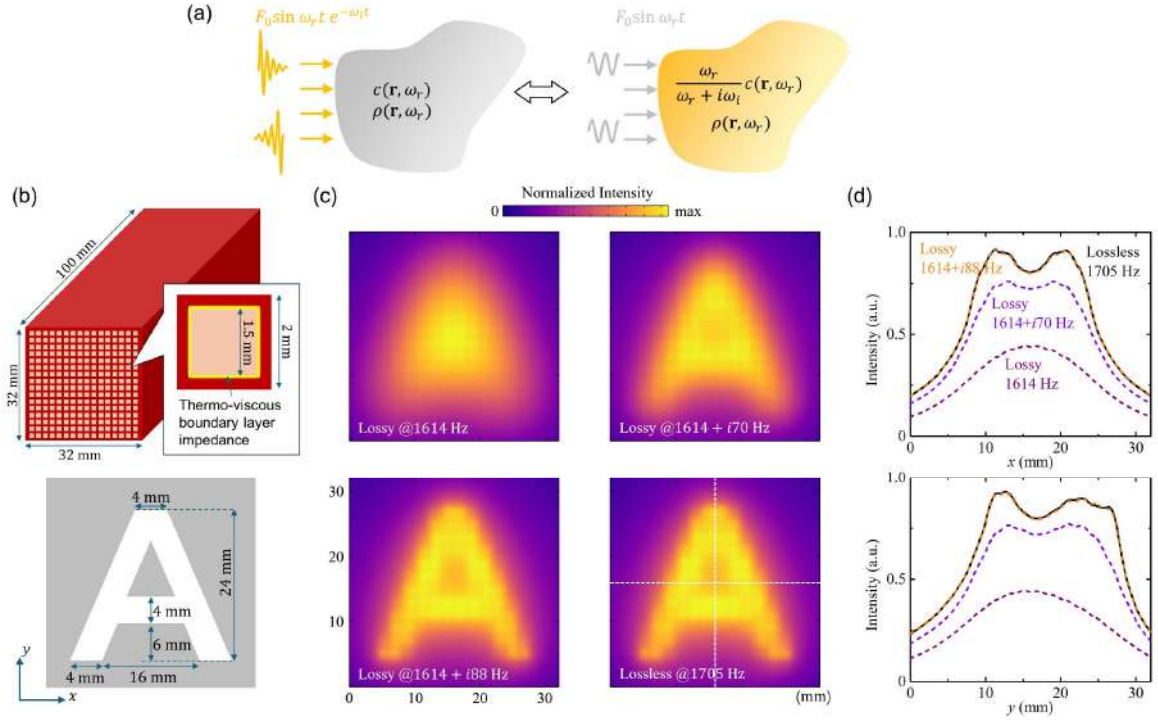

Fig. 1. Complex-frequency simulation of a lossy acoustic superlens. (a) Conceptual illustration of the method for complex-frequency calculation. (b) Schematics of the holey-structured metamaterial lens and object to be imaged. The object/image plane is 0.5 mm away from the lens inlet/outlet. (c) Simulated sound fields at the image plane. (d) Intensity magnitude distributions along the dashed lines in (c). Properties of air in the simulation: density $1.21\ \mathrm{kg/m^3}$, speed of sound 343 m/s, heat capacity at constant pressure $1.005 \times 10^3\ \mathrm{J/(kg \cdot K)}$, ratio of specific heats 1.4, thermal conductivity $0.0258\ \mathrm{W/(m \cdot K)}$, and dynamic viscosity $1.81 \times 10^{-5}\ \mathrm{Pa \cdot s}$.

Vibrational dynamics of single supported plasmonic nanodisks

Abstract: The vibrational dynamics of single substrate-supported gold nanodisks were investigated using optical methods and numerical simulations, allowing to address the dependence of vibrational frequencies and quality factors on both nanodisk and substrate characteristics. The transient optical response caused by nanodisk vibrations was also studied.

Metal nanoparticles constitute mechanical resonators with many potential advantages, including high vibrational frequencies (f in the GHz-THz range), small mass and developed chemical synthesis and optical probing methods. However, their vibrational quality factors Q are typically low, resulting in fQ values too low for ultrasensitive mass sensing applications or for quantum phononics experiments at room temperature.[1] It is therefore desirable to achieve a deeper understanding and minimization of vibrational mode damping, which arises from both internal processes and acoustic emission in the environment, as done for larger size resonators.[2]

In this context, we present here investigations of the vibrational dynamics of gold nanodisks based on the combination of single-particle optical experiments with finite-element numerical investigations. Optical experiments were performed by combining spatial modulation spectroscopy, a tool allowing the localization and extinction spectroscopy of single nano-objects randomly deposited on a solid substrate, and single-particle pump-probe spectroscopy, which provides access to the ultrafast electronic, acoustic and thermal dynamics of the investigated nano-objects.

Previous work in our group had demonstrated that the vibrational quality factors of supported nanodisks are highly morphology-dependent, and show largely enhanced values for specific values of their diameter/thickness ratios.[3] These observations could later be ascribed to the radiative coupling of two distinct nanodisk modes.[4] We present here new experimental studies on this theme, addressing the roles played by both the nanodisk and substrate properties. The nanodisks considered here were synthesized using colloidal chemistry rather than electron beam lithography, which is expected to reduce the density of crystalline defects in the nanoparticles. They were deposited on various solid substrates, differing by their composition and thicknesses. Comparison of the measured frequencies with finite-element simulations allowed the identification of the detected vibrational modes. Moreover, our experiments confirmed the strong dependence of vibrational quality factors on the nanodisk diameter/thickness ratio.

We also investigated the transient optical response induced by nanodisk vibrations, which was quantitatively addressed by tuning the wavelength of the probe beam used for transducing the vibrations of the nanodisks into an optical signal. This transient response dramatically differ from that, also measurable in our experiments, induced by nanodisk heating. Indeed, while the latter primarily reflects a broadening of the nanodisk surface

plasmon resonance, vibrations appear to mostly spectrally shift the resonance. Our measurements open the way to precise tests of the numerical models recently introduced in the literature to describe acousto-plasmonic coupling in metal nanoparticles.[5]

Mechanically time-modulated 2D phononic crystal

D. Shymkiv[1], M. Li[1], Ying Wu[2], and A. Krokhin[1*]
[1]University of North Texas, USA
[2]King Abdullah University of Science and Technology, Saudi Arabia
arkady@unt.edu (corresponding author)

Abstract

A periodic arrangement of bimetallic rods in solid matrix is proposed as time-modulated phononic crystal. The rods oscillate along their axes. High elastic contrast between the components of the rods provides deep time modulation. A band structure with mixed gaps formed from coalescence of energy and momentum gaps is calculated and analyzed.

Formal symmetry between time and space variables in the wave equation opens new possibilities for active manipulation of sound by periodic temporal modulation of elastic properties of the constituents of phononic crystals. Spatial periodicity gives rise to frequency band gaps (ω-gaps) in spectrum, provided the elastic contrast between the inclusions and the background material is sufficiently high. For frequencies within ω-gap the Bloch vector $\mathbf{k}$ is pure imaginary and the eigenfunctions decay exponentially with coordinates. Periodicity over time may generate momentum gaps, i.e., regions in $\mathbf{k}$-space within Brillouin zone where solutions of the eigenvalue problem for ω are complex with increasing and decaying eigenfunctions. For the momentum gaps to appear, time modulation must be sufficiently deep. This requirement is not easy to satisfy since elastic properties are robust against external perturbations. Electrical modulation of piezoelectric constituent of a phononic crystal may be not sufficiently deep to generate experimentally resolvable $\mathbf{k}$-gap. Here we propose pure mechanical temporal modulation of elastic properties of 2D phononic crystal of bimetallic cylindrical rods. Temporal modulation occurs not due to weak variation of elastic modulus of a given material but due to sharp temporal alternations of the material of the scatterers. This method, as well as other mechanical methods [1–3] lead to deep level of modulation and relatively wide momentum band gaps.

The phononic crystal structure is shown in Fig. 1. The scatterers are bimetallic, Cu-Al, rods of radius$R = 6$ cm distributed in a square lattice in the $x \in y$ plane with period $a = 15$ cm. The rods vertically oscillate in phase with frequency f_{vib} along axis z. The background matrix is epoxy. Sound wave propagates perpendicular to the rods. The dispersion relation is obtained from the solution of the eigenvalue problem for the displacement vector $\mathbf{u}(\mathbf{r}, t) = (u_x, u_y)$, which satisfies the wave equation. Due to spatiotemporal periodicity the wave equation can be reduced to an infinite set of linear equations for the Fourier components of the displacement vector

$$\mathbf{u}(\mathbf{r}, t) = e^{i(\mathbf{k}\cdot\mathbf{r}-\omega t)} \sum_{\mathbf{G},\Omega} \mathbf{u}(\mathbf{G}, \Omega) e^{i(\mathbf{G}\cdot\mathbf{r}-\Omega t)}, \tag{1}$$

where $\mathbf{G} = (G_x, G_y)$ are the reciprocal lattice vectors and $\Omega = 2\pi f_{\text{vib}}$.

In a temporally modulated medium the eigenvalue problem for $\mathbf{u}(\mathbf{G}, \Omega)$ is quadratic, i.e., there are matrix terms proportional to ω^0, ω and ω^2. The spectrum of the eigenfrequencies $\omega(\mathbf{k}, f_{\text{vib}})$ for the quadratic eigenvalue problem can be calculated by the method of linearization [4]. Three lowest bands of the numerically calculated dispersion relation for $f_{\text{vib}} = 4$ kHz are plotted in Fig. 1b. There are several relatively wide momentum band gaps. Inside these gaps, highlighted in red dots, the eigenfrequency acquires an imaginary part. Here a propagating sound wave can be amplified by gaining energy from the vibrating rods. The

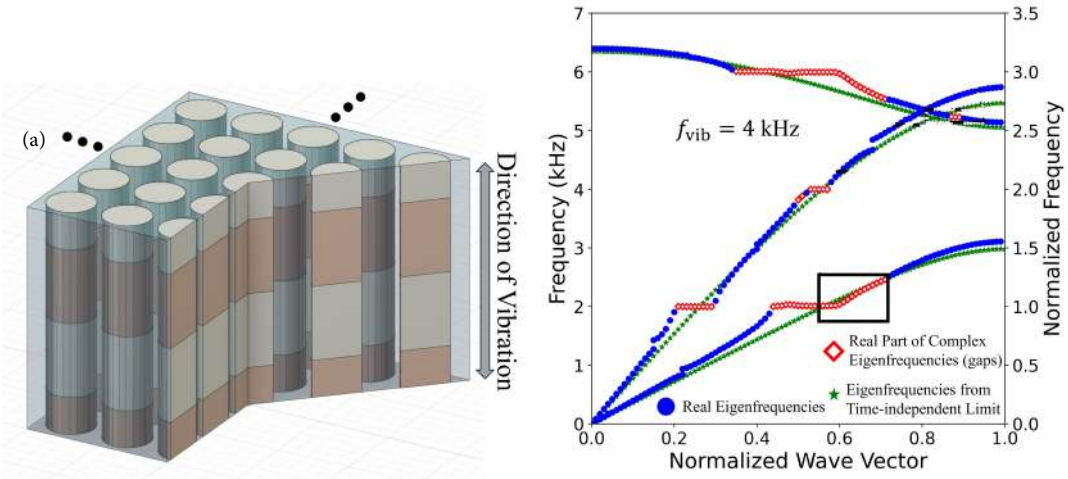

Figure 1: (a) Geometrical scheme for experimentally feasible spatiotemporal 2D phononic crystal consisting of oscillating bimetallic rods arranged in a square lattice and imbedded in an elastic background. (b) Unfolded band structures along the ΓX direction. The band structure for the time-independent crystal, where $f_{vib} = 0$, is shown in green dots. The region of the mixed band gap inside the black rectangle is zoomed in Fig. 2.

band structure in Fig. 1b exhibits a new type of band gap – a mixed band gap where ω and k become complex, $\omega = \omega_0(k_0) \pm i\Omega(k_0)$ and $k = k_0 + \delta'(\omega_0) + i\delta''(\omega_0)$. The region of the mixed band gap inside a black rectangle is zoomed in Fig. 2. The eigenfunctions inside a mixed band gap may exponentially decrease or increase with time and coordinate. The imaginary part, $\pm\Omega_0(k)$, is represented by the vertical distance between each green and red dot for every real Bloch vector k_0. Numerically calculated corrections δ' and δ'' for $k_0 = 0.65$ are shown by multicolored dots, where the color gradient represents the imaginary part δ'' of k.

Enhanced ultrasound focusing through dense barrier

Zhongming Gu, Jie Zhu[1*]
[1]Institute of Acoustics, School of Physics Science and Engineering, Tongji University, Shanghai 200092, People's Republic of China
[*]corresponding author: jiezhu@tongji.edu.cn

Abstract: The substantial impedance mismatch between dense materials and the surrounding medium poses a challenge to the transmission of ultrasound waves through dense barriers. To address this challenge, we propose an inverse design scheme aimed at achieving ultrasound focusing through dense layers with multiple foci, resulting in significantly enhanced transmission efficiency.

Ultrasound waves are essential in a wide range of practical applications across various fields, including diagnostic imaging, nondestructive testing, and medical treatment, due to their unique properties. However, the presence of dense objects (such as tissue in biomedical applications) in the ultrasound propagation path can lead to significant reflection and reduced transmission. This occurs because the dense materials have a much higher acoustic impedance compared to the surrounding medium. Additionally, dense layers can cause scattering of ultrasound waves, which disperses energy and diminishes focusing capability, further complicating effective imaging or therapeutic applications.

Recent advancements in acoustic metamaterials offer promising strategies to enhance ultrasonic focusing, thereby improving the accuracy and effectiveness of ultrasound applications. Metamaterial lenses have been successfully designed to enhance transmission through impedance-mismatched layers. For instance, complementary acoustic metamaterials have been theoretically proposed to achieve enhanced noninvasive transmission through such layers, utilizing doubly negative acoustic properties. However, experimental demonstrations of complementary acoustic metamaterials have been limited due to the challenges of precisely prototyping either the membranes or complex metallic meta-atoms. Very recently, a metamaterial lens featuring a simple structure made from commonly used materials has demonstrated enhanced focusing and transmission through impedance-mismatched layers [1, 2], albeit limited to a single focus.

In this work, we have designed a meta-lens that focuses ultrasound through a dense layer with multiple foci, thereby enhancing the effectiveness and versatility of ultrasound technologies in both medical and industrial applications. A hemispherical structure made of brass (Young's modulus: 110 GPa; density: 8960 kg/m^3; Poisson's ratio: 0.35) is considered to act as a dense barrier, mimicking the human skull. Due to the significant impedance mismatch between brass and water, a considerable portion of the ultrasound wave is reflected, as shown in Fig. 1(a). Given that the structure is immersed in water, the acoustic-solid interactions must be taken into account. Therefore, we propose utilizing an inverse design method to fabricate a metamaterial lens that allows the ultrasound wave to transmit efficiently through this dense layer. This inverse design approach combines the Non-Superiority Sorting Genetic Algorithm II with the Finite Element Method, circumventing the challenges of deriving analytical solutions. The meta-lens consists of ten concentric rings, with a periodicity of 5 mm. The width (d) and height (h) of each ring are the parameters to be optimized, with the goal of maximizing the ultrasound intensity at the designated positions. The output of the meta-lens demonstrating optimal performance is illustrated in Fig. 1(f). When this lens is positioned on the upper side of the dense layer, the

ultrasound wave can effectively transmit through the barrier and be focused at specific locations, as demonstrated in Fig. 1(b).

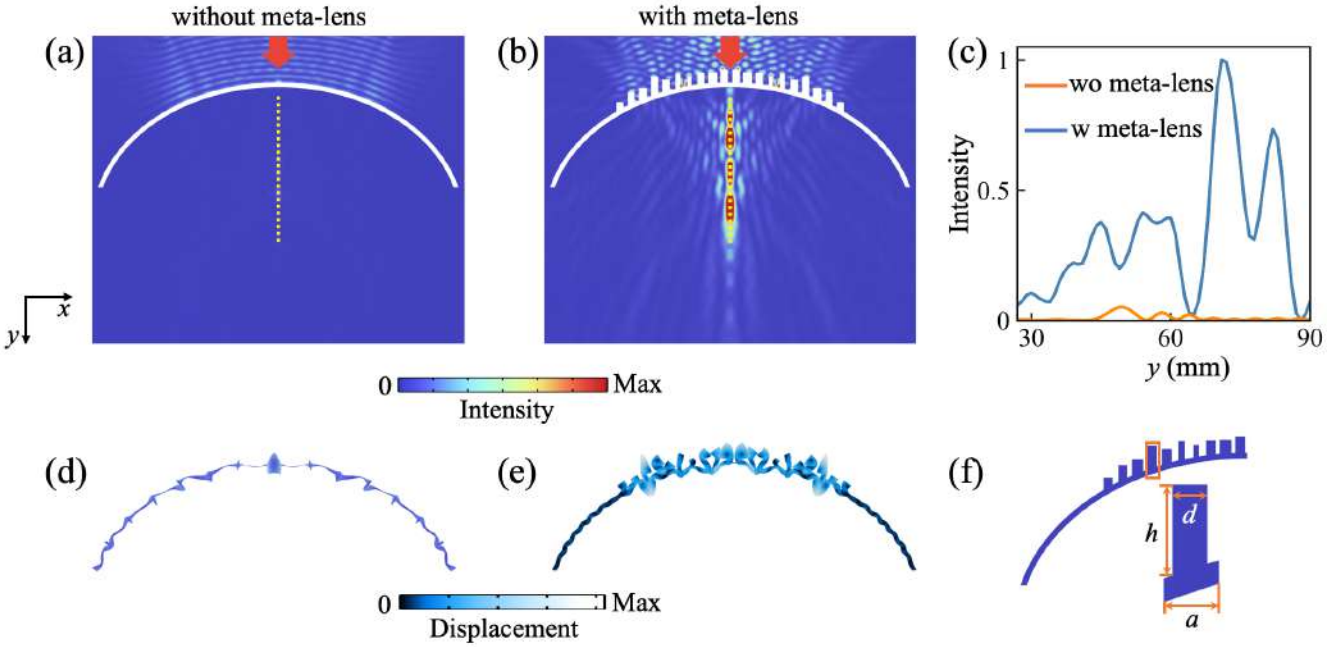

Figure 1. Numerically calculated ultrasound field distributions for the dense barrier: (a) without the optimized meta-lens and (b) with the optimized meta-lens. (c) Intensity profiles along the white dashed lines in (a) and (b), respectively. Simulated total displacement for the dense barrier: (d) without the optimized meta-lens and (e) with the optimized meta-lens. (f) Detailed cross-sectional view of the patterned barrier. In (a), (b), (d), (e), the results represent the fields in the central *xy* plane.

To clearly compare the transmission enhancement and multi-foci focusing effect, we calculated the intensity profiles along the white dashed lines in Figs. 1(a) and 1(b). The ultrasound power for the dense layer patterned with the optimized meta-lens [blue line in Fig. 1(c)] is significantly higher than that of the bare dense layer [orange line in Fig. 1(c)]. Moreover, four distinct foci are observed behind the patterned dense layer, confirming the multi-foci focusing capability of the designed meta-lens. Additionally, we numerically calculated the total displacement of both the bare dense layer and the patterned dense layer, as depicted in Figs. 1(d) and 1(e), respectively. It is evident that the layer equipped with the meta-lens exhibits much higher vibrational displacement, allowing more ultrasound waves to pass through. The proposed scheme to achieve enhanced ultrasound focusing with multi-foci demonstrates a significant ability to precisely target multiple locations simultaneously, facilitating complex manipulations of ultrasound waves and paving the way for breakthroughs in medical treatment and industrial processes.

Abstract: We present novel optomechanical (OM) photonic crystal cavity geometries based on either monolithic silicon or hybrid silicon/silicon oxide nanopillars integrated with adjacent waveguides. These structures enable optical transduction of cantilever-like modes with OM coupling rates exceeding 1 MHz. We also demonstrate sensitivity to local forces by tracking mechanical resonance shifts.

One-dimensional photonic crystal (1D-PhC) pillar cavities provide a compelling platform for integrated optomechanics, offering enhanced mechanical transduction and nanoscale force sensing. In this work, we present two complementary approaches: (i) full-silicon 1D-PhC cavities with high optical and mechanical Q-factors (Figure 1a), [1] and (ii) hybrid silicon/silicon oxide pillar cavities (Figure 1b) optimized for integration with adjacent waveguides. [2] These structures enable strong light-matter interaction, efficient optical transduction of cantilever-like mechanical modes, and seamless on-chip integration for photonic applications.

We demonstrate 1D-PhC cavities where each nanopillar acts as an independent mechanical resonator that can modulate the optical cavity resonance. By engineering the pillar geometry, we achieve vertical light confinement and a photonic bandgap in the near-infrared regime for transverse-magnetic (TM) polarization. Optical characterization reveals high-quality factors greater of about $2x10^3$ in the case of monolithic silicon pillars and $4x10^3$ in the case of the hybrid geometry. Mechanical transduction of flexural modes up to the fourth order is achieved, with optomechanical coupling rates exceeding 1 MHz.

The hybrid architecture facilitates integration with photonic circuits, indeed enabling efficient evanescent coupling with adjacent waveguides that have been accessed using a butt coupling technique with lensed fibers. Experimental measurements validate the feasibility of transducing thermally activated mechanical modes in the MHz frequency range via the integrated waveguide, eliminating the need for external tapered fiber coupling. By varying the waveguide-cavity distance, we optimize optical coupling for enhanced mechanical transduction.

The sensitivity of 1D-PhC pillar cavities to external forces has been studied by bringing a tapered fiber into contact with the pillars and tracking RF spectral shifts. Mechanical damping caused linewidth broadening, while fiber contact increased oscillation frequencies in relation to an effective elastic constant increase. Peaks stabilized upon detachment, indicating mechanical resonance recovery.

Our work advances the field of optomechanical photonic crystals by demonstrating high-performance silicon and hybrid silicon/silicon oxide pillar cavities. The combination of strong optomechanical interactions, high Q-factors, and waveguide integration paves the way for practical implementations in force sensing, biosensing, and nanoscale optomechanics.

Time-resolved two-dimensional imaging of GHz acoustic waves in phononic crystals and metamaterials

Osamu Matsuda
Division of Applied Physics, Faculty of Engineering, Hokkaido University, Japan
omatsuda@eng.hokudai.ac.jp

Abstract

The all optical time-resolved two-dimensional imaging of GHz surface acoustic waves is efficient to study the GHz acoustic properties of media. Here the principle of the technique is explained briefly, and some applications of the technique to micron-scale phononic crystals and metamaterials are shown.

1 Introduction

Surface acoustic waves in MHz-GHz frequency region have been exploited in filter devices in microwave communications, sensor devices for gas molecules, various data-processing devices, etc. For developing these applications as well as understanding the fundamental physics of acoustic waves, the spatiotemporal observation of the waves is quite efficient.

We have been developing an all optical time-resolved two-dimensional imaging technique for MHz-GHz surface acoustic waves or vibrations. [1–3] In this paper, the principles of the above-mentioned imaging technique is overviewed, and some representative results for the imaging of acoustic waves on phononic crystals and phononic metamaterials are presented.

2 Principle

The imaging technique is based on the optical pump-probe method which utilizes periodic light pulses of sub-picosecond temporal widths. We use a mode-locked Ti-sapphire laser generating light pulses at the repetition frequency around 80 MHz. The light pulses are focused onto the sample to be imaged using a microscope objective to a small spot of diameter around 1 μm. These are named "pump light pulses" and are used to generate acoustic waves mostly through the thermal expansion caused by the light absorption. The same light pulses are delayed and focused onto the sample surface to detect the acoustic field at the moment of the light pulse arrival to the sample surface. These are named "probe light pulses". The small surface-normal displacement ($<$ nm) is detected using an optical interferometer. To achieve the two-dimensional imaging, the probe light focusing position is scanned across the sample surface typically in a rectangular region with the edge length of several hundreds microns at a fixed delay time. To achieve the time-resolved measurement, the delay time is varied from 0 to 13 ns (period of pulse repetition) using an optical variable delay line (the optical path length varies from 0 to 4 m). Taking the "snap-shot" images with varying the delay time, the spatiotemporal variation of the acoustic field is obtained as a movie. [1, 2].

3 Results

Figure 1 shows an example of the measurement for a two-dimensional phononic crystal. [4] Circular holes of diameter 2.8 μm and depth 1.3 μm are aligned in a square lattice of period 5.6 μm in a square region of 110×110 μm^2 on a crystalline Si (100) surface. The acoustic waves are generated by focusing the pump light around the center of the phononic crystal region, and the area 200×200 μm^2 including the surrounding pristine Si substrate is imaged. Though the raw obtained data is a set of acoustic fields as a function of delay time and probing position, and involving several frequency components, the shown is a real-part of temporal Fourier transform of the raw data, corresponding to a snapshot of the acoustic field at 884 MHz. A plus-sign-shaped phonon collimation pattern (phonon focusing) is seen in the phononic crystal, and each collimated beam is split into two when it goes out from the phononic crystal region to the surrounding pristine silicon substrate. Further detailed analysis clarifies the dispersion relation of the phononic crystal.

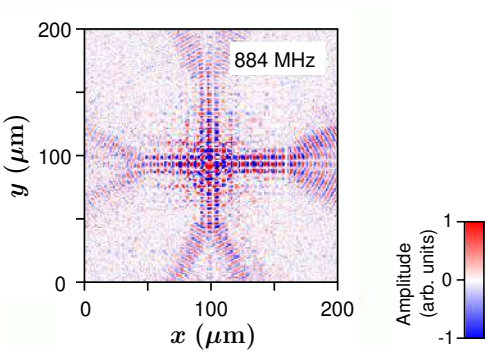

Figure 1: Snapshot image of the acoustic field strength of a square lattice phononic crystal on a Si (100) substrate at 884 MHz.

Figure 2 shows an example of the measurement for a phononic metamaterial which consists of a monolayer of silica spheres of diameter 1.08 μm and density 2.0 g cm^{-3} on a float glass substrate coated with a 100 nm Al film. The shown is the dispersion relation of the acoustic waves: it is obtained by the spatiotemporal Fourier transform of the raw time-resolved data. To have the frequency resolution much finer than the laser repetition frequency, a special frequency controling technique is used. [3] The coupling of the propagating modes and the localized modes are clearly seen around 250–300 MHz.

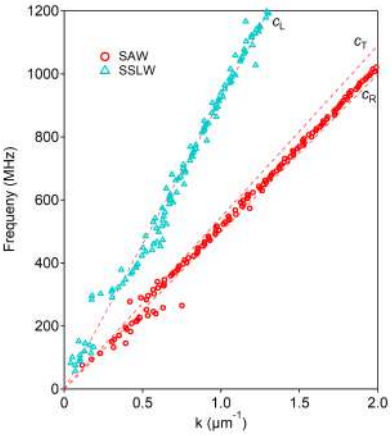

Figure 2: Dispersion relation of the acoustic waves of a phononic metamaterial.

4 Conclusion

The all optical time-resolved two-dimensional acoustic wave imaging technique has been developed and utilized to clarify the acoustic properties of medium. It can be utilized for detailed study of phononic crystals and phononic metamaterials up to GHz frequency region, and would be useful for developing functional devices based on them.

Surface acoustic waves-driven magnon spin Hall effect in atomically thin van der Waals antiferromagnets

R. Sano[1*], Y. Ominato[2], and M. Matsuo[3]

[1]Kyoto University, Japan
[2]Waseda University, Japan

Abstract: Van der Waals antiferromagnets have lacked comprehensive tools for probing their intricate magnetic properties. We propose using surface acoustic wave-driven intrinsic magnon spin Hall currents to mechanically detect and manipulate magnetic order in two-dimensional antiferromagnets. This innovative method overcomes weak magnetic responses, offering a promising foundation for future antiferromagnetic spintronics.

Intrinsic magnetism in two-dimensional (2D) materials had long been believed to hardly survive due to the enhanced thermal fluctuations. However, the recent discovery of exfoliated van der Waals (vdW) magnets has opened up a new avenue for 2D magnetism at finite temperatures [1,2]. Especially, transition metal phosphorus trichalcogenides $MPX3$ (M = Fe, Ni, Mn; X = S, Se) are a family of easily exfoliatable vdW antiferromagnets [3]. These materials share the same honeycomb lattice structure, but the bulk antiferromagnetic (AFM) phase varies depending on the magnetic elements [4]. It therefore provides an ideal platform to investigate magnetism and magnetic excitations in the 2D limit. Furthermore, compared to ferromagnets, antiferromagnets exhibit ultrafast dynamics in the terahertz regime, null stray field, and robustness against the external magnetic field perturbation. Therefore, the investigation of these materials paves the way towards not only the fundamental understanding of 2D magnetism, but also the possibility of high-speed and compact AFM spintronics.

Standard methods such as magnetization measurements and neutron diffraction, which could only access macroscopic magnetic properties, are not suitable for the study of atomically thin magnets. Especially, antiferromagnets do not have net magnetization, direct measurement of AFM ordering using the magneto-optical Kerr effect is not available either. Although recent studies have focused on the Raman spectroscopy [5,6] and the second-harmonic generation [7,8] to detect the crystal symmetry lowering associated with the AFM transition, these signals often do not provide clear identification of the AFM order in the monolayer limit. Therefore, a comprehensive method which suits for exploring the magnetic properties of 2D antiferromagnets is highly desired.

Here, we propose an ac intrinsic magnon spin Hall current mechanically driven by surface-acoustic waves (SAWs) as a novel method to probe the magnetic structures of such 2D honeycomb antiferromagnets [9]. Owing to extremely large mechanical flexibility of 2D materials, SAWs are ideally suited for fundamental research of them [10]. When an inhomogeneous strain is applied to 2D honeycomb magnets, a spatial modulation of exchange energies mimics the role of artificial gauge fields for magnons. These strain gauge fields work at two valley points of the Brillouin zone in the opposite direction, which in turn activate the valley degrees of freedom (DOF). Therefore, the valley DOF with the use of SAWs is a promising concept for mechanical detection and

manipulation of the magnetic order in 2D vdW antiferromagnets. Furthermore, our mechanically driven magnon spin Hall effect will overcome the difficulties with weak magnetic responses inherent in the use of antiferromagnets and hence provide a building block for more sophisticated AFM spintronics.

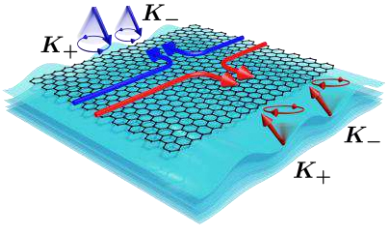

Fig. 1. Schematics of the acoustomagnonic spin Hall effect. A spatial modulation of the exchange energies due to strain mimics the role of artificial gauge fields for magnons in a honeycomb lattice. Both the strain-induced electric fields and the magnon Berry curvature work at the two valley points in the opposite direction, leading to a net spin Hall current.

Acoustic trapping, emission enhancement, and harvesting from bound states in the continuum

Sibo Huang[1], Yong Li[2], Jie Zhu[2], and Din Ping Tsai[1*]

Abstract: Acoustic bound states in the continuum (BICs) are special modes characterized by high quality factors and strong localization. By constructing a series of coupled Friedrich-Wintgen BICs and appropriately tuning their radiation and intrinsic losses, we achieved novel and efficient acoustic trapping, emission enhancement, and energy harvesting.

Acoustic Bound States in the Continuum (BICs) demonstrate infinite Q-factors and complete isolation, facilitating high Q-factors and external radiation access when transformed into quasi-BICs. These quasi-BICs enable tunable, minimal radiation losses, enhancing various high-quality and high-performance acoustic devices for sound trapping [1,2,3], emission [4,5], and harvesting [6].

In Figures (a)-(d), we introduce a BIC-supporting system composed of two closely-coupled cavities. This configuration achieves BIC when the cavities satisfy the condition of $\kappa(\gamma_A-\gamma_B)=\sqrt{\gamma_A\gamma_B}(\omega_A-\omega_B)$. Here, $\omega_{A(B)}$ is the angular resonant frequency of cavity A(B), $\gamma_{A(B)}$ and $\Gamma_{A(B)}$ indicate the radiation loss and the intrinsic loss of cavity A(B), respectievly. κ and $\sqrt{\gamma_A\gamma_B}$ indicate the near-field and the far-field coupling among cavity A and cavity B. Additionally, radiation losses can be modulated freely by adjusting the depth difference between the cavities, while intrinsic losses are tuned by altering the cavities' cross-sectional sizes. This simple architecture facilitates effective modulation of radiative and intrinsic losses, beneficial for acoustic devices requiring high Q-factors.

Figures (e)-(f) display the acoustic trapping phenomenon enabled by BICs. When intrinsic losses in our two-cavity system are minimized and further adjusted along with the cavities' height differences to match radiative losses, the system captures all incident sound waves, resulting in zero reflection as shown in Figure (e). Moreover, due to the system's low intrinsic losses, sound waves persist for extended periods, leading to extreme acoustic trapping as depicted in Figure (f).

Figures (g)-(i) manifest the acoustic emission enhancement achieved by BICs. We establish a theoretical framework considering both radiative and dissipative losses and systematically investigate the acoustic Purcell effect. Our results reveal that the acoustic Purcell factor is governed by the system’s radiative and dissipative factors, necessitating a simultaneous reduction in both to achieve significant emission enhancement. Initially demonstrated in a dual-cavity system supporting a quasi-BIC with a Purcell factor of 84.7, we further employ collective BICs in multi-resonator systems to achieve broadband emission enhancement.

Figures (j)-(k) illustrate enhanced acoustic harvesting with BICs. Sound, an ubiquitous, clean, and renewable energy source, is often underutilized due to its low energy density. Our study introduces a two-state system supporting a Friedrich-Wintgen BIC, achieving an unprecedented enhancement in sound energy density—up to 1849 times the incident intensity. Integrating this BIC-supporting system with energy conversion mechanisms, such as piezoelectric films, we realize high-performance acoustic energy harvesting.

Abstract: The lightweight nature of locally resonance-based metamaterial solutions is a key design factor. A topology optimization framework is proposed to maximize the modal effective mass (MEM) of structural resonators. A novel design achieving a MEM of 96.2% is presented and validated through vibration attenuation evaluation for a finite metamaterial structure.

Introduction: Vibroacoustic metamaterials are known to be lightweight structures achieving exceptional vibrational or acoustic attenuation. Although mass is an important design aspect, the modal effective mass (MEM) of typical resonance-based metamaterial designs varies between 40-90% [1,2]. This work presents a topology optimization routine to maximize the modal effective mass of a resonator at a specified frequency under both connectivity and mass constraints. The paper first elaborates on the applied optimization framework, after which the results are discussed for a specified case study.

Methodology: The MEM describes the amount of mass in motion in a specific direction for a given modeshape ϕ_p. In this work, the translational MEM normal to a base plate is of interest. Assuming mass-normalized modeshapes, the normal MEM of mode p reads [3]:

$$MEM_{z,p} = \left(\phi_p^H \mathbf{M}\boldsymbol{\tau}\right)^2 \quad \text{with} \quad \left(\mathbf{K} - \omega_p^2 \mathbf{M}\right)\phi_p = 0 \tag{1}$$

with $\mathbf{K}, \mathbf{M}$ the stiffness and mass system matrices of the clamped-based resonator, ω and ϕ, respectively the p[th] eigenfrequency and eigenmode, $\boldsymbol{\tau}$ the normal-translational selection vector and the superscript H the Hermitian transpose. The optimization routines aims at obtaining a resonator design with the highest possible MEM at a targeted frequency ($\bar{f}$). A density-based topology optimization is applied. The envisaged design space is divided into finite elements while each element contains a design variable ξ_i which varies between 0 and 1, representing the void and solid phase. To alleviate numerical instabilities and force the design towards black and white, both a density-filtering and Heaviside projection are applied [4]. The topology optimization problem is given as:

$$\begin{cases} \max\limits_{\xi} & \sum_1^{N_m} \exp\left(-\frac{1}{2}\left(\frac{f_p - \bar{f}}{\sigma_f}\right)^2\right) MEM_{z,p} \\ st. & v \geq V_{min} \\ & v \leq V_{max} \\ & \theta_{sw} \leq \mu\, \bar{\theta}_{sw} \\ & 0 \leq \xi_i \leq 1 \end{cases} \tag{2}$$

in which the objective function is defined as the weighted MEM_z sum of the first N_m modes considered using a Gaussian frequency window, while σ_f is a parameter to control the relative penalty for eigenfrequencies away from $\bar{f}$. This parameter is decreased during the optimization. The optimization is subjected to both a minimum and maximum volume constraint, a connectivity constraint and box constraints. The connectivity constraint is required to diminish the presence of solid islands of materials. A self-weight compliance constraint is used in which the resonator is subjected to self-weight loading, while the corresponding compliance energy (θ_{sw}) is limited with respect to the compliance energy of a full design domain ($\bar{\theta}_{sw}$). In order to ensure well-connected, black and white designs, the self-weight force is considered from the design itself while it is subjected to an eroded version of the design of interest. Since a gradient-based optimization solver is applied, the sensitivities are required which are analytically derived using the adjoint method.

Result: The proposed optimization framework is applied on a design space of 4 x 40 x 40 mm, while a discretization of 80 x 80 linear shell elements is used. The material is PMMA with Young's modulus 4850 MPa, density of 1188.38 kg/m^3, Poisson's ratio of 0.31 and structural damping of 5%. The targeted frequency is set to $\bar{f} = 1500$ Hz, while the volume is restricted between 40-50% and μ equals 100. The resonator is added in post-processing on a base plate of 6 mm PMMA while the unit cell spacing is 45 x 45 mm leading to Bragg frequency of the base plate of 2855 Hz.

Figure 1a shows the resulting optimized resonator. The fourth mode of the resonator consist of a near-perfect vertical translation of the mass, achieving a MEM of 96.2% at 1500 Hz. The leg design of the resonator makes a perfect trade-off in minimizing material usage while obtaining adequate stiffness and frequency tuning. The corresponding dispersion curves (Figure 1b) of the resonator on the 45 x 45 mm unit cell show a bandgap around the tuned frequency (1448-1667 Hz). A vibration transmission is computed on the finite plate with 6 x 3 resonators (Figure 1c). The resulting vibration transmission (Figure 1d) shows a large attenuation of the structural waves at the targeted frequency of 1500 Hz.

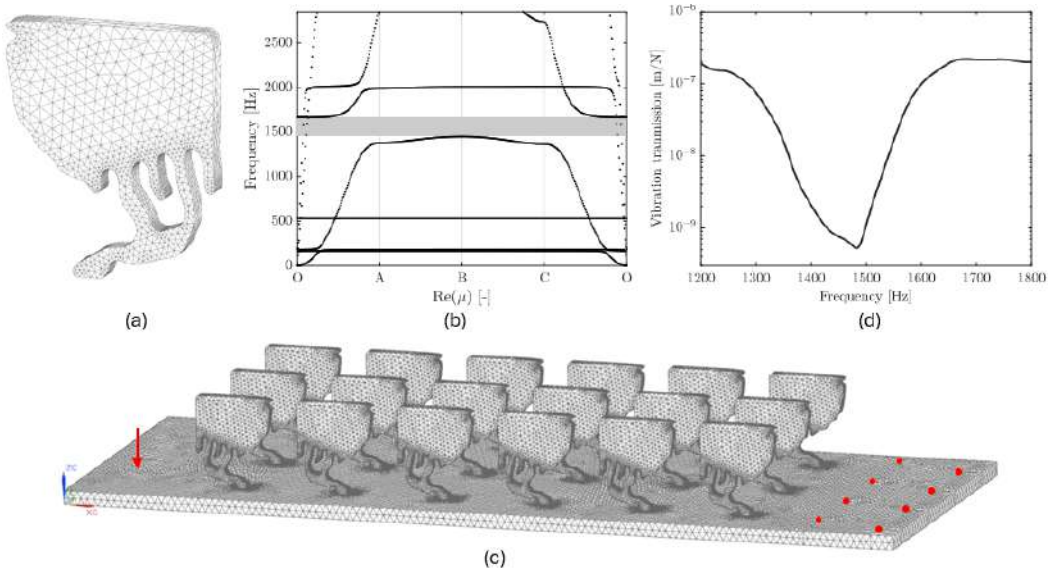

Figure 1. Result of the optimization. a) Optimized resonator, b) corresponding dispersion curves, c) problem set-up to compute the vibration transmission and d) resulting vibration transmission.

Conclusion: This work introduces a density-based topology optimization framework for the maximization of the translational modal effective mass of metamaterial resonators. A novel resonator design with effective mass of 96.2% is presented while an investigation on the resulting vibration transmission shows high attenuation levels at the targeted frequency.

Spectral methods for designing quasiperiodic metamaterials

B. Davies
Mathematics Institute, University of Warwick, Coventry, UK
bryn.davies@warwick.ac.uk (corresponding author)

Abstract

Quasiperiodic metamaterials hold significant potential to unlock novel phenomena. We present convergence analyses of popular methods to approximate their spectra (superspace and supercell methods) and show how they can be used to design new metamaterials.

1 Introduction

Quasiperiodic metamaterials have been the subject of significant recent excitement, thanks to their ability to support spectra with exotic properties. This exciting class of new materials use non-periodic arrangements of meta-atoms to unlock spectra with fractal, dense patterns of spectral gaps, giving engineers the ability to build devices with novel, broadband properties.

Although using non-periodic geometries can unlock some exciting properties, removing the assumption of periodicity means that standard analytic techniques (based on Bloch's theorem) are no longer directly applicable. In practice, the spectral properties of a quasicrystal are typically approximated by methods that replace the quasicrystal with a periodic version of the geometry (meaning that calculating the spectrum is then straightforward). There are two main variants of this in the literature, the *supercell method* and the *superspace method*. We summarise these here and show how the resulting Bloch spectra converge to the spectrum of the quasiperiodic metamaterial.

2 Approximating spectra

Quasicrystals are a special class of non-periodic geometries that can be obtained by taking a projection from a higher-dimensional periodic function. For example, a function $f : \mathbb{R}^n \to \mathbb{R}$ is said to be quasiperiodic if there exists some $m > n$ and some $g : \mathbb{R}^m \to \mathbb{R}$ such that

$$f(x) = g(Rx), \tag{1}$$

for all $x \quad \mathbb{R}^n$, where R is a rectangular m-by-n matrix that "lifts" the vector $x \quad \mathbb{R}^n$ up to Rx in the higher-dimensional space $\mathbb{R}^m$. An example is given in Fig. 1. This means that, although quasiperiodic functions are not generally periodic, they have underlying periodicity that is responsible for their exotic properties and can be exploited to yield efficient methods to compute spectra of systems with quasiperiodic coefficients.

The most widely used approach in the physical literature is a so-called *supercell* method, whereby a non-periodic material is approximated by a periodic one by taking a large piece of the non-periodic material and using it as the periodic unit cell for Bloch spectral calculations (depicted on the right in Fig 1). The intuition is that, if the supercell is sufficiently large, then you will get a reasonable approximation of the desired spectrum. In [1, 2] convergence in the limit of large unit cell size is proved. This means that any features that are common to all the spectra in the sequence (such as the *super band gaps* established for Fibonacci tilings [3]) will exist in the limiting spectrum also.

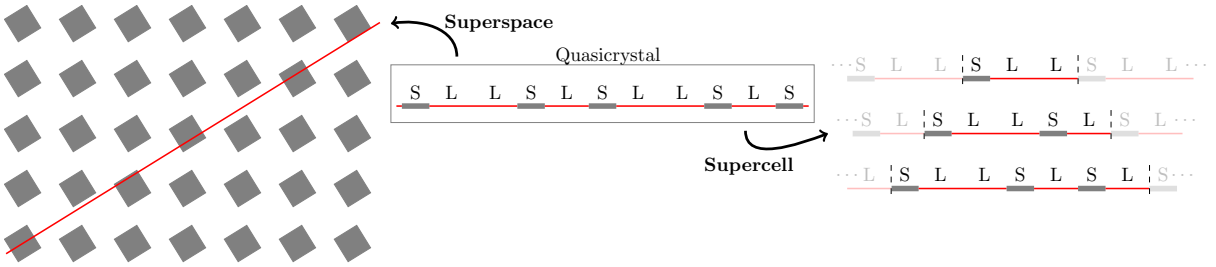

Figure 1: A quasiperiodic crystal can be approximated by a periodic geometry either by lifting into the higher-dimensional *superspace* (left) or by choosing sections to use as a *supercell* (right).

The other promising method is to take advantage of the higher-dimensional periodicity from 1 and solve the differential problem in the higher-dimensional periodic superspace. The challenge here is that the resulting differential operator is somewhat difficult to handle, so it is important to choose the right numerical method to solve the superspace problem. For example, the plane wave expansion method leads to spurious modes appearing [4] (since the operator is not elliptic so we can't expect decay of the Fourier coefficients). However, methods such as finite differences and finite elements give convergent approximations [1].

Given these methods for approximating the spectra of quasicrystals, we can use them to design novel metamaterials. For example, it is possible induce strong wave localisation by introducing an artificial axis of reflectional symmetry, see [5] and references therein. Similarly, graded metamaterials can be created by slowly modulating the projection angle from the superspace. In the framework illustrated in Fig 1, for example, this corresponds to projecting onto a curve instead of a straight line. In [6] it was shown that projecting onto a quadratic givels a *fractal rainbow effect* whereby broadband signals are sorted according to their frequency (a fractal version of the rainbow effects observed in classical graded metamaterials).

Tunable Phonon-Electron Fano Resonance in Si Nanoparticles via Electromagnetic Confinement and Anharmonic Decay in Engineered Media

Michel Kazan

Department of Physics, American University of Beirut, P.O. Box 11-0236, Riad El-Solh, Beirut, 1107-2020, Lebanon
Email: mk140@aub.edu.lb

Abstract: We introduce strategies for modulating phonon-electron Fano resonance in silicon nanoparticles through a designed nanoparticle environment. By leveraging prolonged laser irradiation and electromagnetic field confinement, the resonance can be enhanced, whereas anharmonic phonon decay provides a mechanism for its attenuation. These findings offer new opportunities in photonics and phononics.

The phonon-electron Fano effect, a quantum interference phenomenon between discrete phonon modes and an electronic continuum, plays a pivotal role in nanoscale light-matter interactions [1, 2]. Controlling this resonance is essential for applications in quantum technologies, photonics, phononics, and energy conversion [3-8]. Conventional modulation techniques primarily rely on laser intensity variations [9-11], yet achieving fine-tuned control remains challenging.

This study introduces a dual-approach strategy that integrates external perturbations (laser exposure) and structural modifications (nanoparticle embedding) to achieve precise resonance modulation. Silicon (Si) nanoparticles were embedded within granular matrices composed of zinc oxide (ZnO), monoclinic gallium oxide (β-Ga_2O_3), and graphite (C), and their phonon-electron interactions were investigated via Raman spectroscopy. The analysis focused on the effects of laser-induced electronic transitions, electromagnetic field confinement, and anharmonic phonon decay on the Fano resonance.

Prolonged laser irradiation increased electronic transitions, thereby enhancing phonon-continuum coupling. Raman spectral analysis revealed increased asymmetry and coupling strength over time, signifying an intensification of the Fano effect. Embedding Si nanoparticles within ZnO and β-Ga_2O_3 resulted in multiple light-scattering events that confined the electromagnetic field around the Si nanoparticles. This confinement significantly enhanced the local electric field, strengthening phonon-electron interactions.

In contrast, when Si nanoparticles were embedded in ZnO, laser heating induced a redshift in their phonon resonance frequencies, aligning them with a key feature of the ZnO two-phonon density of states. This alignment facilitated strong anharmonic decay, effectively shortening the phonon lifetime and attenuating the Fano resonance.

The study demonstrates that laser exposure time serves as a crucial parameter for tuning phonon-electron coupling strength, providing a new degree of control beyond conventional laser intensity modulation. Additionally, multiple light scattering in ZnO and β-Ga_2O_3 offers a scalable approach to field confinement and resonance enhancement without requiring intricate nanostructuring. Furthermore, coupling Si phonons with the vibrational modes of the surrounding medium enables controlled attenuation of the Fano resonance, a critical capability for applications requiring selective suppression of phonon-electron interactions.

These modulation strategies unlock new possibilities for optimizing Fano-based sensing, photonic devices, and phononic metamaterials for thermoelectric applications, enabling precise, scalable control over phonon-electron interactions.

In conclusion, this work advances the understanding of phonon-electron Fano resonance in Si nanoparticles, experimentally validating methods for both enhancing and suppressing the effect. By leveraging laser-induced electronic transitions, electromagnetic field confinement, and anharmonic phonon interactions, this study introduces a versatile, cost-effective platform for fine-tuning nanoscale interactions across a wide range of technological applications.

Distinct Exceptional Points in Hermitian Phononic Laminates

A. Fishman, B. Lustig, G. Elbaz, A. Muhafra, V. Varma and G. Shmuel*
Technion – Israel Institute of Technology, Israel
Corresponding author: meshmuel@technion.ac.il

Abstract: Breaking Hermitian symmetry creates degenerate states called exceptional points, typically requiring a challenging gain-loss material design. We exploit the unique nature of elastodynamics to obviate the need for gain or loss, enabling access to distinct exceptional points and excitation of anomalous frozen modes and negative refraction in conservative phononic laminates.

Open systems, which are described by non-Hermitian operators, can exhibit degeneracies where two or more of their eigenmodes coalesce. These degeneracies, termed *exceptional points* (EPs), present exotic wave phenomena, such as anisotropic transmission and negative refraction, and thus serve as a tool for metamaterial design.

Most studies focus on temporal EPs, which form when two (or more) resonance frequencies coalesce. These works incorporate gain and loss that are often balanced to form parity-time symmetry for temporal stability.

Spatial EPs, which form in the complex wavevector space at real frequencies, have received less attention, particularly in elastodynamics, despite their robustness against imperfections. However, elastic waves exhibit features not found in sound and light waves that can be leveraged to design spatial EPs. To appreciate this, consider the ubiquitous scenario of isotropic media, where acoustic waves are longitudinal, electromagnetic waves are transverse, while only elastic waves exhibit both polarizations.

Here, we present a framework that eliminates the need for material gain or loss by breaking spatial Hermitian symmetry using the aforementioned features of elastodynamics. The analysis considers a conservative solid with open boundaries and a sustained driving source. More specifically, we revisit a canonical scattering problem of monochromatic plane waves impinging on a semi-infinite periodic laminate made of two conservative materials. By designing the composition of a unit cell with two isotropic materials, we tuned the energy transfer between the two elastic polarizations at the material interfaces such that two of the forward quasi-transverse and quasi-longitudinal Bloch modes coalesce inside the Brillouin zone [1] (Fig. 1a), forming a second-order EP (EP2). This is in sharp contrast with the well-known scenario of degeneracies at the band edges between forward- and backward Bloch modes of the same polarization. These non-resonant EPs are surrounded by a self-intersecting Riemann surface whose curvature is related to the energy flow, and therefore, the unique topology of these surfaces can be leveraged for anomalous energy transport. We showed that these spatial EPs give rise to negative refraction (Fig. 1b), as they are the crossing of branches of opposite slopes [1].

We extended our design beyond EP2 to achieve the coalescence of three Bloch modes (EP3) by replacing one of the isotropic materials in the unit cell with an anisotropic one [Fig. 1(c)]. This higher-order, non-resonant degeneracy further expands the toolbox for elastic wave shaping by forming waves with zero axial group velocity and finite transmittance (known as 'axially frozen modes' [3]), which can even reach unity [Fig. 1(d)]. Notably, these modes, previously discovered in 3D dielectric laminates [3], are now accessible in simpler, planar settings in elastodynamics, thanks to the distinct tensorial properties of elastodynamics.

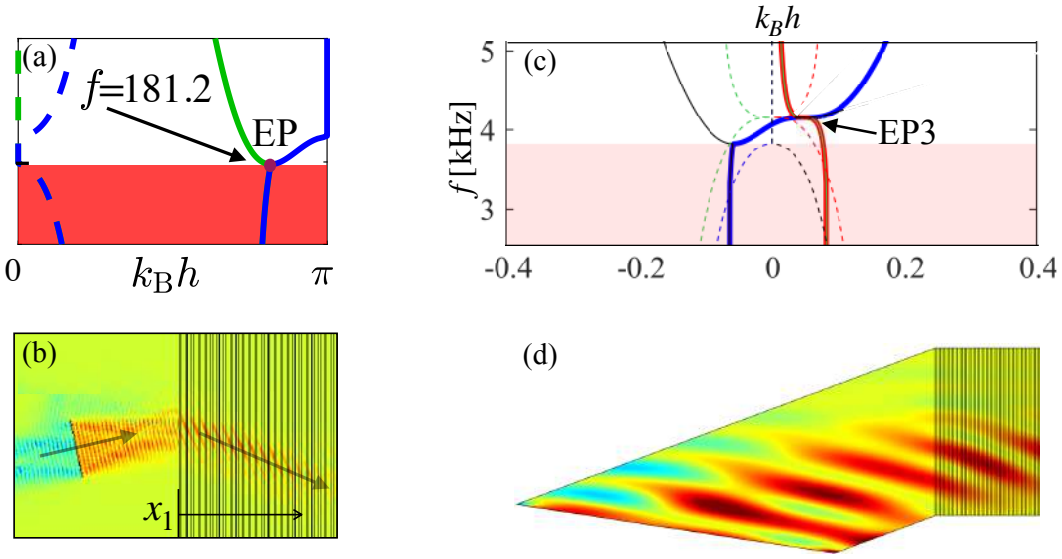

Figure 1: (a) The coalescence of two Bloch modes of the exemplary conservative laminate considered by Lustig et al. [1]. The EPs are shown in a cut in the frequency-Bloch wavenumber (f, k_B) diagram for specific vertical wavenumber about 181.2 kHz. $\mathrm{Re}\, k_B$ and $\mathrm{Im}\, k_B$ are shown in solid and dashed curves, respectively. The real and imaginary parts of a certain branch are plotted using the same color. (b) Full-wave finite element simulations of the axial energy flux in the pertinent scattering problem near the EP. The energy flux is preserved in the laminate and exhibits negative refraction. (c) Coalescence of three Bloch modes of the exemplary conservative laminate considered by Fishman et al. [2]. This EP3 is shown in a cut in the (f, k_B) diagram for certain vertical wavenumber about 4.15 kHz. (d) Full-wave finite element simulations of the axial energy flux in the pertinent scattering problem near the EP, giving rise to axially frozen modes with unity transmittance.

Abstract: An artificial phononic molecule that emulates the electronic properties of trans-polyaminoborane with second-nearest-neighbor hoppings is studied. The numerical band structures obtained with COMSOL Multiphysics agree with tight-binding calculations of the κ-deformed Dirac equation. Topologically protected states are obtained in a 1D finite chain.

Trans-polyaminoborane, a molecule quite similar to trans-polyacetylene, is a polymeric molecule with fundamental properties from an electronic point of view. Being a polymer with high conductivity, it became a cornerstone in organic semiconductors. Its atoms, boron and nitrogen, are located instead of the two carbon atoms composing trans-polyacetylene. We study this molecule with first- and second-nearest neighbors and, in a certain regime, it satisfies the κ-deformed Dirac equation. Although a photonic realization was proposed earlier [1], a fine-tuning of higher couplings is very difficult or almost impossible in that area [1]. As we will show, the engineering of first- and second-nearest neighbors in the coupled-resonator phononic version of these molecules is straightforward. Fig. 1 shows the molecular and artificial representation of the trans-polyaminoborane.

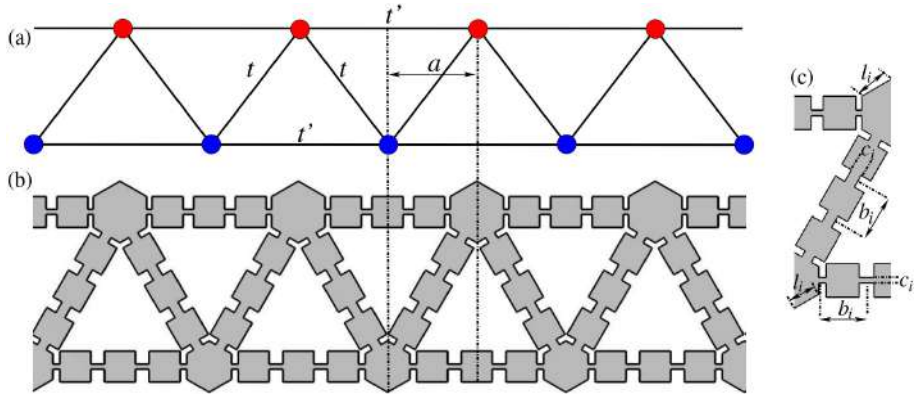

Figure 1: (a) Schematic representation of trans-polyamynoborane with first (t) and second-nearest-neighbors (t´) hoppings. (b) Coupled-resonator phononic molecule of trans-polyamynoborane. (c) Unit cell of length a and l_i is the size of hexagon resonator and b_i the size of connector between resonators and c_i control the detuning hopping parameter. For i = 1, 2 that represent first and second-nearest-neighbors.

The coupled-resonator phononic metamaterials (CRPnMs) [2,3,4] are inspired by the coupled-resonator optical waveguides [5]. In the CRPnMs, resonators are coupled through finite phononic crystals. To build a CRPnM, the following condition is needed: When a normal-mode frequency of the resonator falls within the bandgap of the phononic crystal, the modes of the resonators couple to each other through evanescent waves. In

this case, a phononic tight-binding (TB) regime similar to the TB regime of condensed-matter physics emerges. Additionally, a fine-tuning of the hopping parameters in the CRPnMs opens the opportunity to explore phenomena predicted in solid-state physics and molecular physics that are difficult to observe in those areas.

The band structure of the TB Hamiltonian given in the Eq 1 agrees with finite element simulations. Also, the TB model with second-nearest-neighbor hoppings follows a κ-deformed Dirac equation; the bands are shown in Fig 2. The Dirac cone in one case and the deformation of the bands confirm the theoretical predictions for different hopping values of the second nearest-neighbor hopping.

$$H(ka) = \begin{pmatrix} f_A + 2t_2\cos(ka) & t_1 + t_1' e^{-ika} \\ t_1 + t_1' e^{ika} & f_B + 2t_2'\cos(ka) \end{pmatrix} \quad \textbf{(Eq 1)}$$

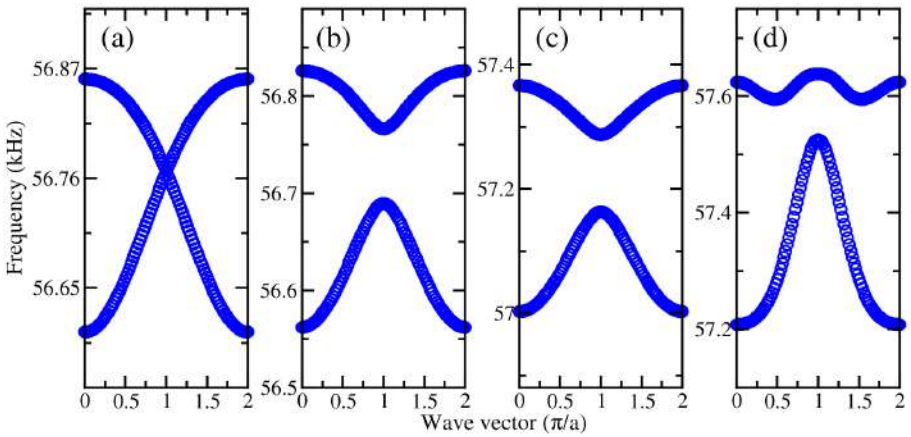

Figure 2: Band structure of the artificial trans-polyamynoborane calculated using finite-element. (a) $f_A = f_B$ and t = 1 and t′ = 0. (b) $f_A \neq f_B$ and t=1 and t′ = 0.1 (c) $f_A \neq f_B$ and t = 1 and t′ = 0.2. (d) $f_A \neq f_B$ and t = 1 and t′ = 0.5.

Realizations of acoustic and elastic meta-structures to reduce noise and vibration

W. Jeon[1*]

[1]Korea Advanced Institute of Science and Technology (KAIST), Republic of Korea
[*]corresponding author: wonju.jeon@kaist.ac.kr

Abstract: We present three meta-structures with audiovisual demonstrations aiming at real-world applications. The first is an ultra-light soundproofing meta-panel to insulate broadband noise from electric vehicles. The second is a meta-liner to insulate noise in ducts while allowing flow. The third is a modified acoustic black hole to suppress structural vibrations.

Acoustic and elastic meta-structures have garnered significant attention as a new technology capable of overcoming the limitations of traditional materials for sound and vibration control. We propose three meta-structures to reduce noise and vibration. The first one is the lightweight soundproofing meta-panel. This light-weight panel efficiently blocks two separate broadband noises simultaneously, offering a solution for isolating and mitigating diverse noise sources. The second one is an acoustic meta-liner. This structure allows airflow while blocking noise, striking a balance that enables the passage of air while impeding the transmission of unwanted sounds. The last one is the meta-damper, and this structure is a waveguide absorber designed based on a spiral acoustic black hole (ABH). The meta-damper absorbs and dissipates elastic waves, effectively reducing vibrations and minimizing their impact.

Our meta-structures for controlling wave energy initially stemmed from conceptualization and theory- and simulation-based examination. The pivotal aspect of the present work lies in the advancement of these conceptualization into realization, marking a breakthrough in wave (e.g. noise/vibration) control technologies.

Acoustic and elastic metamaterials are proposed in this study, showcasing extraordinary performance as wave absorbers and insulators. These characteristics are revealed through fabrication and experimental realization of metamaterials.

1. Meta-panel: “ultra-light soundproofing meta-structure”

The proposed meta-structure consists of membranes and a multi-scale lattice structure and achieves high sound isolation with the aid of negative effective material properties of the meta-panel in each target band [1]. The soundproof performance was experimentally tested in an anechoic chamber using the fabricated meta-panel for practical applications in electric cars. The experimental results show that the meta-panel having area density 1.51 exhibits better insulation performance with a 1/20 times lighter weight compared to a steel plate. We are attempting to utilize the meta-panel to reduce road noise in the low-frequency band and motor noise in the high-frequency band of electric vehicles.

2. Meta-liner: “noise insulator without flow resistance in a duct”

Traditional methods for noise reduction in dusts, such as acoustic mufflers, often impede airflow, compromising system, and exhibit poor performance at low frequencies. To overcome these limitations, a meta-liner is proposed that can attenuate noise for various grazing flow speeds, considering the effect of flow, with little flow resistance. The proposed meta-liner attenuates noise in ducts while allowing airflow. The meta-liner consists of two different sub-wavelength Helmholtz resonators in order to induce hybrid-resonance,

leading to high absorption in upstream direction as well as high transmission loss in downstream direction. The meta-liner is designed using a theoretical model established in a recent study [2] and simulation, which demonstrates high transmission loss per unit length of more than 45 dB/m with a bandwidth of 10% of the target frequency for various flow speeds of 0, 17, and 34 m/s.

3. Meta-damper: "waveguide absorber based on spiral acoustic black holes"

An ABH is a structure with a wedge-shaped geometry, where the thickness decreases according to a specific power law [3]. It concentrates elastic wave energy near the tip of the wedge, utilizing a small amount of damping material to absorb and dissipate the concentrated energy as heat. While such acoustic black holes can significantly attenuate vibrational energy within a structure, they have been limited by their large occupying space due to the long wedge-shaped structure. We address this limitation by proposing a spiral ABH [4]. Its wave absorption performance is validated through fabrication and experiment [5]. Recent advancements include the application of spiral ABH to plate or box-type structures by modifying the spiral ABH into a waveguide absorber [6]. The surface-averaged mobility of the host plate with and without meta-dampers are compared and the results show that reductions in peaks up to 20 dB could be obtained using the meta-dampers. Compared to the traditional material to dampen vibrations, the meta-damper is more light-weight and could achieve superior damping performance by absorbing elastic waves propagating in the plate.

Abstract: This work proposes and realizes a mosaic plate system with a zero-frequency bandgap extending from 0+ up to 6800 Hz, while maintaining translational degrees of freedom. Simulation and experimental results show that this structure exhibits significant vibration cancellation in the 50-6800 Hz range and offers notable sound insulation advantages over a homogeneous plate with the same mass density.

In this work, we propose a mosaic design strategy to achieve a broadband zero-frequency bandgap for flexural modes of a structured plate. By linking finite-sized tile pieces (TPs), we form a mosaic plate (MPt). Multilayered corner joiner pieces (JPs) connect adjacent TPs (Fig.1a and b), enabling the desired zero-frequency bandgap while maintaining TPs' locally resonant modes. This approach effectively disables low-frequency bending wave excitations in the linked system.

The overall MPt structure exhibits static rigidity while displaying an absence of modes at frequencies between 0+ and the locally resonant mode at 6.8 kHz, which can be reflected in the simulated dispersion (Fig. 1c). The vibrational transmission spectrum referenced to a point harmonic vibrator source, obtained by laser vibrometer test, can also support the above conclusion. The experimental results also agree well with the Green function fitting. Compared to a homogeneous plate with the same mass density, the vibration transmission of the MPt shows a significant reduction of amplitude in the 50-6800 Hz range (Fig. 1d to f).

Furthermore, the application of the MPt in sound insulation was analyzed through both simulations and experiments, showing an excellent sound insulation effect that exceeds the performance predicted by the mass density law (Fig. 1g). Our results provide valuable insights into the design and application of acoustic and mechanical metamaterials, especially in the low-frequency regime.

Conditions for Weak Scattering in Flexural Waves

M. Lázaro[1*], V. Romero-García[1], and L.M. García-Raffi[1]

[1]Universitat Politècnica de València, Spain
[*]corresponding author: malana@upv.es

Abstract: This work examines wave propagation in continuous media with weakly coupled scatterers. We rigorously analyze the quantification of weak scattering and the applicability of the Born approximation to elastic waves. The eigenvalues of the scattering matrix are evaluated, and the spectral radius is selected as a representative parameter of scattering behavior.

Metamaterials are structured composites with engineered wave propagation properties. In elasticity, they offer advanced control over flexural waves, with applications in vibration isolation, energy harvesting, and cloaking. The wave response in such systems is influenced by multiple scattering interactions between discrete resonators. When these interactions are weak, simplified models, such as the Born approximation, provide accurate solutions. However, a rigorous criterion for weak scattering in flexural wave systems is necessary. We consider a thin elastic plate governed by the Kirchhoff-Love equation and analyze the scattering induced by a collection of point-like resonators. The total wave field is expressed as:

$$w(\boldsymbol{r}) = \psi_0(\boldsymbol{r}) + \sum_{\alpha=1}^{N} G(\boldsymbol{r} - \boldsymbol{R}_\alpha) T_\alpha \, w(\boldsymbol{R}_\alpha)$$

where $G(r)$ is the Green's function of the plate, T_α characterizes the local response of the scatterers, and $\psi_0(\boldsymbol{r})$ is the incident wavefield. The scattering coefficients satisfy a matrix equation:

$$\boldsymbol{\Psi} = (I - \boldsymbol{g})^{-1} \boldsymbol{\Psi}_0$$

where $\boldsymbol{g} = \boldsymbol{GT}$ encapsulates the interaction between scatterers. If the spectral radius $\rho(\boldsymbol{g}) < 1$, the solution can be approximated by the Neumann series expansion, leading to the Born approximation. To assess the validity of the weak scattering assumption, we analyze periodic and random distributions of resonators. The spectral radius $\rho(\boldsymbol{g})$ is found to depend on both the spatial arrangement of the scatterers and their local mechanical properties. For periodic structures, strong scattering occurs at Bragg frequencies, whereas for random distributions, scattering is governed by the spectral properties of **g**. The solution can be expanded in terms of the Neuman series of the above expression as

$$\boldsymbol{\Psi} = \boldsymbol{\Psi}_0 + \boldsymbol{g}\,\boldsymbol{\Psi}_0 + \boldsymbol{g}^2\boldsymbol{\Psi}_0 + \cdots \equiv \boldsymbol{\Psi}_0 + \boldsymbol{\Psi}_1 + \boldsymbol{\Psi}_2 + \boldsymbol{\Psi}_3 + \cdots$$

Which constitutes the evaluation of the different orders of the scattering problem. Mathematically, this series converges provided that the spectral radius of the matrix is less than the unity. Numerical examples confirm that the Born approximation provides accurate results when $\rho(\mathbf{g}) < 1$.

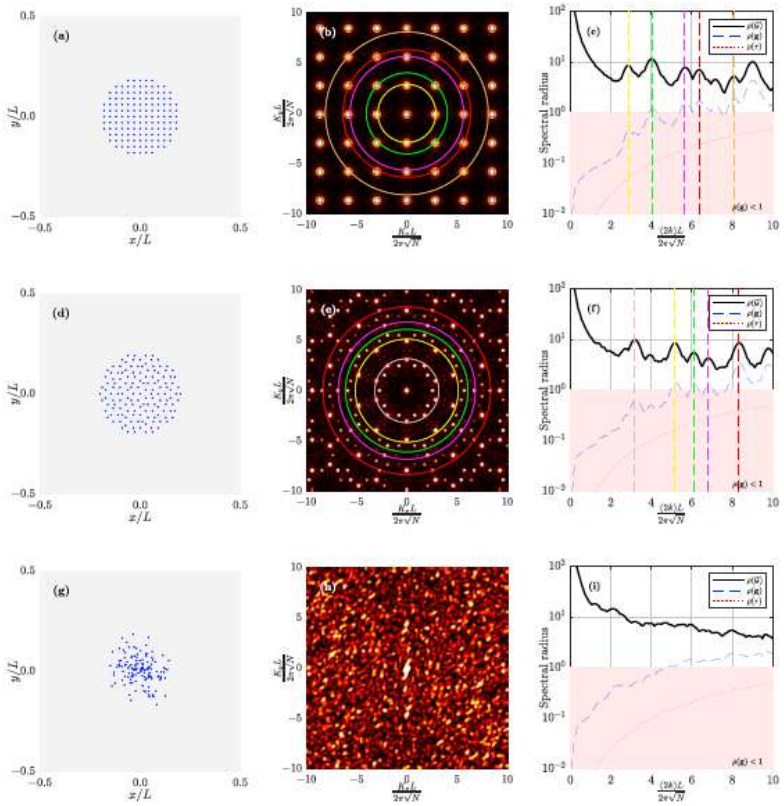

Figure 1. Three mass clusters with different geometric distributions confined within a circle of 80 cm centered on the 2 mm thick aluminum plate. Point distribution patterns: (a) periodic, (d) quasiperiodic (Penrose crystal), and (g) random. The graphs in the central column show the intensity of the structure factor in reciprocal space for each distribution. The right column reproduces the spectral radius of the scattering matrix g and its components, G and, as a function of the plate wavenumber k. The circles centered at the origin of graphs (b) and (e) have radii corresponding to the abscissas of graphs (c) and (f), respectively (same color).

Towards a generalized theory for aeroacoustic metacontinua

U. Iemma[1*] and G. Colombo[1]

[1]Department of Civil, Computer Science and Aeronautical Technologies Engineering, Roma Tre University, Italy
[*]corresponding author: umberto.iemma@uniroma3.it

Abstract: Acoustic metamaterials enable unconventional wave manipulation but lose efficiency in a moving medium, if designed for static conditions. This work encloses the past decade's progress toward a generalized theory for acoustic metacontinua modelling, incorporating convective effects and integrating spacetime differential geometry into enhanced formulations of existing methodologies for aeroacoustic analysis.

Acoustic metamaterials have become one of the research fields that experienced remarkable growth in the last 20 years. This interest is due to their versatility, originating from the possibility of manipulating incoming wavefronts in unconventional ways. Each application requires a specific distribution of parameters that imparts the desired deformation to the incoming wavefronts. Aim of the present work is to present a summary of the recent findings and main achievements attained in the last decade in the development of aeroacoustics noise abatement strategies using metamaterials. One of the outcomes of the European project AERIALIST (H2020, 2017-2020) is the assessment of the substantial increase in the efficiency of the design process when an analytical model of a generic acoustic metacontinuum is used to define the characteristics of the desired meta-device, with the additional advantage of an easier integration in any existing multidisciplinary optimization framework. Indeed, the availability of a model based on unconventional constitutive equations makes possible the achievement of a wide range of targeted wave manipulations, independently of the specific architecture of the device, by simply interpreting it as a black box characterized by the equivalent parameters' distribution. However, in aeroacoustic applications, the performance of acoustic meta-devices deteriorates due to the non-quiescence of the medium in which they operate. This undesired behaviour arises from the underlying physics of the convection phenomenon which, in the mathematical perspective, is represented by the mixed space and time derivatives in the differential operator.In 2013 Garcia-Meca et al. proposed the Analogue Transformations Acoustics (ATA) where, through the reinterpretation of the equations into the spacetime, they circumvent the problematics associated with the background flow presence and create a link between isotropic propagations and convective ones by introducing spacetime coordinate transformations. The methodology relies on the modification of the characteristic of the propagating medium preserving the formal invariance of the governing equation under spacetime coordinate change, with the limitation of not being able to account for anisotropic distributions of its parameters.

Taking inspiration from this work, the authors proposed a similar approach, where the spacetime reinterpretation is integrated into the acoustic metacontinuum modelling procedure: in this fashion, spacetime mappings are used to fictitiously induce convective–like propagation patterns within exotic devices. Since then, the research efforts were directed toward the validation of the spacetime framework and into the analysis of the intimate relationship between the propagation mechanism and the curvature to which the spacetime is subject. So far, the spacetime framework has been validated through the implementation of specific spacetime coordinate transformations associated with specific flow conditions typical of aeronautical applications. Specifically, the methodology's performances rely on the convective effect that the spacetime mapping used is inducing in the acoustic metacontinuum and, therefore, it has been proven that whenever the convective-like propagation

patterns are introduced through a spacetime transformation non-comprehensive of generic flow conditions, analytical errors are inevitably introduced in the model. This effect takes the form of an incomplete performance recovery, which has been demonstrated to be independent of the specific acoustic mirage aimed at, being only related to the properties of the spacetime coordinate transformation used. In fact, the use of an approximate spacetime coordinate change introduces a mismatch between the convective behaviour induced in the metacontinuum and the external conventional flowing medium with which it is communicating. This aspect becomes more relevant the higher the intensity of the background flow, as the relevance of the convection effects that have been neglected is accentuated and, therefore, the difference between the differential operators involved. Consequently, the adapted meta-device reveals a sensitivity to the variations of the background flow intensity and the relative position of the treated zone and the acoustic source: these two aspects represent determining factors in minimizing the residual correction defect and must therefore be considered during the design process of engineering applications. Nevertheless, if one can provide a spacetime mapping fully comprehensive of the characteristics of general flow conditions, then the total recovery of acoustic metacontinua performances can be feasible for any operative condition. The ultimate goal of the present research is to define a generalized theory for the design of aeroacoustic metacontinua that foresees the integration of the mathematical tools of the spacetime differential geometry into the already existing methodologies for aeroacoustic analysis. In particular, one of the objectives of the work is the derivation of an extended, generalised boundary/field integral formulation based on an event-dependent Green function, comprising both anisotropic features and spacetime curvature.

Acoustic and Mechanical Features of Polymer Colloidal Crystals – Brillouin Spectroscopy Studies

Bartlomiej Graczykowski[1]

[1]Adam Mickiewicz University Poznan, Faculty of Physics and Astronomy,

Uniwersytetu Poznańskiego 2, 61-614 Poznań, POLAND

[*]corresponding author: bartlomiej.graczykowski@amu.edu.pl

Abstract: Colloidal crystals (CCs) of polymer nanoparticles exhibit tunable acoustic and mechanical properties but are often brittle. Using Brillouin light scattering, we study GHz sound filtering and elasticity mapping in 2D and 3D CCs. We also demonstrate a supercritical fluid-based cold soldering method to enhance CCs robustness while preserving periodicity.

Colloidal crystals (CCs) made of polymer particles are low-cost and low-effort volumetric structures that serve as promising metamaterials for surface coatings and light and sound manipulation. Colloidal crystals composed of sub-micrometer particles can host features typical for photonic (PhCs) and phononic crystals (PNCs), operating in the visible light and hypersound regimes, respectively.

Typically, CCs are formed through the self-assembly of nanoparticles (NPs) into 1D (chains), 2D (monolayers), or 3D (bulk) structures. The mechanical and acoustic properties of CCs are mostly fixed and predetermined during fabrication and depend on particle size, elasticity, and interfacial forces. However, due to the weak van der Waals forces binding the constituent particles, self-assembled CCs are often brittle, which may limit their applications and performance.

This work presents results of experimental studies utilizing Brillouin light scattering spectroscopy (BLS) to investigate the acoustic and mechanical properties of 2D and 3D CCs made from self-assembled polymer (polystyrene and PMMA) nanoparticles. Specifically, we demonstrate multiband GHz sound filtering in 2D colloidal PnCs) attributed to three distinct types of acoustic band gaps that can be tuned by particle size and are influenced by adhesion and unavoidable fabrication impurities at contact interfaces.

Additionally, we introduce upgraded BLS capabilities by integrating it with a microscope and a scanning sample stage for elasticity mapping of colloidal mesostructures with micrometer spatial resolution. Our focus includes CCs and colloidal glasses (CGs) with varying spatial distributions of particle sizes and degrees of order. These include CGs with monodisperse systems, binary mixtures, bilayer structures, continuous size-gradient structures, and size-gradient mixtures.

Finally, we demonstrate how CCs can be mechanically reinforced into robust systems using a non-chemical treatment with supercritical fluids at temperatures well below the glass transition. This method, termed solid soldering, leverages two key effects: plasticization of the particle surface and compressive hydrostatic pressure. This process results in permanent physical contact between nanoparticles while preserving the periodic arrangement of the colloidal crystal. Using BLS, we determined the optimal pressure, particle size, temperature, and time range for effective soldering.

Locally Resonant Elastic Metagratings: Theory, Experiment, and Applications

L. Cao[1*], Y. -F. Wang[1], B. Assouar[2] and Y. -S. Wang[1]
[1]Department of Mechanics, School of Mechanical Engineering, Tianjin University, China

Abstract: This report introduces the concept of Locally Resonant Elastic Metagrating (LREM), a new paradigm for efficient, compact, and lightweight wave manipulation in elastic wave systems. By combining elastic impedance modulation and hybridization of evanescent waves, LREM overcomes size limitations and challenges posed by vibration modes in traditional metastructures.

Metamaterials and metasurfaces have revolutionized the manipulation of waves, enabling new control over electromagnetic, acoustic, and elastic waves. However, these technologies have been limited by challenges such as low efficiency and complex fabrication processes. Optical and acoustic metagratings have helped address some of these issues, but challenges remain, especially in the context of elastic wave manipulation. This research presents a new type of metagrating called the Locally Resonant Elastic Metagrating (LREM), which combines the benefits of both locally resonant materials and metagrating principles to overcome limitations in size, efficiency, and real-world application hurdles.

The concept of the LREM is based on the idea of elastic impedance modulation and the hybridization of intrinsic evanescent waves, which leads to highly efficient and compact wave manipulation. By adjusting local resonance properties, the LREM structure can achieve performance characteristics that are difficult or impossible for conventional elastic metagratings and metasurfaces to replicate. The LREM overcomes some of the most significant challenges posed by traditional metastructures, particularly the issue of vibration modes in finite structures, which often hinder their practical implementation in real-world applications.

To demonstrate the effectiveness of the LREM, we conducted both theoretical analyses and experimental validations. The LREM can achieve wide-angle perfect absorption, direct wavefront reflection with unitary efficiency, and other complex wave-manipulation behaviors. These results indicate that LREM structures are not only efficient but also versatile in their ability to control wave propagation in elastic systems.

The potential applications of the LREM are vast. The ability to control elastic wave propagation with high efficiency, compactness, and minimal mass makes it a promising candidate for integration into micro-electromechanical systems (MEMS). MEMS-based sensors and signal processors could benefit significantly from the integration of LREM structures, allowing for more efficient, smaller, and more functional devices.

Moreover, the LREM's ability to enable advanced wave transformations, such as focusing and holography, makes it ideal for cutting-edge applications in fields like medical imaging and

wave-based computing. The unique properties of LREM could also lead to further innovations in the design of elastic wave systems, opening the door for future investigations into impedance-engineered wave manipulation across a range of physical wave systems.

Applications of mechanical metamaterials in microsystems: challenges and perspectives

V. Zega[1,*]

[1]Politecnico di Milano, Italy
[*]corresponding author: valentina.zega@polimi.it

Abstract: Mechanical metamaterials, thanks to their exceptional properties, are entering the world of microsystems as valid solutions for the increasing request of better performances at reduced power-consumption, footprint and costs. Here, an overview of the main results achieved on the topic are reported together with the main challenges and perspectives.

Mechanical metamaterials are artificial materials designed with specific geometric structures to achieve unique mechanical properties and/or to control wave propagation in unconventional ways [1].

Among different examples of mechanical metamaterials available in the literature, here the ones that find a direct application in the Micro-Electro-Mechanical Systems (MEMS) world are identified and described. A special focus will be addressed to the recent research activity carried out in the Civil and Environmental Engineering Department of Politecnico di Milano on the integration of metamaterials on microsystems.

MEMS, because of the large variety of their possible applications spanning from the consumer electronics, to the automotive industry up to the aerospace field, are indeed asking for innovative solutions in terms of mechanical design and working principles to satisfy the increasing request for better performance, reduced footprints, low power consumption and low costs. To date, mechanical metamaterials represent a valid candidate for achieving such goal.

Auxetic materials, i.e. mechanical structures exhibiting a negative Poisson's ratio, have been demonstrated at the small scale exploiting the typical capacitive MEMS actuation/readout mechanism [2]. The auxetic unit cell has been optimized to obtain a negative Poisson's ratio and at the same time to represent a valid alternative to motion coupling mechanisms needed in MEMS devices like e.g. gyroscopes.

The bandgap property of a periodic arrangement of properly shaped unit cell has been then exploited to design, fabricate and test an innovative vibration isolation platform to be installed between the MEMS device and the external package [3]-[4]. The unit cell, fully compatible with standard MEMS fabrication processes, has been optimized to provide a total isolation of the MEMS resonant device from the external unwanted vibrations that could compromise the correct functioning of the sensor/actuator. The proposed solution has been firstly validated at a bigger scale by considering a manual assembly of the vibration isolation platform with the MEMS device under test [3] and then designed to be fabricated in a fully-integrated system through the Thelma-Double fabrication process developed by STMicroelectronics [4]. Fabrication of the last device is currently in progress.

The bandgap property of a properly designed unit cell has been also optimized for applications in MEMS resonators for clocks applications. In such devices, indeed, it is crucial to minimize damping sources. The bandgap property of a phononic crystal surrounding the MEMS mechanical structure has been demonstrated to strongly reduce anchor losses, which is one of the dominant dissipation mechanisms in MEMS resonators packaged in near-vacuum conditions [5].

The last two results summarized in the present review contribution, regards the elastic waves manipulation through metamaterials. In particular, a MEMS waveguide has been designed, fabricated and tested by

introducing a defect line in a periodic matrix disposition of properly shaped unit cells [6]. The waveguide, fully compatible to standard MEMS fabrication processes, is able to transfer energy from one resonator to another one located far apart in the silicon wafer. Finally, aware of the promising results achieved at the macroscale [7], a MEMS lens has been designed and fabricated to amplify and focus elastic waves on a specific point where a piezoelectric patch is able to acquire the signal and, in principle, harvest energy. Experimental testing is currently ongoing.

Despite some applications of metamaterials in MEMS have been demonstrated in the literature, there is still a lot of work to do to bring such technology in the industrial practice. Main limitations are at the moment related to the lack of knowledge in terms of reliability, but also to the not negligible encumbrance with respect to standard MEMS requirements.

Part of the research activity is funded by the European Union's EU Framework Programme for Research and Innovation Europe Horizon under Grant Agreement No 101119917.

Part of the research is funded by STMicroelectronics through the Joint Research Platform STEAM.

Developing active acoustic metamaterials using magneto-rheological fluids

R. L. Watson[1*]

[1]University of Warwick, United Kingdom
[*]corresponding author: r.watson.2@warwick.ac.uk

Abstract: Active acoustic metamaterials are being developed through incorporation of magneto-rheological fluids to allow control of fluid/ metamaterial structure interactions and provide active control of metamaterial systems. Investigation of Magneto-rheological fluids, non-magnetic phononic crystals and their acoustic properties has been undertaken with locally manufactured magnetic field generation systems.

Acoustic metamaterials are formed through the construction of structures which show metamaterial properties. These structures are typically fixed and unable to be varied resulting in desired properties only at specific fixed frequencies[1,2]. The ability to vary the performance of metamaterials both in action and frequency of operation would widen the possible applications in acoustics and ultrasonics. These vary from sound absorption (minimising unwanted industrial or road noise), and filtering of specific ultrasonic frequencies for NDT and medical applications[3].

The operation principles for acoustic metamaterials are dependent on the dimensions of the acoustic metamaterial and the acoustic impedance difference between the metamaterial structure and the surrounding fluid. Acoustic impedance difference controls the fraction of the total energy of the acoustic waves passing into the metamaterial structure[4]. A large difference also results in greater surface reflection and minimizes sound wave energy entering the metamaterial structure. Control of acoustic impedance between the metamaterial substrate and the fluid with its structure is also essential for the operation of both phononic crystals and metamaterials with resonant cavity structures.

Magneto-rheological Fluids (MRFs) are fluids which change their properties due to an applied external magnetic field. MRFs are composed of a carrier fluid (typically mineral or silicone oils) and micron sized magnetic (typically iron) particles. When a magnetic field is applied, the particles align and form chains along the magnetic field. These chains alter the rheological properties of the fluid, and hence the application of an external field to an active fluid enables external control of metamaterial properties[5]. MRFs are widely used in adaptive suspension systems in cars due to this behaviour. The ability to change the rheological properties of the fluid allows the possibility of changing the acoustic impedance of the metamaterial fluid interaction, and hence to allow the development of active acoustic metamaterials. This would allow alteration of frequency of operation for the metamaterial system without changing the structure of the metamaterial.

MRFs have been prepared and their acoustic and ultrasonic properties have been studied in different magnetic fields, with further investigation of non-magnetic phononic crystal structures. Manufacturing of the required apparatus has been undertaken at Warwick to allow the control of the applied magnetic fields, shown in Figure 1.

Abstract: It is well known that, to compete in the global market, the design of modern aircraft is driven by the continuous improvement of the safety and cabin comfort. The surrounding environment and particularly noise and vibration (N&V) can deeply affect passengers and pilots in cabin and cockpit, especially during long haul flights. On the other hand, spacecraft and its payload are subjected to high structural vibrations, during launch phase, that are crucial in view of the overall success of a spacecraft's mission. In this sense, reducing the acoustic loads plays a significant role in cost optimization of the mission. A possible solution to the problem of noise is the conception of high-performance acoustic treatments for the trim panels of aerospace vehicle.

An overarching challenge is the design of 2D structures capable of providing exceptional sound insulation on a wide frequency range, especially in the aerospace field where the materials are required to obey several criteria that usually clash with the acoustic one, such as lightness, thinness, mechanical strength, fire-resistance, etc. Low frequencies are especially difficult to absorb with conventional materials, as the order of magnitude of the wavelength is much greater than the reasonable thickness of trim panels. Therefore, a new research field has emerged to study acoustic metamaterials (AMM).

Aircraft noise is due to the combination of different sources such as powerful propulsion systems, high-speed aerodynamic flow over vehicle surfaces and operation of on-board systems, as air conditioners, pressurization system, etc. In order to evaluate noise levels and vibration transfer paths in the whole frequency range, there are various methods to consider, because none of them has shown a complete reliability, but can be used only in a limited frequency region. In the low frequency range, the behavior of a structure is deterministic and the basic tool applied for the analysis of vibration problems is the finite element analysis on the numerical side [101].

The Finite Element Method (FEM) is well-established and yields accurate results for the structural analysis of any geometrical shapes. However, the metamaterials require a mesh of all the details of the constituent unit cells, so this method can become very costly in computational time when large components are analyzed. Efficient FEM models have been recently implemented on the basis of Carrera Unified Formulation (CUF) to perform the vibro-acoustic analysis of advanced materials coupled with fluid [2] and the dynamic characterization of composite metamaterials [3].

Applying these innovative models, the present work aims to analyze the transmission loss properties of sandwich structures with metamaterial core. The metamaterial configurations considered are inspired to the work

[4]. The results demonstrate that a new concept of sandwich light-weight structures can be conceived by taking into account the acoustic requirement in the design of aerospace trim panels. The Figure 1 shows an example of metamaterial core considered and some curves of transmission loss computed with the advanced FEM models employed in this work.

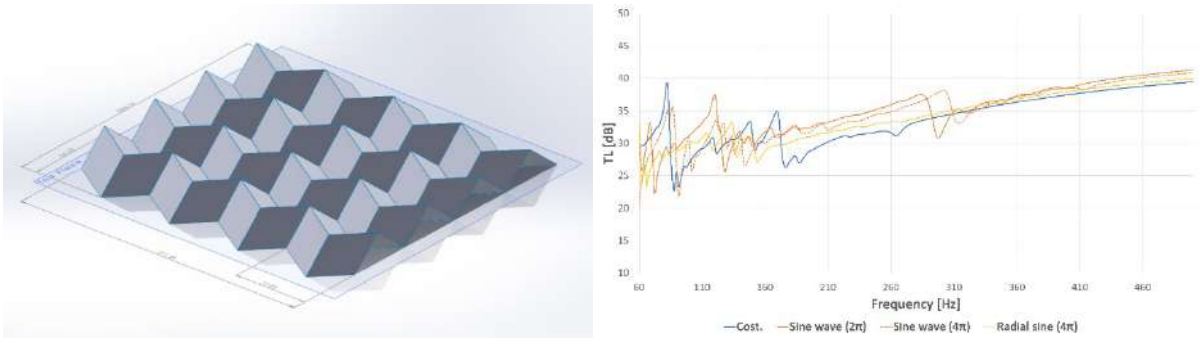

Figure 1: Miura-ori phononic structure and transmission loss curves computed for different AMM configurations.

Abstract: Hypersonic surface acoustic wave (SAW) propagation was experimentally studied by laser Doppler vibrometry. The SAW was measured along different regions of nanocrystalline silicon devices at excitation frequencies from 2-2.3 GHz. The data reveals wavelength variations, phase velocity differences and acoustic impedance mismatches which contribute to the dissipation of mechanical energy.

The study of hypersonic surface acoustic waves (SAW) propagation and its interaction with nanostructures enriches our understanding of elastic energy coupling and dissipation in micro and nano scale phononic circuits [1-3]. This is relevant for acousto-electric interactions [4], phononic waveguiding, and quantum applications [5].

We report the propagation of hypersonic SAWs along a 220 nm thick nanocrystalline silicon (nc-Si) supported by silicon dioxide (SiO_2) and free-standing nc-Si nanomembrane. The geometrical parameters are depicted in Fig.1(a). Showing the structure studied from the bottom to the top: silicon substrate, 1000 nm silicon dioxide (SiO_2), 220 nm nc-Si, 550 nm thick aluminum nitride (AlN) film, and 100 nm thick aluminum (Al). The interdigitated transducer (IDT) was patterned on the Al layer by optical lithography with about 500 nm spacing between the electrodes and 500 nm in width. Optical microscopy image of the fabricated device is shown in Fig.1(b).

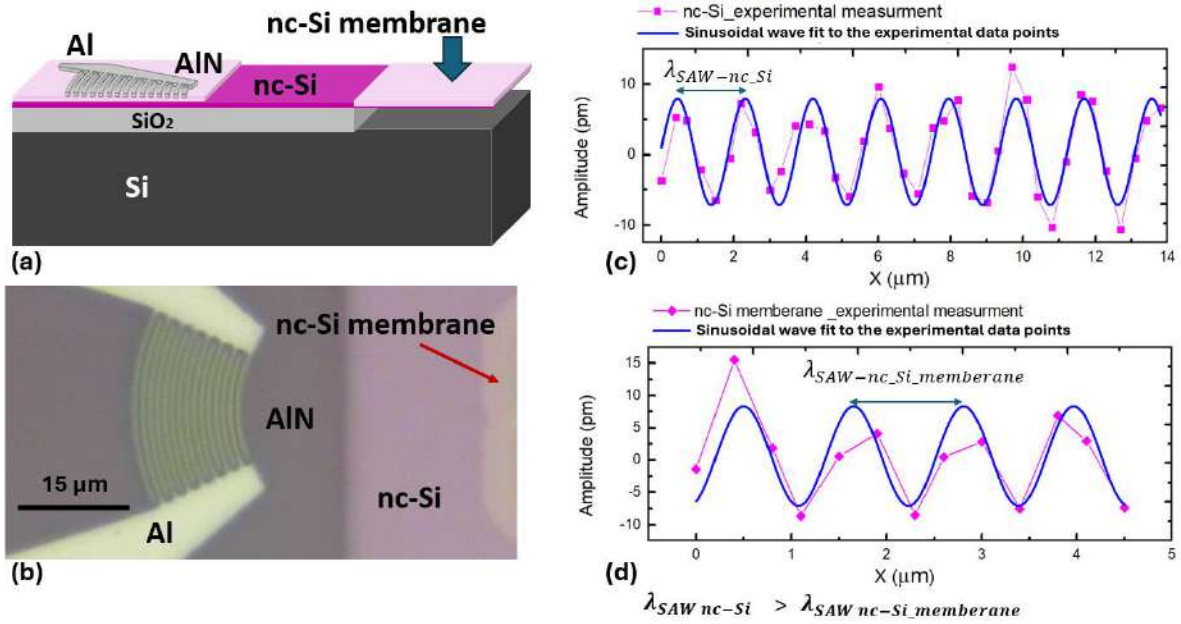

Figure. 1 (a). Schematics of the device. (b). Its optical microscopy image. (c). Out-of-plane displacement amplitude as a function of position (x) along the supported nc-Si, and (d). along the nc-Si membrane.

We measure the out-of-plane SAW displacement over nc-Si and the nc-Si membrane at frequencies range

from 2.0 to 2.3 GHz with a 50 MHz resolution by laser Doppler vibrometry. The SAW was excited by a coherent electrical signal generated by a vector network analyzer and delivered to the Al electrodes via electrical probes. The out-of-plane displacement amplitude as a function of position (x) is shown in Fig.1(c). and Fig.1(d). for the supported nc-Si and the free-standing nc-Si membrane, respectively. A sinusoidal wave fits the experimental data is shown by the blue line in Fig.1(c, d).

Fig.1(c, d). reveal the variations in the SAW wavelength along the supported nc-Si and nc-Si membrane, respectively. The SAW propagates at different phase velocities based on the variation of its wavelength along *x*. This indicates changes in phase velocity and acoustic impedance. The impedance mismatch at the interface leads to partial wave reflection, mode conversion, and energy dissipation, contributing to attenuation. In other words, due to the change in phase velocity at the interface and consequently, the acoustic impedance mismatch, a portion of the energy does not couple to the membrane and is dissipated within the multilayer structure. These effects influence the acousto-electric interactions, the phononic waveguiding, coupling, and signal transmission.

The study in [6] discusses various factors contributing to mechanical energy dissipation, including clamping losses, air /surrounding medium friction, body radiation and material properties. By analyzing SAW propagation and its phase velocity, our data suggests that the acoustic impedance mismatch contributes to the dissipation. This observation will improve the understanding of the coupling efficiency of acoustic waves to membrane-based devices [7].

Metastructures: New Approaches to Enhancing Disaster Resilience and Reduced Embodied Carbon

O. S. Bursi[1], T. Guner[1]

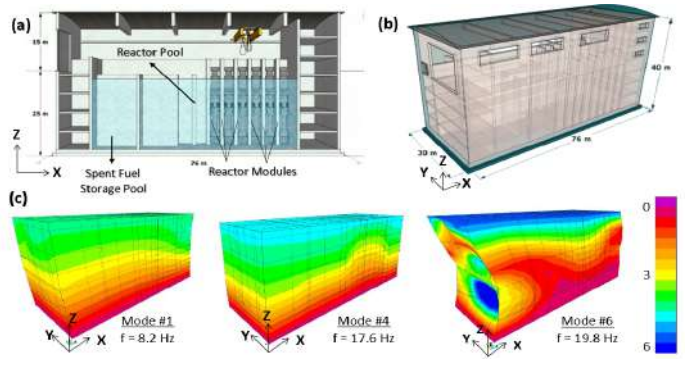
"Symposium V: Architectured Elastic and Acoustic Metamaterials & Phononic Crystals."

Abstract: Locally resonant linear and nonlinear metafoundations have been conceived for seismic isolation of small modular reactors also for significant vertical components of earthquakes. Along the same lines, metastructures have been introduced into typical steel frames enhanced with locally resonant metastructures in view of weight reduction and, hence, reduced embodied carbon.

Differently from the word metamaterials, the word metastructure denotes concepts and applications for which a performance is defined not only by the configuration of atoms or molecules that influence material bulk properties, but also by overall dimensions, i.e. geometry and boundary conditions imposed on an assembly consisting of a finite number of units – a finite lattice -. Along these lines, some researchers proposed the seismic isolation of nuclear power plants by means of metastructures with massive solutions [1]. Conversely, we study the seismic mitigation of a typical nuclear small modular reactor (SMR) where extreme loading conditions are considered by the safe shutdown earthquake (SSE). For this purpose, to reproduce the main dynamic properties of the reactor's reinforced concrete system, a detailed structural model was synthesized, also taking into account the presence of the reactor pools, as shown in Fig. 1. Thus, to protect the reactor from strong earthquakes, finite locally resonant multiple degrees of freedom metafoundations were developed; and resonator parameters were optimized by means of an improved frequency domain multivariate and multiobjective optimization procedure [2]. Also, the stochastic nature of the seismic input was taken into account. It is then proposed: i) a linear metafoundation endowed with multiple cells, linear springs and linear viscous dampers as shown in Fig. 2.; and ii) a foundation equipped with additional nonlinear vertical quasi-zero stiffness (QZS) cells. QZS cells were obtained by horizontally precompressed springs in an unstable state with vertical springs in parallel. With this arrangement, additional flexibility and dissipation against non-symmetrical modes of the SMR and vertical seismic loadings are proposed.



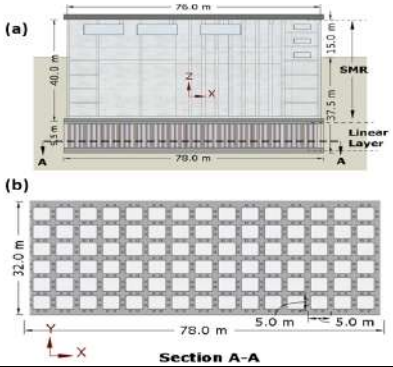


Fig. 1 Schematic of the SMR and FE modal analysis results: (a) inner view; (b) outer view; (c) deformed shapes relevant to Modes 1,4 and 6.

Linear Metafoundation (LM) layout: (a) Section view of coupled LM-SMR, (b) Plan view of the linear layer.

Thus, the performance of the optimized metafoundations was assessed by means of frequency and time history analyses, and finally, results were compared with an SMR endowed with both rigid foundation and conventional base-isolation solutions.

In 2021, the construction sector accounted for 37 per cent of worldwide carbon emissions and 36 per cent of the global primary energy supply [3]. Thus, the issues of sustainability and embodied carbon are important [4]. In this respect, we introduce controlled steel buildings endowed with novel locally resonant metastructures inspired by metamaterial concepts. A major limitation of finite locally resonant metastructures in low-frequency vibration control is the requirement for large additional masses. Conversely, properly designed periodic structures inside a main structure can function as locally resonant metastructures with limited extra mass and proper damping. By incorporating locally resonant metamaterials, this study advances the potential of seismic steel frames, to enhance seismic performance while reducing material usage, thus addressing both structural efficiency and sustainability. Therefore, our research covers both the elastic and the inelastic range, where frames are optimally designed to meet both immediate occupancy and life safety performance limit states. In particular, to demonstrate the efficacy of the proposed approach two case studies, one involving a 25-story moment resisting steel frame, see Fig. 3 and 4, and the other focusing on a 20-story eccentrically braced steel frame structure, are analysed. A multi-objective optimisation methodology is employed to illustrate the trade-off between metastructure inherent damping ratio and material usage, i.e. embodied carbon emissions, highlighting the environmental benefits alongside structural performance improvements. The results demonstrated that optimal mass reduction for the proposed metastructures in both lateral-resisting systems was feasible, with reduction rates of at least 11.3 per cent and 13.7 per cent without additional damping in the metastructures compared to the original configurations. Finally, the reduction in embodied carbon was analyzed based on the material usage in the framed structures.

On the practical use of wooden logs sonic crystals as road traffic noise barriers

P. Amado-Mendes[1*], and L. Godinho[1]

[1] University of Coimbra, ISISE, ARISE, Department of Civil Engineering, Portugal

Abstract: The concept of sonic crystals for road traffic noise mitigation has been explored, making use of a highly sustainable solution made of wooden logs. Complementary approaches have been adopted, with extensive numerical analyses, concept validation in laboratory conditions and in situ prototype acoustic characterization.

Since the mid-twentieth century, the developed world has been aware of the harmful effects of noise caused by road and rail circulation on users near the communication pathways. Recent studies by the World Health Organization point to the annual loss of 1 million years of healthy life, only in Western Europe as a consequence of exposure to environmental noise and, in particular, traffic noise. A widely implemented mitigation solution has been that of physical sound attenuation systems, positioned in the vicinity of the pathways, designated by noise barriers. Currently, there are several solutions on the market for noise attenuation from road and rail traffic, the vast majority of them based on a vertical and continuous, usually with opaque structure, solutions that are already widely studied, thus being known their behavior and performance limits.

In order to overcome some disadvantages of traditional noise barriers, in the last two decades, investigations have addressed the concept of noise barriers based on sonic crystals. These are manmade periodic structures, created with scatterers periodically arranged in regular configurations with a constant lattice and exhibiting contrasting properties to the host acoustic medium where they are embedded [1]. Because of the periodicity effect, this arrangement of scatterers generates a well-defined frequency range (usually called bandgap), where significant sound attenuation occurs. In fact, sonic crystals are considered a promising solution, especially for the selective attenuation of sounds, e.g. as road traffic noise barriers [2]. The idea developed in the scope of a recent research project corresponds to a highly sustainable solution, with the scatterers being made up of wooden logs collected from forest cleaning operations and only requiring very low processing of the timber logs. Thus, a contribution to the state of the art of sonic crystal barriers is proposed, with data registered from experimental tests and compared to numerical results computed through different numerical and simulation methods [3,4,5].

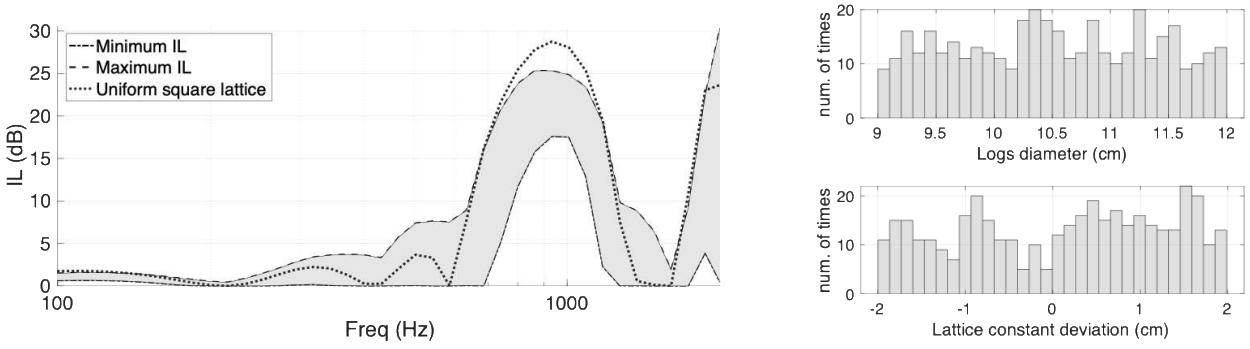

Figure 1. Left: Insertion Loss variation range resulting from randomization of both scatterer position and diameter; Right: histograms accounting for the lattice constant deviation and logs diameter change.

The noise barriers' behavior and obtained insertion loss values have been studied for different scatterer arrangements and shapes, as well as the effect of variations in the regular arrangement of the logs (Figure 1) [6].

In a further step, a wooden sonic crystal noise barrier prototype has been proposed and designed, man crafted and installed along a roadway, giving the opportunity to fully characterize the in situ acoustic behavior of this sustainable and innovative noise mitigation device [7]. Both the in situ airborne sound insulation under direct sound field conditions, in accordance to EN 1793-6 standard, and the in situ Insertion Loss of the outdoor noise barriers, following the ISO 10847 standard, have been evaluated, and the corresponding global acoustic indices have also been computed, demonstrating very interesting attenuation values in practical real context.

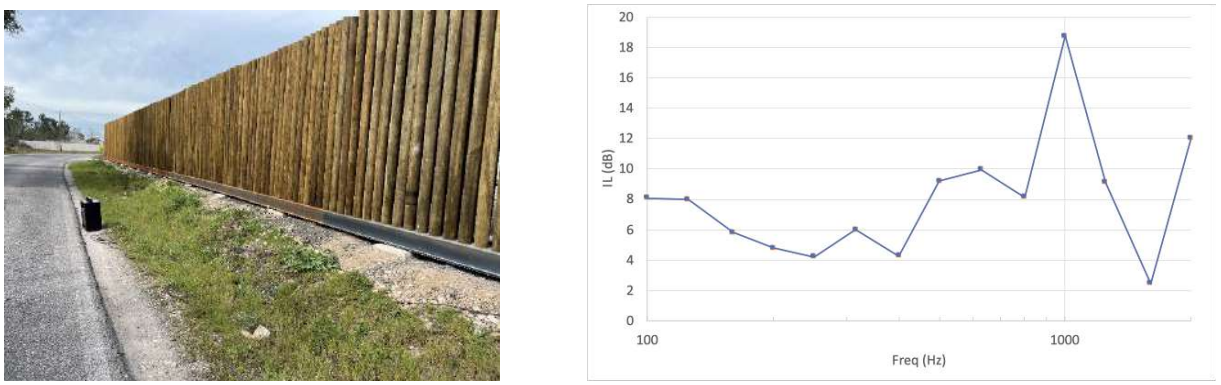

Figure 2. In situ Insertion Loss measurement. Left: Setup for wooden sonic crystal noise barrier prototype characterization; Right: Insertion Loss measured data in 1/3 octave frequency band, following ISO 10847.

Abstract: We report phononic waveguide interfaces capable of supporting topological edge modes. We investigate the topological properties of the edge modes in different waveguide interfaces, revealing robust propagation with negligible backscattering. Our results provide valuable insights for the design of low-loss phononic components for device applications.

Topological waveguide systems have recently emerged as one of the important platforms for the control of electromagnetic and elastic waves due to their unique properties like unidirectionality, robustness, backscattering-free propagation in the presence of structural defects/disorders, etc. [1-4]. Here, we investigate different topological waveguide interfaces using hypersonic phononic crystal structure consisting of patterned plates and exhibiting Dirac gaps in the range of 13-14 GHz. The design of the proposed topological phononic waveguide is illustrated in Fig. 1.

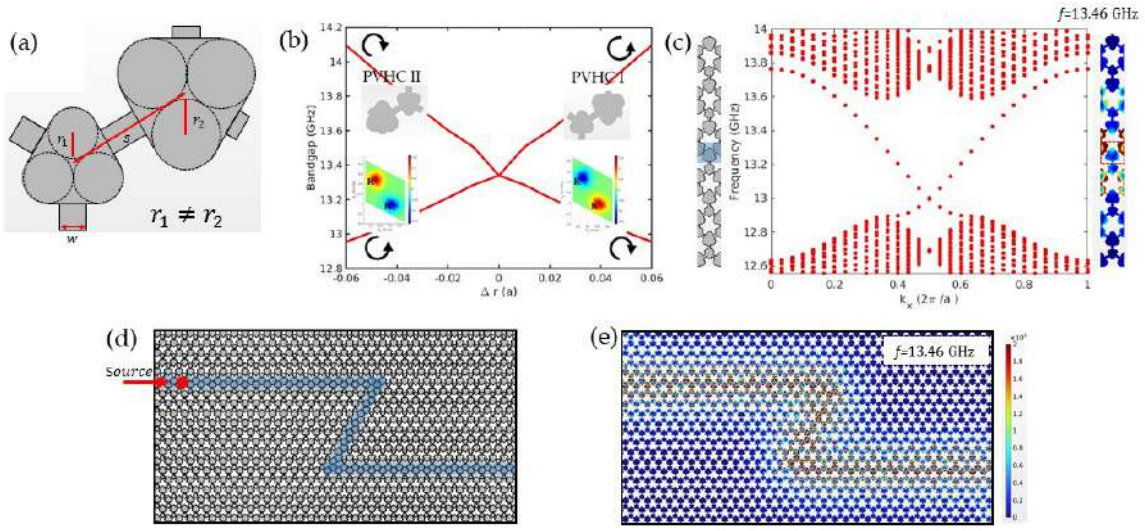

Figure 1. (a) Unit cell for PVHC. (b) Bandgap variation as a function of asymmetry (Δr); Inset shows the unit cell and corresponding Berry curvature distributions. (c) Dispersion plot for the Zigzag interface with a periodicity of a = 381 nm, r_1= 0.11a and r_2= 0.15a; Right: shows the supercell along with the displacement field. (d) Z-path topological waveguide, and (e) Robust topological wave propagation through a Z-path waveguide.

The waveguide structure is formed by using two topologically different phononic valley Hall crystals (PVHCs), whose unit cell comprises of two rounded triangles made of silicon. When $r_1 = r_2$, a degeneracy exists at $f \sim$ 13.3 GHz, which is lifted when $r_1 \neq r_2$. Topological invariants such as the Berry curvature (inset of Fig.1(b))

and Valley Chern number exhibit non-zero and opposite values around the K-points for the PVHC-I and PVHC-II structures confirming their nontrivial and distinct topological nature. The topological waveguide is then engineered by interfacing these two PVHC structures.

The supercell for the topological Zigzag type waveguide is shown in the left panel of Fig. 1(c). By examining the dispersion plot (Fig. 1(c)), it is observed that topological edge modes are excited within the band gap. The displacement field distributions (right panel of Fig. 1(c)) indicate that the field is primarily confined to the larger triangles forming the interface. To assess the robustness of the proposed topological waveguide, we probe the transmission through a Z-path waveguide, as shown in Fig. 1(d). For this, a point source is introduced at the waveguide's input and the transmission is examined along the Z-path. The displacement field distributions (Fig. 1(e)), reveal stronger confinement of field close to the interface. A detailed inspection of the transmission before and after the sharp bends of the Z-path waveguide shows that displacement field amplitudes remain nearly unchanged thus, confirming the robust nature of the excited edge modes. Further studies are performed for different cases of asymmetry as well as waveguide configurations. Our results demonstrate backscattering immune robust propagation of elastic waves paving the way for low-loss phononic device applications [5,6].

Abstract: This talk will focus on the novel discoveries emerging from the integration of artificial intelligence and artificial structures, and explore how this synergy has led to groundbreaking advancements in relevant application fields including such as acoustic imaging and noise reduction.

The recent emergence of acoustic metamaterials has overcome the limitations of acoustical properties of naturally available materials and enabled novel wave-steering phenomena, opening up new applications in a wide range of scenarios. Meanwhile, artificial intelligence is already making a significant impact in many other scientific disciplines and research fields. In this talk, I will first briefly review some of our recent advances obtained by coalescing acoustic metamaterial and artificial intelligence. To go beyond the limitation in current acoustic metamaterials that can only manipulate the sound fields in a predetermined way, we build an acoustic "neuromorphic system" based on artificial structures, and proved that an array of unit cells following deep-learning-assisted design of parameters is endowed with the 'intelligence' to solve various complicated tasks in a simple, precise, fast and passive manner. Additionally, a new imaging mechanism based on synthetic frequency codec, achieved by integrating disordered metamaterials with artificial intelligence, will also be introduced, which enables reducing the imaging system's dimension in both space and time simultaneously and thereby allows real-time imaging from only a single signal. On the other hand, based on the unconventional wave-steering functionality and high design flexibility, we propose to inversely design acoustic metamaterials with the aid of machine learning technique and realize a series of acoustic functional devices with superb performance, whose applications in various scenarios such as absorption and isolation of low-frequency sound are also demonstrated.

Sound-absorbing Metasurface using Hybrid Resonators with Embeded Necks and Micro-perforations

Hyeonbin Ryoo[1*], Ki Yong Lee[2], and Wonju Jeon[2]

[1]Korea Institute of Machinery and Materials, Republic of Korea

[2]Korea Advanced Institute of Science and Technology, Republic of Korea

Abstract: This study introduces a hybrid resonator combining Helmholtz resonators with micro-perforations to achieve perfect sound absorption with a low Q-factor. Based on a theoretical model to outline the effective impedance, an acoustic metasurface is designed to achieve the 90%-absorption bandwidth from 380 to 790 Hz with a compact thickness (λ/15).

Mitigating noise from mechanical systems remains a critical challenge, particularly in developing sound absorbers with strong performance in targeted frequency ranges. Conventional approaches to acoustic absorption have primarily utilized porous or fibrous materials, where sound energy is dissipated through viscous and thermal boundary layers in their microstructures, as well as through internal heat conduction.[1,2] Numerous researchers[3-7] have attempted to design absorbers with subwavelength scales, as alternatives to conventional acoustic materials, by using such resonance-based structures as Helmholtz resonators (HRs). Acoustic metasurfaces (AMS) based on hybrid resonance between coupled HRs have emerged as promising solutions due to their compatibility with cost-effective 3D printing techniques. In 2016, a metasurface achieved perfect absorption at a specific frequency through hybrid resonance between adjacent HRs.[5] However, their numerical simulations accounted for losses only within limited frequency and geometric conditions. More recent studies have advanced AMS designs using hybrid resonance mechanisms to create thin absorbers with broader bandwidths, guided by theory-based, tunable design methods[6,7].

This study proposes a novel sound-absorbing metasurface whose unit cell consists of a hybrid resonator (HybR). As shown in Fig. 1(a), each HybR contains a parallel array of an embedded neck and a front panel with multiple micro-perforations, designed to achieve perfect absorption with a low Q-factor at a target frequency via hybrid resonance.[4] This resonance arises from strong near-field interactions between the neck and perforations and destructive interference in the far field. To predict performance and enable rapid design, the frequency-dependent effective impedance of the HybRs is analytically derived, taking into account visco-thermal losses and end corrections due to radiation impedance at discontinuities of surface areas. These derivations yield optimal geometrical parameters for impedance matching with ambient air at the target frequency, facilitating wider high-absorption bands (over 0.9) compared to traditional absorbers.

We explore how broader absorption can be realized by arraying multiple HybRs with distinct geometrical configurations for multiple target frequencies. Unlike conventional arrays using coupled Helmholtz resonators (HRs) that require 2N resonators for N frequencies, the proposed HybR-based array needs only N, offering a more spatially efficient broadband absorber. As shown in Fig. 1(b), supercells with N = 4 HybRs are fabricated via 3D printing and validated through impedance tube experiments.

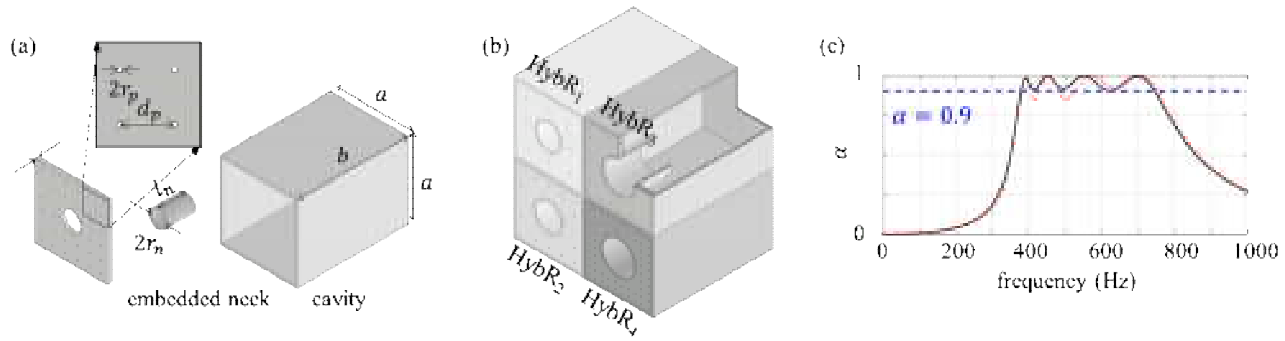

Fig. 1. (a) Geometrical configurations of a HybR that consists of three components: a front panel, a neck, and a cavity. (b) Geometry of the supercell composed of four types of $HybR_1$, $HybR_2$, $HybR_3$, and $HybR_4$. (c) Absorption spectrum of designed supercell, which shows over 90% of energy absorption in frequency range of 380 to 790 Hz with the blue dashed line.

As shown in Fig. 1(c), the trained model predicts geometrical configurations that optimize the figure of merit (FOM) and average absorption coefficient (α_{avg}). As the dataset size increases, the FOM converges to 9.18. The final design achieves over 90% absorption in the 380–790 Hz range. Theoretical predictions and finite element (FE) simulations closely align, confirming the model's validity.

Overall, this work demonstrates that combining HybR-based metasurfaces with machine learning enables efficient, compact, and high-performance acoustic designs, achieving significantly improved absorption bandwidths within limited space.

Unlocking Large-Scale Metasurface Fabrication with Electron Beam Lithography through Algorithmic Patterning

M. Kahl[1*], F. Nouvertné[1], R. Schmid[2] and V. Boegli[1]

[1]Raith GmbH Dortmund, Germany
[2]Raith America Inc., USA
[*]corresponding author: michael.kahl@raith.com

Abstract: Algorithmic patterning enhances electron beam lithography (EBL) by reducing data overhead, enabling large-scale metasurface fabrication and intricate photonic designs. By adding new shapes and tailored design data formats at the pattern generator level, it streamlines workflows, accelerates exposures, and expands design possibilities for next-generation photonic devices.

Electron beam lithography (EBL) has been instrumental in fabricating electronic and photonic devices, traditionally relying on the GDSII format for pattern definition. However, the Manhattan-style layouts inherent to GDSII pose challenges for complex geometries, particularly in photonics applications such as metasurfaces, photonic integrated circuits (PICs), and augmented reality/virtual reality (AR/VR) devices. The demand for diverse patterns, including circles, ellipses, and other non-polygonal features, has exposed the inefficiencies of conventional data handling, leading to excessive file sizes and impractical exposure times.

To address these challenges, we present an advanced algorithmic patterning methodology that enables the direct integration of user-defined algorithms into the pattern generator software via custom C# code [1]. This approach allows real-time generation of complex geometries, bypassing traditional file-based limitations. By embedding a userhook.dll, operators can add user-defined shapes and dynamically compute complete exposure patterns [2], significantly reducing data transfer overhead. Illustrating the power of algorithmic patterning, we showcase the generation of intricate patterns, including the iconic Mandelbrot set and associated Julia sets, with seamless efficiency. Notably, these patterns are produced on the fly, with the pattern generator computing a pixel stream of over 800 million pixels without the need for data transfer from external files (see figure 1).

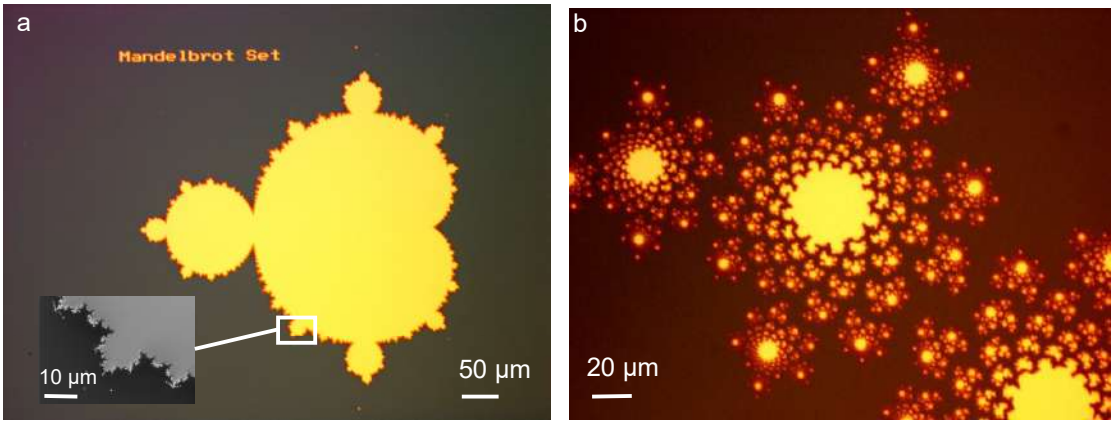

Figure 1. Optical microscope images of patterns exposed as user-defined shapes in PMMA resist, without data transfer from external files: a) Mandelbrot Set (20×), with SEM image inlet, b) Julia set for c= -0.4 + 0.6 i, (50×).

We demonstrate the efficacy of this method in an illustrative example with large-scale metasurface fabrication, where conventional polygon-based approaches generate impractically large files. For instance, a circular, 1 mm diameter metasurface featuring a 2D array of randomly sized circles with a fixed pitch of 500 nm results in a 1.92 GB GDSII file, escalating to an infeasible 4.8 TB for a 50 mm design. Through algorithmic patterning on the Raith VOYAGER system, we have optimized this process by exporting parametric data to 5 MB large ASC files, one per write field, dynamically generating the required structures in real-time during exposure. This enables patterning of a 50 mm metasurface in under two days at a beam current of 13.4 nA (see figure 2 and table 1).

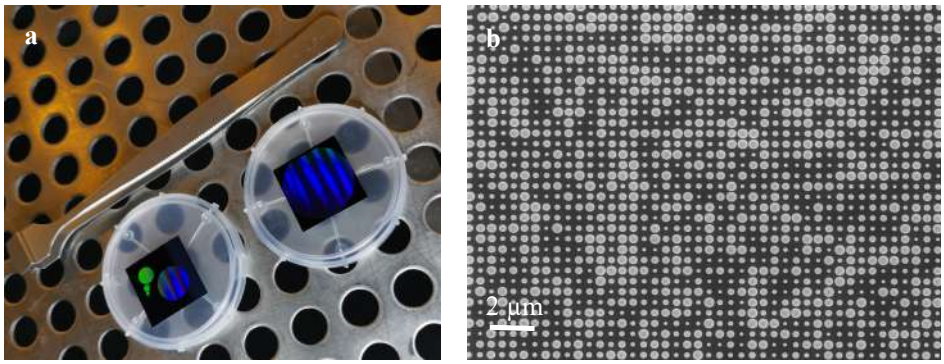

Figure 2. a) Photo of 20 mm large silicon samples with metasurfaces with different diameters, exposed in PMMA resist with algorithmic patterning, b) SEM image of metasurface (5,000×)

Diameter	GDSII file	No. of circles	No. of asc files	Data volume	Exposure time
0.2 mm	80 MB	0.13×10^6	1	4 MB	2 s
1 mm	1.92 GB	3.14×10^6	4	20 MB	1 min 4 s

Table 1. Pattern data of metasurfaces with different diameters

Beyond metasurfaces, our approach extends to aperiodic layouts, rotated gratings, and other complex photonic structures, including proximity effect corrections. By overcoming the limitations of GDSII and unlocking new design possibilities, algorithmic patterning empowers researchers and engineers to push the frontiers of photonic device fabrication, paving the way for next-generation optical technologies.

Abstract: We conceptualize and numerically simulate a resonant metamaterial interface incorporating non local, or beyond nearest neighbor, coupling that acts as a discrete angular filter. It can be designed to yield perfect transmission at customizable angles of incidence, without diffraction, allowing for tailored transmission in arbitrarily narrow wavenumber windows.

In recent years the scattering language of quantum graph theory has been successfully applied to the study of metamaterials, both theoretically [1] and experimentally [2]. The simple formulation allows for wave transport in complex network like systems to be studied (semi-)analytically, allowing for simple expressions that can be written in a closed form [3]. Following this successful formulation we study wave transport of an acoustic pressure field, with wave number k, across a filter formed of a network of thin tubes [4]. The network forms a grating with period ℓ that couples two semi-infinite slab waveguides, as shown in Figure 1 (a). Atop the grating are additional tubes of length ℓ_μ that form a helix that couple μ^{th} nearest neighbor grating channels. In the quantum graph formulation, it is trivial to show that the transmission coefficient t_μ across the filter is given analytically by:

$$t_\mu = \frac{i\sin(k\ell_\mu)}{\cos(\kappa_y \mu\ell) - \cos(k\ell_\mu) + i\sin(k\ell_\mu)} = \begin{cases} 1, & \text{if } k\ell_\mu = p\pi \text{ and } \kappa_y = \kappa_y^{(q)} = q\pi/\mu\ell \\ 0, & \text{if } k\ell_\mu = p\pi \text{ and } \kappa_y \neq \kappa_y^{(q)}. \end{cases} \quad (1)$$

Where κ_y is the wave vector tangential to the interface that defines the angle of incidence. The filter effectively acts as a Kronecker-delta function at resonance where transmission is forbidden accept for at unique angles of incident, as shown in Figure 1 (b) and (c).

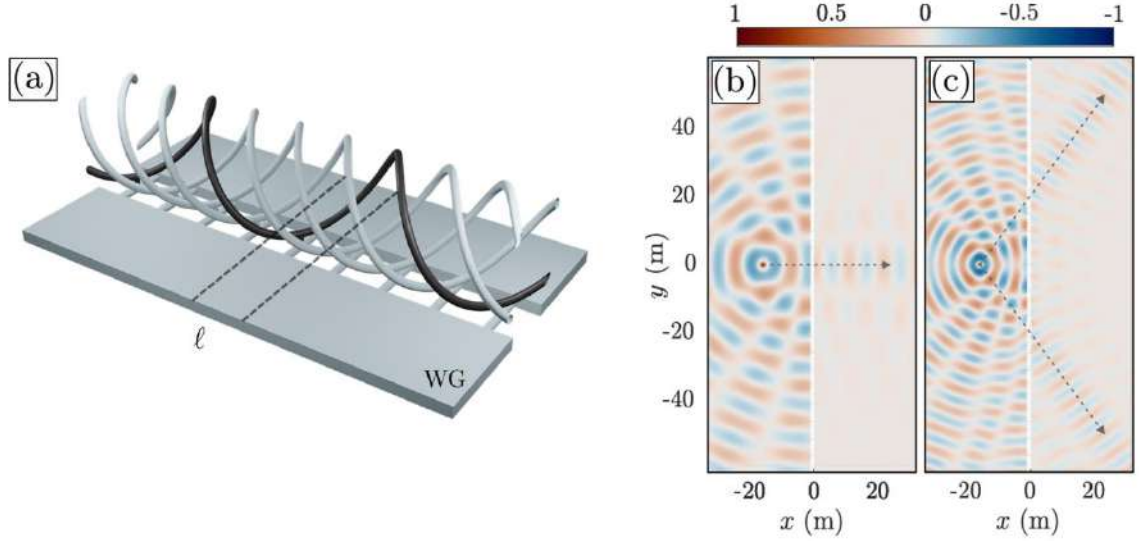

Figure1: (a) shows two semi-infinite slab waveguides connected by a grating of thin tubes, ontop of the grating are additional thin tubes that form beyond nearest neighbour connections that yeild the unit tranmission filtering effect. (b) shows the resulting pressure field from finite element simulation with unit transmission at zero angle, while (c) shows unit transmission at non-zeros angles.

Abstract: Holographic metasurfaces can tailor acoustic wavefronts to produce arbitrary acoustic images; however, current methods are not able to accurately encode the target phase distribution. We propose a novel technique for designing the metasurface by matching the phase at the lens exit with the target phase over a whole volume.

Acoustic holograms are complex lenses that encode customized phase distributions in their structure, allowing the creation of specific acoustic pressure patterns within a medium [1]. The underlying principles of this technology are based on interference and diffraction, much like optical holograms, but applied to sound waves. This technology has proven to be highly adaptable, with a wide range of applications in areas, mainly using ultrasound [2–7]. Between them, a promising application of acoustic holograms is therapeutic ultrasound and in particular transcranial ultrasound, where holograms can compensate for phase aberrations produced by the skull and generate sharp focal spots or arbitrary acoustic images inside the human brain [2].

In current hologram design techniques, the target field is defined along a transverse plane, and the lenses are designed to match the phase of the field in this plane. This approach is ideal when the lens is a perfect flat metasurface. However, its implementation using phase plate lenses often fails to reproduce the desired phase as a result of nonplane wave propagation, refraction, and diffraction effects.

In this work, we propose a novel approach called *phase matching*, where the field is acquired in a volume rather than a plane, and the phase at the lens exit is aligned with the target phase throughout the volume. The proposed method is validated through analytical solutions, simulations, and experiments. First, a single focal lens is designed using a 1.1-MHz circular 50-mm aperture source and various 3D printing materials and a parametric study of its focusing performance is conducted. Second, several complex acoustic images at different depths are generated, with their structural similarity index measure (SSIM) evaluated.

For simple focused beams, our method produces sharper focal spots with greater focusing gain. These focal spots are closer to the diffraction-limited estimations. For materials with a refractive index lower than one, both methods produce hyperbolic phase profiles, but only the phase-matching approach provides the optimal solution as seen in Fig. 1(a-b). For low f-numbers, phase matching outperforms classical methods, while for moderately focused beams, both approaches converge. Furthermore, we observe that the structural similarity index measure (SSIM) of complex acoustic images generated at shorter distances is higher with the proposed method, particularly for short focal lengths as shown in Fig. 1(c).

Phase-matching holograms enable precise synthesis of the target field's phase at the lens exit, surpassing traditional acoustic hologram design methods. This approach is particularly suited for emerging therapeutic ultrasound applications that require precise acoustic beam control, especially in cases where full-wave simulations are computationally intensive to be used for optimization methods.

Abstract: We developed two types of two-dimensional mechanical wave machines to investigate topologically protected edge and boundary vibration modes. One system simulates quantum Hall effects by breaking time-reversal symmetry through the Coriolis force. The other replicates quantum valley Hall effects, where vibrations propagate along a topological interface.

The topological phases that emerged from the discovery of the quantum Hall effect have garnered significant attention for their applications in classical wave phenomena, particularly in artificial periodic structures such as photonic [1,2] and phononic crystals [3]. Topological waveguides in these crystals exhibit inherent robustness against bends and defects, effectively preventing backscattering. In the case of phononics, this holds promise for the realization of more efficient waveguides and non-reciprocal acoustic devices.

Breaking time-reversal (*T*) symmetry is essential for realizing a phononic analog of quantum Hall (QH) systems. Most electronic QH systems achieve this by utilizing magnetic fields and Lorentz forces; however, phononic and acoustic systems generally do not interact with magnetic fields. Initially theoretical methods involving rotating fluids [4] or gyroscopes [5] were proposed and later validated experimentally [6,7]. A more direct approach involves introducing uniform rotational motion into the system instead of a uniform magnetic field. In a rotating reference frame, a mass experiences a Coriolis force perpendicular to its velocity, thereby breaking *T* symmetry in a manner analogous to how an electron experiences the Lorentz forces in a magnetic field. In prior research, a structure called “mechanical graphene,” consisting of masses and springs in a hexagonal lattice, was proposed [8]. Numerical calculations demonstrated that unidirectional vibration propagation along fixed boundaries could be achieved when vibrational excitation was applied to this system. However, in practical experiments, the presence of centrifugal forces disrupted the translational symmetry of the system, preventing its realization.

Fig. 1 (a) Photograph of the rotating wave machine.

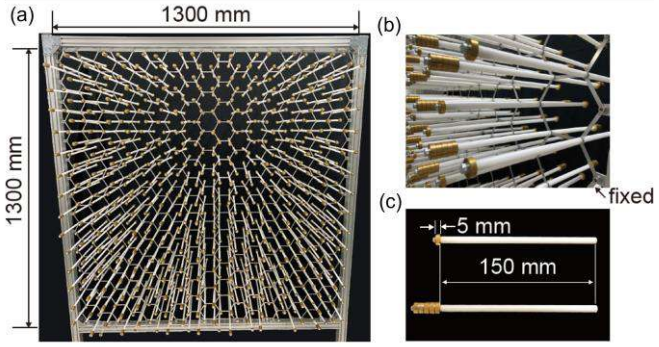

Fig. 2 (a) Photograph of the flexural wave machine. (b) Close-up view. (c) The plastic rods.

On the other hand, quantum valley Hall (QVH) systems can be realized by connecting two regions that break the spatial inversion (*P*) symmetry of the unit cells. QVH phononic crystals have been extensively studied from kilohertz to gigahertz frequencies, but observing the motion of mechanical vibrational modes with small displacements remains challenging, as conventional cameras cannot capture them. Although a low-frequency experimental study on a mechanical QVH system at ~10 Hz, based on magnetically coupled spinners, has been reported [9]. Since this system has only a single degree of freedom per lattice point, it cannot effectively capture modes with high degrees of freedom, such as chiral phonons.

Here, we realize and visualize both QH topological edge modes and QVH topological boundary modes [10] using mechanical metamaterials as two-dimensional extensions of the Shive wave machine. To realize a QH system, we constructed a wave machine with a honeycomb mass-spring lattice supported by spherical bearings embedded in a plastic board (Fig. 1). This design maintains equilibrium despite rotation due to centrifugal forces. In this system, the centrifugal and gravitational forces acting on the front and back surfaces on the plate cancel each other out, while the Coriolis forces remain uncompensated.

To realize a QVH system, we developed a suspended honeycomb lattice flexural wave machine, composed of a stainless-steel thin plate and plastic rods with brass weights (Fig. 2). The rods and weights enhance the moment of inertia, lowering the eigenfrequencies of the topological modes to approximately 5 Hz. To break P-symmetry and induce valley polarization, we adjust the brass weights within each unit cell [10].

The motions of each cell of both mechanical metamaterials were monitored with a motion capture system. In the QH system, a unidirectional topological edge state was observed when the system was rotated. In QVH system, topologically protected vibration modes along a bearded boundary were identified. The measured vibrations of these systems were compared with theoretical and simulation results.

We are also developing a mechanical analog of quantum spin Hall (QSH) system based on a suspended flexural wave machine. Our approach should be applicable to mechanical metamaterials, including reconfigurable and active systems.

Abstract: We demonstrate high-quality flexural wave localization mechanism in symmetric scatterer clusters, where resonance quality (Q) escalates with energy density, approaching bound states in the continuum (BICs) with infinite Q. High-multipole modes form whispering galleries. A cylindrical-shelled metaplate achieves symmetry-protected BICs, enabling compact, high-efficiency wave control for on-chip applications.

Realizing elastic wave modulation with high energy density in small-sized spaces has always been a huge challenge for elastic wave functional devices to move towards engineering applications [1]. Pillared plates composed of pure cylindrical scatterers embedded in a homogeneous material provide a practical and efficient platform for designing bound states in the continuum (BIC). Their simplicity and homogeneity offer significant advantages in fabrication and engineering applications.

Based on the symmetry protection of the bound state of the continuum (BIC), we proposed the reverse numerical design method for achieving compact bound states. The three-dimensional model of the pillared plates in the left panel of Fig. 1(a). In the right panel of Fig. 1(a) is the arrangement of circular clusters, where N is the number of pillars of the cluster, R_{cluster} is the radius of the cluster, and θ defines the angular position of the pillars within the cluster. Finally，the BIC is the real-eigenmodes of scattering matrix [2, 3], which's polarization mode is defined by the order of the Bessel function l [4].

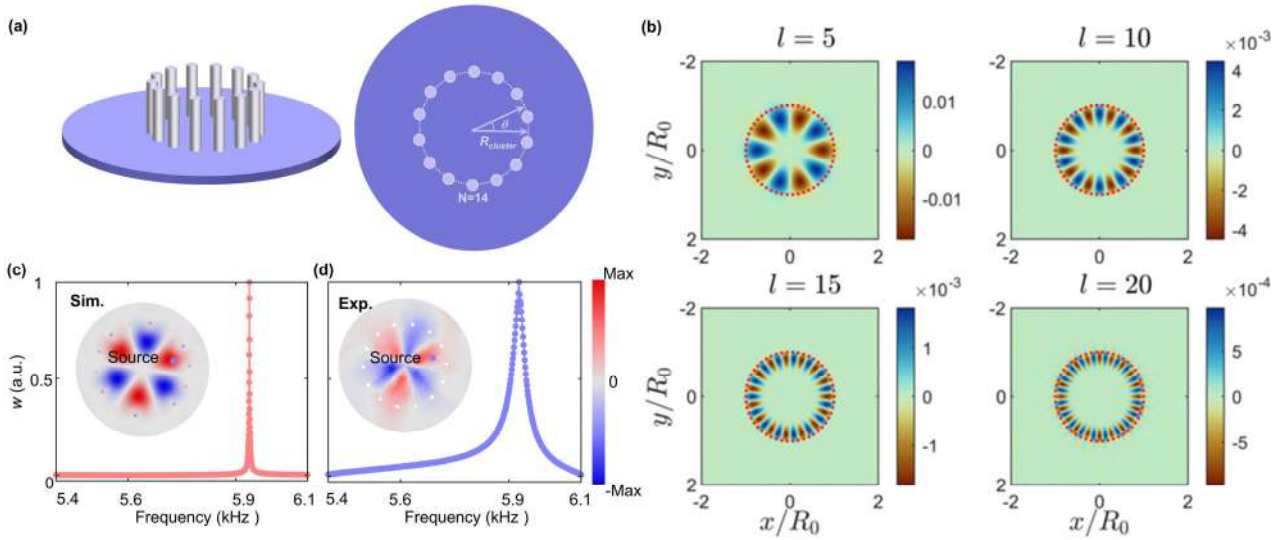

Figure 1. (a) The three-dimensional model of the pillared plates in the left panel. Arrangement of circular clusters, with the number of pillars of the cluster N, the radius of the cluster R_{cluster}, and the angular position of the pillars

θ in the right panel. (b) Real part of the eigenfunction for different resonant index l. The clusters have the same number of scatterers (N = 50) [5]. (c) Normalized response curves of the out-of-plane displacement w(a.u.) from the simulation and (d) the experiment at the maximum displacement of the hexapole mode with the design parameter l = 3 [4]. Insets in panels (c) and (d) show the out-of-plane displacements for the simulation and the experiment, respectively, with the blue points indicating the excitation sources of sine waves.

High-index modes typically localize near scattering structures, forming whispering gallery modes. This method enables the systematic engineering of high-quality whispering gallery modes. Figure 1(b) illustrates such modes for a cluster of 50 scatterers with refractive indices of 5, 10, 15, and 20. As the index increases, the plots clearly show enhanced field confinement near the cluster's perimeter [5].

The normalized response curves of bound states in the continuum (BICs) are presented in Figs. 1(c) and 1(d). The simulated BIC frequency is 5937.8 Hz, while the experimental value is 5926.2 Hz, demonstrating strong agreement with an error $\delta = \left| f_{\text{sim}} - f_{\text{exp}} \right| / f_{\text{sim}}$ of less than 0.2%. The experimental quality factor is Q = 137.8. Minor deviations align with expectations due to damping and fabrication imperfections. Insets in Figs. 3(a) and 3(b) depict out-of-plane displacement fields from simulation and experiment, respectively, which reveal weakly coupled leakage modes [4].

Abstract: Based on a generalized Su–Schrieffer–Heeger model, we design a non-Hermitian periodic or disordered elastic platform with feedback control where we theoretically study the topological phase diagrams and edge states. Considering both one and two-dimensional structures, we demonstrate in theory and simulations the relative effects of non-Hermiticity and disorder.

Topological states have been receiving a great deal of interest in various wave problems and have been used to design novel artificial structured materials to manipulate acoustic and elastic waves robustly. However, most studies have focused on periodic and Hermitian systems characterized by real-valued eigenfrequencies and orthogonal eigenvectors, while the role of non-Hermiticity and disorder in topological properties needs to be further explored. Recently, it was shown that novel topological phase transitions can be driven by non-Hermiticity and disorder. Inspired by these models, we study in this work the topological phase transitions induced by periodic and disordered on-site non-Hermitian modulations in one-dimensional (1D) and two-dimensional (2D) systems.

We first develop a theoretical approach, based on a generalization of the Su-Schrieffer-Heeger (SSH) model, to investigate the full topological phase diagram as a function of the physical parameters and non-Hermitian strengths. To characterize the topological phase transitions of the system, the polarization P_x in real space for a system is defined as [1-3]:

$$P_x = \frac{1}{2\pi}\,\mathrm{Im}\left\{\log\left[\det(U_l^{\dagger}\,\hat{Q}\,U_r)\sqrt{\det(\hat{Q}^{\dagger})}\right]\right\}, \tag{1}$$

where $\hat{Q}$ is the coordinate operator represented by a diagonal matrix with $\hat{Q}(j,j) = e^{i2\pi j/N}$. U_l and U_r are the matrices constituted by the normalized and occupied left and right eigenstates of the Hamiltonian matrix H, respectively. For the system with pseudo-anti-Hermiticity symmetry, P_x becomes a quantity taking the values of 0 (corresponding to a trivial system) or 0.5 (corresponding to a nontrivial system).

We find that an initially trivial system can become nontrivial under periodic or moderately disordered non-Hermitian modulations for 1D systems. The 2D systems are more sensitive to disorder and trivial-nontrivial phase transitions only survive under periodic and weak disordered non-Hermitian modulations.

Besides, it is shown that similar phase diagrams as in disordered structures can also be reproduced in some super-periodic structures exhibiting the same average of the non-Hemiticity strength. Therefore, the relative roles of non-hermiticity and disorders in the creation of the various phase diagrams are discussed.

We construct an elastic analog of the SSH model consisting of elastic square plates with thin connecting

beams, where the non-Hermitian modulations are introduced by attached piezoelectric patches with a feedback control loop. The trivial-nontrivial phase transitions as well as topological edge/corner modes driven by non-Hermitian modulations are demonstrated in elastic structures.

Our study provides a novel way to explore topological states based on periodic/disordered non-Hermitian modulations. The proposed elastic platform has the advantage of active tunability and intelligent control, which presents a versatile platform for studying disordered and non-Hermitian metamaterials and has potential applications in vibration control, energy harvesting, and sensing.

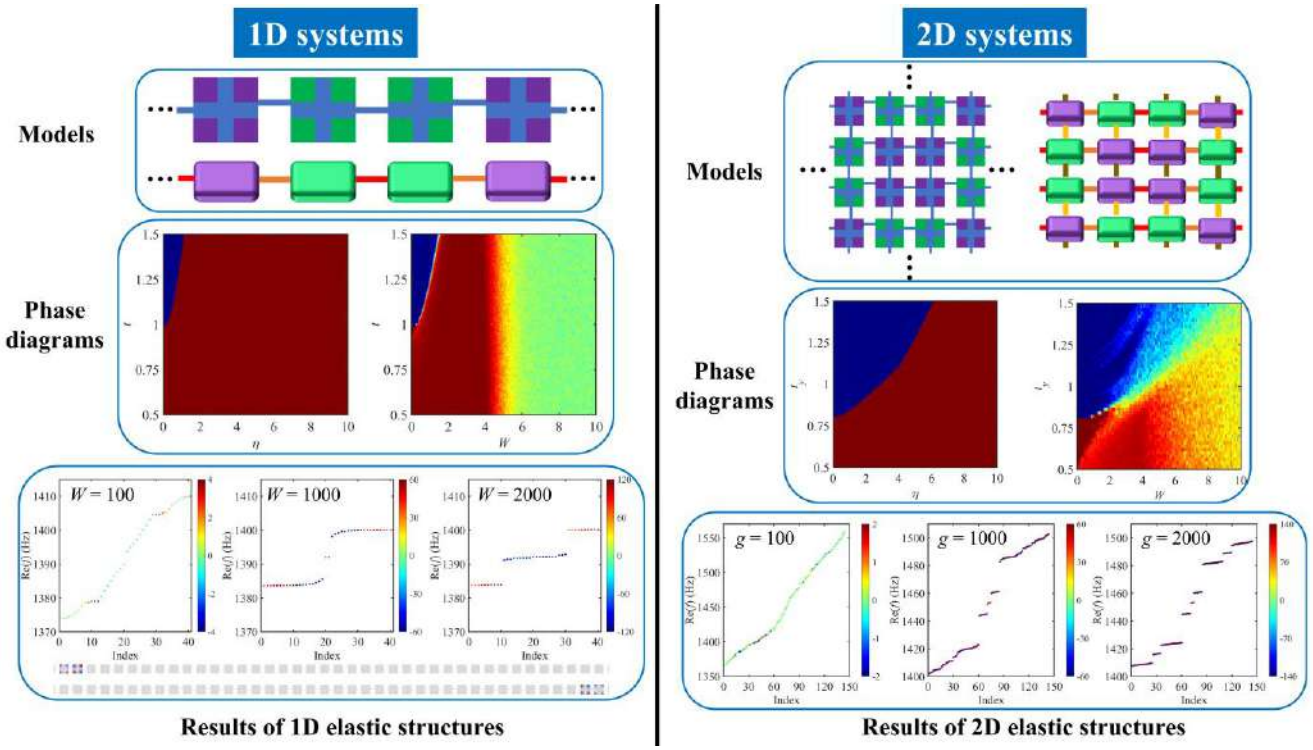

Figure 1. Graphical abstract of this work. The left panel shows, for 1D systems, from top to bottom: the elastic and analytical models, the topological phase diagrams as a function of non-Hermiticity strength and the eigenfunctions of elastic structures. The right panel shows similar results for 2D systems.

Skewing of guided waves in anisotropic plates close to zero-group-velocity points

D. A. Kiefer*, S. Mezil, and C. Prada
Institut Langevin, ESPCI Paris, Université PSL, CNRS
Corresponding author: daniel.kiefer@espci.fr

Abstract: In anisotropic media the power flux of waves is usually skewed, i.e., it is not collinear to the wave vector. We describe how this effect impacts the measurable dispersion spectrum of guided elastic waves in plates. The theory is generally applicable to linear wave propagation in anisotropic media.

Guided waves in plates [1] are often measured on a line away from the source. A spatio-temporal Fourier transform yields the dispersion spectrum in the frequency-wavenumber domain. We performed such measurements on a 525-µm thick, [001]-cut, monocrystalline silicon wafer of cubic anisotropy and the results are depicted in Fig. 1. It is striking that the spectrum excited with a point source contains additional contributions compared to that of the line source. The multiple contributions are all due to the same mode. This effect can be explained with the wave's skew angle, i.e., the angle between the wave vector and the power flux [2].

We show that guided waves close to zero-group-velocity resonances are particular in that they exhibit skew angles between 0° and 360°. As a consequence, the modal multiplicity always exists–independent of the measurement direction. To illustrate this, we study the particular case of *transverse-group-velocity waves*, whose power flux is orthogonal to the wave vector [3]. We have measured this wave on the same sample and the resulting spatio-temporal intensity field is shown in Fig. 2. This wave packet is radiated along the line source instead of orthogonally away from it. This behavior affects the measured dispersion spectra and needs to be accounted for in the corresponding model. A point on the dispersion surface where the power flux is along the measurement direction is called a *stationary phase point*. The ensemble of stationary phase points precisely models the observed point-source spectrum, including the "additional

;

Figure 1: Dispersion spectra obtained by scanning a line at [110]+22.5° away from (a) a line source and (b) a point source. The thermoelastic excitation is performed with a pulsed laser. The normal surface displacement is measured with a laser interferometer. From Ref. [2].

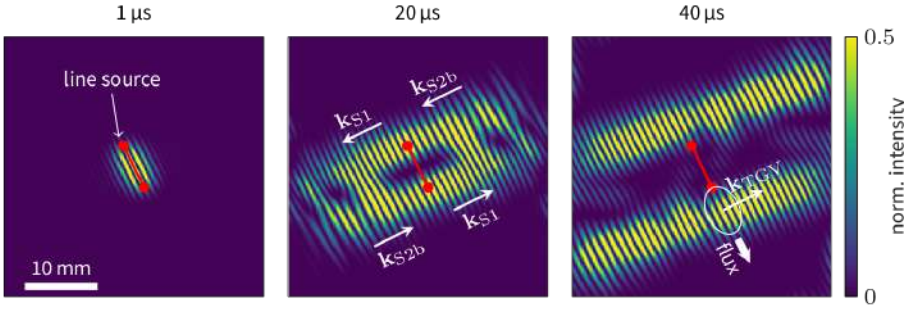

Figure 2: Transverse-group-velocity wave radiated from a synthesized line source. The experimental setup is as before. Frequency-wavenumber filtering has been applied to isolate the mode. From Ref. [3].

contributions" [2]. Since the power flux of waves is not known in advance, the computation of stationary phase points is particularly challenging. We have done so by computing the dispersion surface on a dense grid of about two million points and selecting the waves whose power flux is in the desired direction within a fixed tolerance. Our open source software `GEWtool` [4] achieves this in one to two minutes on eight cores of an Apple M1 Pro processor.

The extreme skewing yields multi-directional information on the material behavior even when performing only a single line scan. Hence, it is highly valuable for anisotropic material characterization.

Abstract: Beyond the traditional paradigm of Hermitian physics, the concept of non-Hermiticity has recently inspired a surge of nontrivial principles and applications. In this work, we propose several active and passive non-Hermitian metasurfaces that enable unprecedented elastic-wave manipulations, including skin-like effects, asymmetric wave propagation, and perfect absorption.

The past decades have witnessed the remarkable development and explosive implications of meta-structures in elastic-wave steering under the Hermitian systems that disregard material loss. However, the reality of practical applications is inevitably intertwined with loss, leading to the dissipation of elastic wave energy. Traditionally, such losses were viewed as detrimental, potentially compromising the performance of elastic wave devices. Yet, a paradigm shift has emerged from recent groundbreaking research, which has uncovered the potential of strategically engineered loss/gain within non-Hermitian systems to facilitate remarkable wave steering phenomena[1-3]. In this work, we achieve highly flexible and precise non-Hermitian modulation by integrating a piezoelectric sheet-shunt circuit system with a metasurface. The transmittance curves of piezoelectric metasurface units were calculated across a broad frequency range, and the effects of loss and gain induced by positive and negative resistances in the shunt circuit were analyzed. We present various non-Hermitian piezoelectric supercells, as shown in Fig. 1, which enable the enhancement or attenuation of energy in higher-order diffraction waveguides across different modes. In the experimental phase, we designed and fabricated a negative-resistance and tunable inductor synthesis circuit, which allowed for precise tuning of phase delay and energy transmission characteristics of the piezoelectric metasurface. Our study provides new methods and insights for the manipulation and stable implementation of energy gain, offering valuable technical references for the active control of guided waves and precise non-Hermitian modulation.

Abstract: This study explores a 3D-printed Helmholtz resonator (HR)-based metasurface lens for high-resolution imaging microscale defects in 4mm metal plates. Enhancing resolution over twofold with MHz-frequency acoustic transducers, the lens improves defect detection in extreme applications like nuclear reactors, advancing scanning acoustic microscopy for early fault identification.

Metasurface lenses are gaining attention for manipulating acoustic waves in applications like wave focusing. These lenses use subwavelength units to create a gradient phase distribution, functioning as point sources with engineered phase and amplitude. They are classified as space-coiling (path-length engineering) or resonance-based (localized resonance), with Helmholtz resonators (HR) demonstrating the latter through strong acoustic confinement for complete 2π phase control and excellent impedance matching [1-3]. By engineering the spherical phase gradient, HR metasurface lenses focus sound waves with minimal aberrations, achieving superior resolution. However, microscale fabrication for MHz operation faces challenges, and current acoustic metasurface demonstrations are limited to kilohertz frequencies with millimeter-scale resolution. In critical settings like nuclear reactors, micron-sized defects can cause catastrophic failures. Traditional acoustic transducers struggle with resolution and rely on high-frequency, power-intensive systems for detecting small defects. Also, higher-frequency ultrasonic imaging may not be feasible due to scattering and surface conditions.

Acoustic imaging using HR metasurface lens and practical considerations. **(d)** Underwater acoustic imaging microscopy setup. **(e)** Numerical simulation of wave focusing using a 10 MHz water-coupled HR metasurface lens. **(f)** A small 3D printed sample of 10 MHz water-coupled HR metasurface lens (only 13 units of total 125 units) showing collapse of overhangs. 2PP stands for two-photon lithography. **(g)** A 3D printed sample of 30 kHz air-coupled metasurface lens showing broken wall and deformities induced by printing support. DLP stands for digital light processing.

Recent advances in additive manufacturing, particularly two-photon lithography, enable intricate nanostructures for subwavelength metasurfaces. Our goal is to develop an HR metasurface lens that detects microscale defects at several millimeters within a sample, integrating metasurface lenses with planar acoustic transducers at low frequencies to improve resolution from conventional ultrasound imaging (over 1.5λ) to subwavelength resolution (less than λ). We examine a metasurface featuring a subwavelength unit cell that integrates four Helmholtz resonators arranged in series, interconnected via a common duct, as illustrated in Fig. 1(a). The resonator's geometry is defined by the wall thickness (t), the width of the resonator cavity (w_2), cavity height (h_2), neck width (w_1), and duct height (h_1). The overall height of the unit (h) is limited to λ/5. At the same time, the total width (w) is set at λ/2 to maintain the subwavelength condition critical for sub-diffraction focusing through these units. This design is particularly effective for achieving a highly efficient frequency-selective transmission response. Adjusting the duct height controls variations in the transmitted output phase and amplitude; a complete 2π phase shift can be achieved by modifying the duct height, while the amplitude of the transmission ratio remains relatively stable and close to one across all duct height values, as demonstrated in Fig. 1(b). A metasurface lens consists of multiple such units stacked radially. It creates an asymmetric lens design that focuses a planar wavefront on the input side to a focal point along its axis on the output side, as depicted in Fig. 1(c). The duct height profile along the radial direction of the Helmholtz resonator metasurface lens is engineered to correspond to a spherical transmission phase profile, with f representing the focal length, indicating the distance from the lens at which focusing occurs. The lens design has been iteratively optimized for 3D printing. The application of a metasurface lens for acoustic imaging is illustrated in Figs. 1(d)-(e). Figure 1(d) shows an underwater ultrasonic setup that integrates a conventional planar acoustic transducer with a metasurface lens designed to detect micro-sized defects in 4-mm thick 3D printed metal plates. We validated the wave-focusing capabilities by designing the HR metasurface for 10 MHz underwater operation through numerical simulations, achieving a focal spot size of 0.69λ, as illustrated in Fig. 1(e). This performance significantly surpasses the 1.7λ spot size of a standard 10 MHz focusing acoustic transducer. Currently, we are working on fabricating this design, which has a wall thickness of 4 microns, using a two-photon polymerization (2PP) Nanoscribe 3D printer that offers a printing resolution of 100 nanometers. We are addressing several challenges related to the HR metasurface lens design, including the collapse of overhangs and scaling the design to full size. To date, a small sample containing 13 out of 125 units has been printed in 3D using 2PP, as shown in Fig. 1(f), which is under evaluation. Concurrently, we are exploring an air-coupled HR metasurface lens for concept validation at 30 kHz, which features a wall thickness of 300 microns, utilizing digital light processing (DLP) 3D printing with a precision of 27 microns, as the lens design is scalable (Fig. 1(g)). This research has significant implications for non-destructive evaluation, which is crucial for numerous applications, particularly in critical environments where early detection of small-scale defects facilitated by the metasurface lens can prevent catastrophic failure.

Electromechanical Excitation of Nanostructures by Bulk Acoustic Wave Transducers

T. Makkonen[1], O. Ylivaara[1], S. Pourjamal[1], and J. Ahopelto[1*]

[1] VTT Technical Research Centre of Finland Ltd, Finland

Abstract: An efficient broadband bulk acoustic wave electromechanical transducer at GHz range is demonstrated. The free-standing transducer with a small footprint can be integrated directly into nanostructures to guarantee efficient coupling. The potential applications include optomechanics and topological phononics.

Surface acoustic waves (SAW) generated by an interdigitated transducer (IDT) are usually used to excite nanoscale mechanical structures [1-3]. IDTs can provide a narrow bandwidth excitation at desired frequency range, but to achieve high coupling efficiency can be challenging [4]. Furthermore, the surface area required by the IDTs can, in some cases, prevent integration of nanoelectromechanical devices.

Integration of a miniaturized bulk acoustic wave (BAW) transducer directly to the nanodevice provides high efficiency coupling, broad bandwidth and a small footprint. In Figure 1(a), the transducer integrated to a nanobeam is depicted schematically, and the Figure 1(b) shows an SEM image of a test device. The transducer itself is a very small BAW resonator with aluminum nitride (AlN) or aluminum scandium nitride (AlScN) piezo layer sandwiched between the top and bottom electrodes. The transducer is free-standing and isolated from the surroundings by narrow supporting beams. The main loss mechanisms reducing the energy flow only to the nanobeam are the viscous dissipation in the piezoelectric film and the anchor losses to the surroundings.

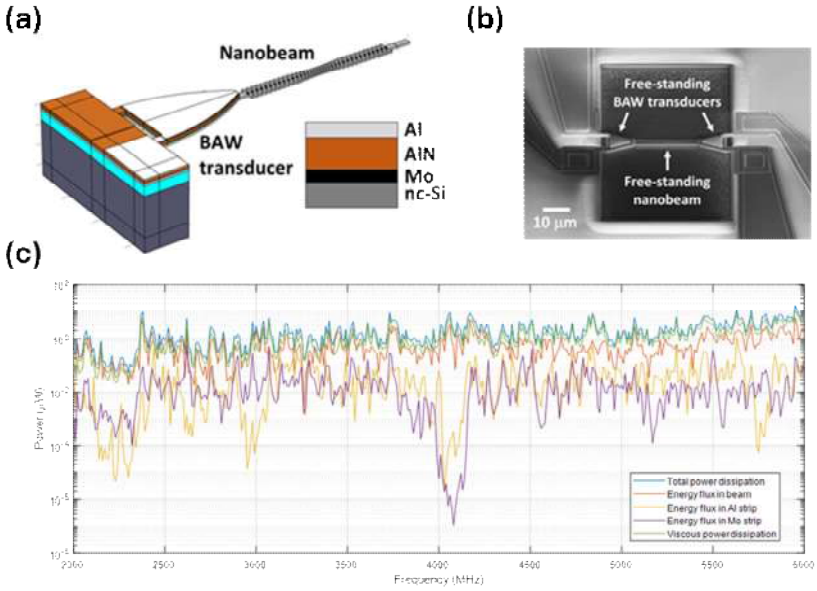

Figure 1. (a) BeamBAW concept shown schematically. A small free-standing BAW transducer is integrated directly to a nanobeam to enhance the coupling efficiency. (b) SEM image of a test structure. (c) Simulation of

the flow of energy in a device with 1D phononic crystal supports as a function of frequency in logarithmic scale. The green line is the total power dissipated, and the red is the flow of energy to the nanobeam. The yellow and purple lines show the leakage to the substrate via the supporting beams. The phononic band gaps of the supporting beams were designed to be at around 4 GHz. The difference between the yellow and purple lines arises from the different designs of the phononic crystals due to the different electrode metals, the bottom being molybdenum and top aluminum.

The leak to the substrate can be minimized by making the supporting beams 1-dimensional phononic crystals with the gap at desired frequency. Figure 1(c) shows the simulated very broad bandwidth of the BeamBAW transducer with a gap at around 4 GHz with 1D phononic crystal supports.

In this presentation, we will describe in more detail the BeamBAW concept and the device properties.

Nanocrystalline Silicon for Optomechanical Metamaterials

G. Conte[1*], O. R. Ranjbar Naeini[1], C. Alves[1], O. Schraidt[1], O. Ylivaara[2], S. Pourjamal[2], J. Ahopelto[2], and C. M. Sotomayor Torres[1]

Abstract: Nanocrystalline silicon is a promising material for nano-opto-electro-mechanical metamaterials to be integrated into information and communication technology. The fabrication of nanocrystalline silicon has an impact on properties associated to grain sizes and grain boundaries, which influence the mechanical quality factor of one-dimensional nanoresonators.

Nanocrystalline silicon (nc-Si) is a novel material consisting of randomly oriented Si grains, so that it has an isotropic behavior. Developed for MEMS applications in the 1980's [1], it has been recently considered as a possible material for optomechanical devices and circuits.

Nc-Si is produced by low pressure chemical vapour deposition (LPCVD) and consequent annealing of 220 nm of amorphous silicon on a 500-nm-thick silicon dioxide layer, which in turn is on a crystalline silicon (c-Si) substrate. The annealing temperature ranges from 650°C to 1050°C. During the annealing, nucleation and growth of nanocrystallites take place, until obtaining a material as the one reported in Figure 1(a). The thermal annealing process determines the electronic, optical and mechanical properties of nc-Si, which can be tuned by varying the annealing parameters [2]. In particular, the annealing temperature affects the grain size distribution and the grain boundaries [2], which impact the thermal transport [3] and, consequently, the performance of the devices [4]. The structural information is one example of characterisation needed to unravel the high mechanical quality factors of optomechanical nc-Si metamaterial devices compared to similar devices fabricated in silicon-on-insulator (SOI) [5]. The size of the nanocrystallites have been investigated by dark-field TEM images acquired at different diffraction areas through the hollow-cone technique [6], so that nanocrystallites with different orientations could be revealed. The resulting average grain size is larger for higher annealing temperatures (57.5 nm and 53.4 nm for 950°C and 1050°C, respectively) rather than the lowest annealing temperature (33.5 nm for 650°C). The different average grain size determines a different volume of grain boundaries, which is crucial to understand electron and phonon transport in the material. The grain boundaries play a key role because they are expected to host a relatively high number of electronic gap states, which affect the optical absorption, in particular the efficiency of one- versus two-photon absorption. In some cases, the grain boundaries appear amorphous. In other cases, the grain boundaries exhibit 3-5 atomic planes.

The devices under investigation consist of suspended nanobeams, which act as both photonic and phononic one-dimensional metamaterials working at hypersonic frequencies. In such devices photons and phonons are confined in a small region, leading to the optomechanical interaction. The performance of these devices is determined not only by the material properties, but also by the device design. Two examples of nc-Si nanobeams are shown in Figures 1(b) and 1(c).

Structural and future optical analysis of nc-Si will shed light on the interplay among electrons, photons and phonons in the material, specifically regarding the role of nanocrystallites and grain boundaries in absorption and dissipation mechanisms at the nanoscale. This knowledge, combined with the structural analysis, will be crucial

for a much improved understanding of the device performance, particularly about losses, variability and device integration technology.

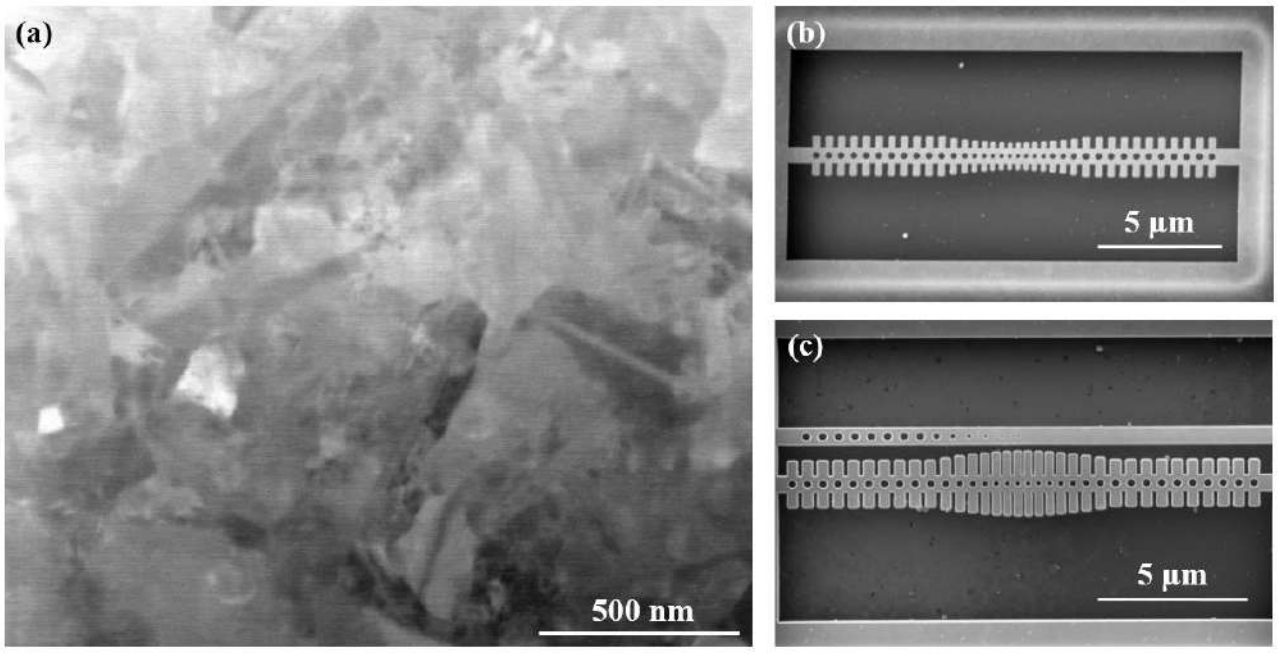

Figure 1 (a) TEM image of nc-Si annealed at 950°C. (b) SEM image of a nc-Si nanobeam operating at a mechanical frequency of 4 GHz. (c) SEM image of a nc-Si nanobeam operating at a mechanical frequency of 2 GHz and coupled to a waveguide.

Tailoring GHz Surface Acoustic Waves by Spatial Modulation of Ultrashort Light Pulses

O. Boyko *, F. Soldevila, V. Bochkarev, L. Belliard
Sorbonne Université, CNRS, Institut des Nanosciences de Paris, INSP, F-75005 Paris, France
Olga.Boyko@insp.jussieu.fr

Abstract: We demonstrate the spatial and spectral manipulation of GHz surface acoustic waves (SAWs) using an ultrafast laser setup integrated with a Spatial Light Modulator. Arbitrary acoustic wavefronts and point-source distributions are dynamically created on flat substrates, providing versatile, non-invasive control critical for acoustic signal processing and phononic circuits.

Miniaturization in electro-acoustic technologies and high-speed communications necessitate advanced control of elastic waves at GHz frequencies [1]. Current phononic systems rely predominantly on fabricated nanostructures that limit flexibility due to fixed geometry, posing significant experimental challenges [2,3].

Here, we present a flexible, optical method for generating GHz-range SAWs by integrating a Spatial Light Modulator (SLM) into a picosecond ultrasonics setup. By modulating the spatial phase profile of ultrashort (140 fs) laser pulses at 800 nm, we non-invasively excite complex acoustic wavefronts on flat surfaces without custom-fabricated nanostructures. The SLM-generated patterns control both spatial distribution and spectral characteristics of the acoustic waves, enabling on-demand reconfigurability.

Figure 1. Generation of multiple source distributions with an SLM. Four different configurations are shown, each consisting of a phase mask codified on the SLM (left, grayscale images) and a snapshot of the surface displacement at different times after the arrival of the pump beam (right, false-color images):

(a) Three point-like sources;
(b) Five point-like sources;
(c) Four point-like sources, arranged in a square array;
(d) Excitation with a linear grating with a well-defined period and oriented at 45°.
Field of view (FoV): (a), (b), and (c) – 100×100 µm²; (d) – 290×290 µm².

Through this approach, we generate precise point-source acoustic arrays and directional wavefronts (Fig. 1), demonstrating significant improvements in acoustic wave engineering capabilities. We further exploit controlled

wavevectors from spatial gratings to measure dispersion relations, validating the method's applicability for material characterization and phononic device optimization. This programmable acoustic source distribution significantly enhances phononic system versatility, paving the way for new developments in high-frequency acoustic signal processing, phonon spectrometry, and non-destructive testing techniques [4,5].

Abstract: At small spatial and temporal scales, in specific materials addressed as temperonic, temperature propagates in a wave-like fashion. The talk covers a finite size temperonic crystal, a superlattice composed of alternating temperonic materials, hallowing coherent control of temperature waves, similarly to the case of phononic crystal for the displacement field.

At small spatial and temporal scales, and in specific types of materials, addressed as temperonic materials, heat transfer can transition into a hydrodynamic regime [1-4]. Within this regime, the temperature scalar field exhibits wave-like behavior, propagating in a coherent manner that resembles the characteristics of acoustic and electromagnetic waves, rather than dispersing through diffusion.

We will first review advances in temperonic materials, which have been marked by important developments in phononic and electronic systems, paving the way for new research opportunities and applications. Specifically, graphene has been shown to exhibit the ability to support phononic temperature waves under cryogenic conditions and ultrafast timescales [5]. Furthermore, layered materials with strong electronic correlations have been found to accommodate a diverse range of electronic heat transport regimes, including ballistic, hydrodynamic, and diffusive regimes, offering a high degree of flexibility and control [6].

We will then cover the concept of a temperonic crystal, a specially designed superlattice composed of alternating temperonic materials, which enables the manipulation of temperature waves on extremely short timescales [7]. This concept is analogous to phononic crystals in solid mechanics and photonic crystals in electromagnetism, and offers a new paradigm for temperature wave control.

The validity of the temperonic crystal concept will be verified through numerical simulations, focusing on a finite structure composed of graphene slabs at varying temperatures, as opposed to an idealized infinite system. The simulations will track the spatio-temporal evolution of a temperature pulse interacting with the temperonic crystal, considering different constitutive equations, including the Fourier law (FL), Cattaneo-Vernotte (CV) equation, and Dual-Phase Lag (DPL) model. These equations yield distinct mathematical formulations, ranging from the traditional diffusive equation to hyperbolic and parabolic equations, which solutions can exhibit wave-like behavior under certain conditions. To characterize the temperature pulse's interaction with the temperonic crystal, concepts analogous to transmission and reflection coefficients will be introduced. The impact of the number of slabs and the presence of disorder on the crystal's behavior will also be examined, providing insight into the finite temperonic crystal's performance.

The present talk widens the concepts of acoustic and electromagnetic wave propagation in metamerials to the realm of thermal transport in solid state systems, paving the way to new paradigms in heat transport. [8-10].

Abstract: We theoretically investigate the interaction of a surface sloshing wave with a vertically oscillating plate inside a water tank, reporting on the stability of the surface elevation with respect to the plate oscillation amplitude and frequency. Using conformal mapping and then a Floquet stability analysis, we identify parametric amplification windows.

Periodically time-varying media can lead to wave phenomena such as parametric or transient amplification [1]- [2], with Mathieu equation governing the dynamics in various periodically forced systems. This work explores wave amplification for water waves by using an infinitely thin plate that is vertically oscillating at the fluid bottom. First, the 2D problem in the linearised water wave theory framework is schematically represented in Figure 1a, where $\Phi(x,z,t)$ denotes the velocity potential and $\mu(t)$ the dimensionless plate height. Because of the complexity of the moving bottom boundary condition, it is convenient to map the problem into a new domain where the plate is absent (see Figure 1b). For a family of bathymetric profiles, including vertical plates, there exists a conformal transformation in explicit form which maps the initial domain in the (x,z,t) plane into a rectangular domain of constant depth in the (ξ,χ,τ) plane with $t=\tau$. We denote the transformation as $w=F(\zeta,t)$ with $w=x+iz$ and $\zeta=\xi+i\chi$ and its illustration at $\chi=0$ is shown in Figure 1c. Thus, the modified set of equations in the transformed domain is written as

$$\partial_\xi^2\Phi+\partial_\chi^2\Phi=0, \quad \Omega(\tau), \tag{1a}$$

$$\partial_\chi\Phi=0, \quad \chi=-1, \tag{1b}$$

$$\partial_\chi\Phi=-r(\xi,\tau)\mathcal{L}_{(\tau,\xi)}\Phi, \quad \chi=0, \tag{1c}$$

$$\partial_\xi\Phi=0, \quad \xi=\pm L(\tau), \tag{1d}$$

where $\mathcal{L}_{(\xi,\tau)}=\partial_\tau^2+\left(\frac{\partial\xi}{\partial t}\right)^2\partial_\xi^2+2\left(\frac{\partial\xi}{\partial t}\right)\partial_{\tau\xi}+\frac{\partial^2\xi}{\partial t^2}\partial_\xi$ and $r(\xi,\tau)=\left.\frac{dF(\zeta,\tau)}{d\zeta}\right|_{\chi=0}$. The oscillation of the wall position $x=\pm L(\tau)$ is linked to $\mu(t)$ which in turn translates into the blockage coefficient time variation $B_\mu(t)$ from the expression $\mu=1-\frac{2}{\pi}\arcsin\left[\exp\left(-\frac{\pi}{2}B_\mu\right)\right]$. In this study we set $B_\mu(t)=B_{\mu,0}+B_{\mu,1}\cos(\Omega_p t)$ with Ω_p the dimensionless frequency of oscillation.

In order to solve system (1), we consider a solution in the form of a Fourier series: $\Phi(\xi,\chi,\tau)=\sum_n\alpha_n(\tau)\cosh\left(\frac{n\pi(\chi+1)}{2L(\tau)}\right)\gamma_n(\xi,\tau)$, $\gamma_n(\xi,\tau)=\sqrt{\frac{2-\delta_{0n}}{2L(\tau)}}\cos\left(\frac{n\pi(\xi+L(\tau))}{2L(\tau)}\right)$, with $n\in\mathrm{N}$. This solution satisfies directly Equations (1a), (1b) and (1d) and its substitution on the surface condition (1c) yields after projecting on the γ_n an ordinary differential equation for the coefficients α_n:

$$\ddot{a}_m+2A_{mn}(\tau)\dot{a}_n+B_{mn}(\tau)a_n=0, \tag{2}$$

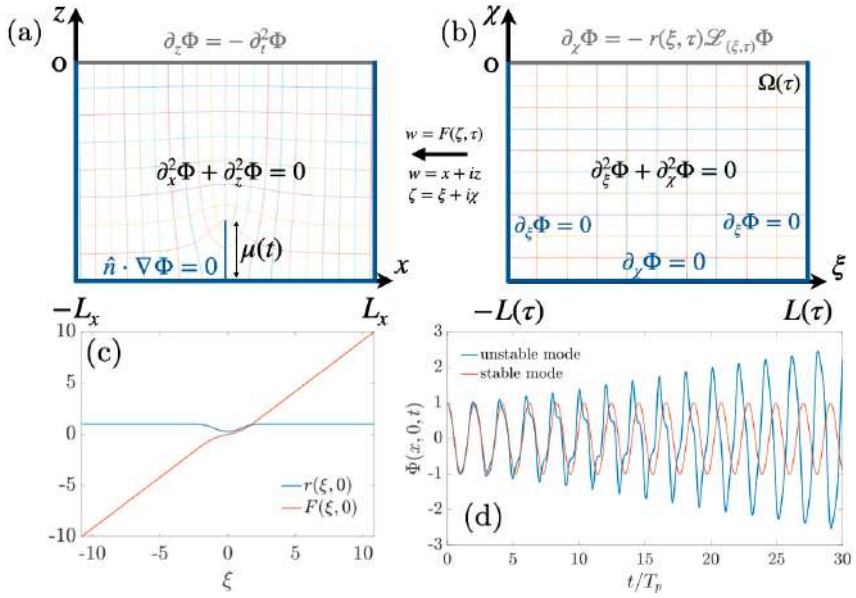

Figure 1: The time-varying sloshing problem in (a) and its transformation in the (ξ, χ, τ) plane in (b). (c) Variation of $F(\xi, 0)$ and $r(\xi, 0)$ with ξ at $\chi = 0$ when $\mu = 0.82$. (d) Evolution of the surface elevation at the wall position $x = L_x$ for parameters $(\epsilon, \Omega) = (0.1, 2.08)$ (stable case) and $(0.6, 2.08)$ (unstable case).

where $A_{mn}(\tau)$ and $B_{mn}(\tau)$ are time-dependent coefficients. In order to characterise the stability of Equation (2), and as an extension the stability of the full system, we need to follow a Floquet stability analysis [3]. We proceed by rewriting Equation (2) in the form

$$\frac{dX}{d\tau} = \mathrm{C}(\tau)X, \text{ with } \mathrm{C}(\tau) = \begin{pmatrix} \mathrm{O} & \mathrm{I} \\ -\mathrm{B}(\tau) & -2\mathrm{A}(\tau) \end{pmatrix}, \; X = \begin{pmatrix} \mathbf{a} \\ \dot{\mathbf{a}} \end{pmatrix}. \tag{3}$$

Here the matrices A and B have elements $(\mathrm{A})_{mn} = A_{mn}$, $(\mathrm{B})_{mn} = B_{mn}$, I is the identity matrix and $\mathbf{a}, \dot{\mathbf{a}}$ vectors containing $a_n, \dot{a}_n$. Then, by applying Floquet theorem, an independent solution of the system (3) is written as $X_j(t) = e^{\lambda_j t}U_j(t)$, with $U_j(t + T_p) = U_j(t)$ and T_p the period of plate oscillation. Hence, instability occurs if $\Re\{\lambda_j\} > 0$. A more detailed analysis then follows where we study the eigenvalues of the propagator L(t) defined as $X(t) = \mathrm{L(t)}X(0)$ over one period T_p, which are linked to λ_j. This leads to recovering the unstable windows in the (ϵ, Ω) plane, where $\epsilon = B_{\mu,1}/B_{\mu,0}$ and $\Omega = \Omega_p/\Omega_0$, with Ω_0 the dimensionless frequency of the first antisymmetric sloshing mode. Figure 1d shows the evolution of the first antisymmetric mode in time at the wall boundary $x = L_x$ for a plate oscillation that corresponds to either a stable or an unstable case. Finally, in the perspectives part of this work, experiments are in progress with the aim to experimentally observe the parametric amplification and characterise it.

Abstract: We propose a strategy to achieve perfect absorption of flexural waves in transmission problems using coupled monopolar-dipolar resonant scatterers. By enforcing vanishing transmission and reflection, we analytically derive the required scatterer impedance. A perfect absorber design, based on two cantilever beam-mass structures, is proposed and validated through full-wave simulations.

Recent studies have explored low-frequency perfect absorption of acoustic and elastic waves using subwavelength locally resonant metamaterials and scatterers. Achieving perfect absorption requires fulfilling the critical coupling condition, ensuring that the energy leakage of the system is precisely balanced by its intrinsic losses.

Perfect absorption furthermore corresponds to a condition where the eigenvalues of the scattering matrix become zero. In reflection problems (one-port systems), the scattering matrix reduces to the reflection coefficient, and critical coupling can be obtained by tuning the losses of the scatterer at resonance. In transmission problems (two-port systems with one-sided excitation), the scattering matrix has two distinct eigenvalues. Achieving perfect absorption becomes more challenging, since both eigenvalues must vanish at the same exact frequency. To achieve this, a symmetric (monopolar) and an antisymmetric (dipolar) resonance must be activated at the same frequency (degenerate resonances). Furthermore, the symmetry of the scatterer plays a crucial role. For mirror-symmetric scatterers, perfect absorption occurs on both sides of the system, whereas for non-mirror-symmetric scatterers, absorption varies on each side, enabling unidirectional perfect absorption by fulfilling critical coupling only on one side.

The study of critical coupling conditions has been exploited to design various classes of perfect absorbers for acoustic waves in both reflection and transmission problems [1, 2]. This concept is also highly relevant for vibrations, due to the growing industrial demand for low-frequency damping materials. Traditional solutions, such as viscoelastic coatings and tuned vibration absorbers, primarily suppress flexural wave transmission but not reflection in two-port problems. Recent works have explored using open lossy resonators to maximize flexural wave absorption by simultaneously reducing both transmission and reflection, identifying the achievable performance limits [3]. It has been demonstrated that conventional transverse resonant scatterers can achieve perfect absorption only in reflection problems, whereas in transmission problems, maximum absorption is inherently limited to 0.5, as monopolar resonances can critically couple only one of the two eigenvalues of the scattering matrix.

In this work, we address these limitations by introducing scatterers that support both monopolar transverse and dipolar rotational resonances, enabling perfect absorption of flexural waves through the critical coupling of both scattering modes. The scattering behavour is analyzed through an analytical model that accounts for both propagating and evanescent waves in the host medium, as well as for transverse and rotational scatterer impedances. Notably,

mirror asymmetries in the scatterer are captured by cross-coupling terms appearing between the transverse and the rotational impedances. Leveraging this model, we analytically derive the required scatterer impedances for symmetric and asymmetric perfect absorption, by imposing vanishing transmission and (unidirectional) reflection.

Using these theoretical insights, we propose the design of an asymmetric perfect absorber. The scatterer consists of a horizontal cantilever beam-mass structure exhibiting a coupled monopolar-dipolar resonance and a vertical cantilever beam-mass structure exhibiting a pure dipolar resonance. The impedances of the scatterer are expressed as a function of its modal effective masses, which are determined through a fixed-base modal analysis. The geometrical parameters of the scatterer are optimized to match the required impedances and achieve one-sided perfect absorption. Finally, the peformance of the proposed design is validated through full-wave numerical simulations, showing agreement with analytical predictions.

The results of this work demonstrate the feasibility of designing perfect absorbers for flexural wave in vibration transmission problems, representing a significant advancement in wave absorption mechanisms.

Ultrafast Phononic Manipulation of Magnetization

C. S. Davies
HFML-FELIX, Radboud University, Nijmegen, The Netherlands
*corresponding author: carl.davies@ru.nl

Abstract: Upon driving doubly-degenerate optical phonons at resonance within a paramagnetic substrate, we demonstrate that magnetization can be created on an ultrafast timescale. Further, this transient magnetization can remotely switch magnetic ordering in an overlayer. This application of the ultrafast Barnett effect offers a potentially universal method for controlling magnetization.

Over the last few decades, breakthrough experiments have demonstrated that ultrashort laser pulses have the capacity to both temporarily manipulate and permanently switch magnetic ordering [1]. A variety of different mechanisms can facilitate all-optical switching of magnetization, relying for example on ultrafast exchange-driven demagnetization [2] or the excitation of electronic transitions at resonance in dielectric iron-garnet films [3].

Spin-lattice coupling plays a central role in the research fields of magnetism and spintronics. Very recently, it has been demonstrated that ultrafast demagnetization involves the transfer of angular momentum from the spins to the lattice [4]. Reciprocally, it is also feasible for vibrations of the lattice (phonons) to modulate magnetic interactions such as exchange [5]. Going further, it is even possible for one to drive at resonance circularly-polarized optical phonons – the angular momentum of the latter can give rise to emergent magnetization [6] and large effective magnetic fields [7].

Here, I will discuss our experimental measurements studying how we can create and manipulate magnetization by selectively driving optical phonons at resonance. To achieve this, we use ultra-narrowband optical pulses in the infrared spectral range as delivered by the free-electron lasers at the FELIX facility. Upon, for example, irradiating paramagnetic rare-earth trihalide substrates, we find (using a two-color pump-probe scheme) that a magnetization emerges on an ultrafast timescale, consistent with recent measurements published in Ref. [7]. The spectral dependence of the transient magnetic moment scales reasonably well with the population of doubly-degenerate optical phonons. Further, upon pumping magnetic heterostructures mounted atop paramagnetic substrates with circularly-polarized infrared pulses, we find that the magnetic ordering can be switched only when the pulse drives at resonance doubly-degenerate optical phonons within the substrate [8]. The direction of switching can be controlled by adjusting the helicity of the incident pulses. So far, we have identified this mechanism in structures grown on glass-ceramic, c-cut sapphire and zinc oxide substrates.

Abstract: We studied the propagation of ultrahigh frequency coherent acoustic phonons in a ridge waveguide based on multilayered GaAs/AlAs optophononic Fabry-Perot resonator. Additionally, by optically generating two distant phonon sources, we demonstrated the interference of the propagating coherent phonons in such system.

Acoustic phonons at ultrahigh frequencies can be employed as information carriers in the solid state, being an asset for signal processing and quantum technologies. [1-3] During the past decade, confinement of ultrahigh-frequency acoustic phonons in planar structures and micropillars has been achieved. [4, 5] However, coherent manipulation of propagation and dynamics of ultrahigh frequency phonons remains challenging. This study focuses in characterizing the propagation of coherent acoustic phonons in a phononic waveguide system based on multilayered GaAs/AlAs microcavity optophononic resonators confining acoustic phonons at ~20 GHz and light at ~840 nm [6-8], as shown in Figure 1(a).

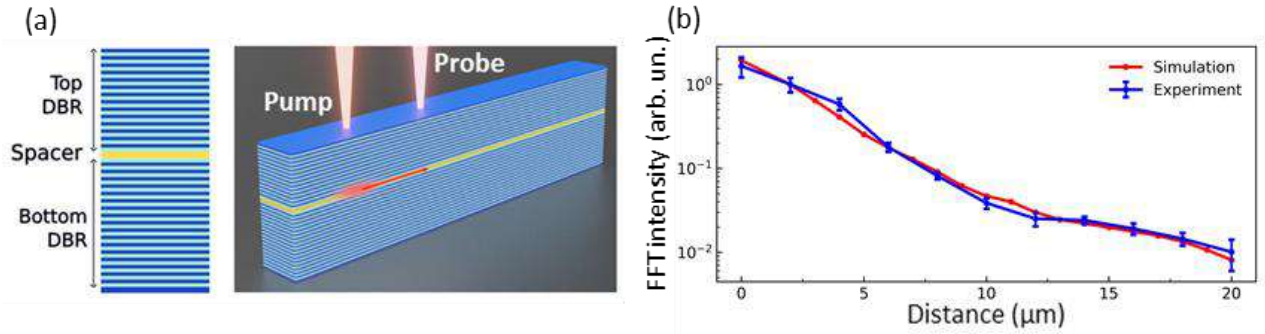

Figure 1. (a) Schematic of the GaAs/AlAs optophononic Fabry-Pérot resonator. The left panel illustrates the vertical structure designed to confine 20 GHz acoustic phonons and ~840 nm photons. The top and bottom distributed Bragg reflectors (DBRs) create a stop-band around 20 GHz, while the GaAs spacer serves as a cavity for phonon confinement. The right panel presents a schematic of the waveguide, showing the pump and probe optical beams. (b) Intensity of the 20 GHz resonance as a function of the separation distance between the generation and detection.

We used a reflection-type pump-probe technique to generate and detect the coherent acoustic phonons via photoelastic interaction. [9] A strong and short pump pulse generates coherent acoustic phonons via photoinduced stress, which modulate the material refractive index. A delayed probe pulse senses the transient reflectivity changes induced by the acoustic phonons. To evaluate the phonon propagation, we performed the

pump-probe measurements in two configurations: local, when pump and probe beams are overlapped, and remote, by spatially separating both beams. The later configuration allows us to observe the contribution of propagating acoustic phonons at different positions in the waveguide. We demonstrated a quasi-continuous and coherent source of acoustic phonons propagating up to 20 µm from the source, as displayed in Figure 1(b). Additionally, we confirmed the coherence of the propagating acoustic phonons through spatio-temporal interference between two distant sources.

These results constitute a promising avenue for revealing the fundamental properties of phonon dynamics and manipulating phonon propagation in more complex structures. They also correspond to a significant step forward in the development of phononic networks for telecommunications and quantum applications.

Wave locking in periodically folded beams: influence of modelling choices on complete band gap prediction

E. Manconi[1*], F. Tatar[1]
[1]University of Parma, Italy
Corresponding author: elisabetta.manconi@unipr.it

Abstract: This work presents a study on the formation of complete band gaps in periodically folded one-dimensional waveguides. The effects of modelling choices on the coupling of contradirectional Bloch waves and the formation of the first band gap are investigated. Numerical examples and a parametric analysis are provided.

Folded waveguides are fundamental elements in numerous structural systems, widely utilised in engineering due to their high strength-to-weight ratio and structural efficiency. The periodic nature of many folded structures, such as origami-based configurations, enables the emergence of unique mechanical and dynamic properties. An interesting phenomenon in periodically folded structures is the formation of complete band gaps. These band gaps significantly affect vibration isolation, acoustic filtering performance, and mechanical energy redirection in engineered structures.

Although many previous studies have investigated wave propagation in conventional thin plates and lattice structures, the effects of fold geometry, plate thickness, and fold modelling on wave behaviour in folded structures have rarely been examined. Traditional modelling approaches frequently treat folds as idealised creases with zeroth-order geometric continuity. However, including finite fold thickness and higher-order continuity at folds can alter the predictions of mechanical response and dynamic behaviour of these structures, as shown, for example, in [1]. The aim of this work is to study periodically folded one-dimensional waveguides, investigating

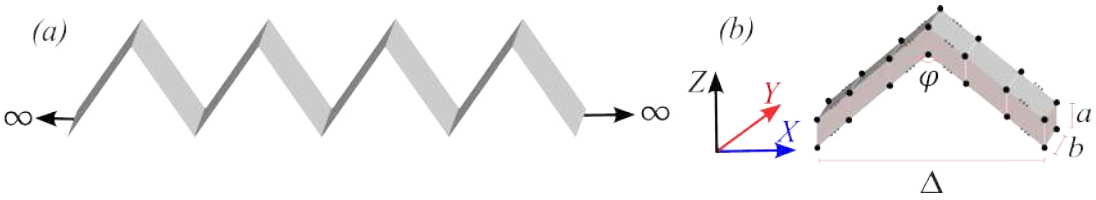

Figure 1: (a) 1D periodic waveguide. (b) model of the unit cell: φ folding angle, Δ periodic length, a and b cross-section dimensions.

the characteristics of wave propagation and explicitly considering the effects of the structure's thickness and modelling of the fold on wave behaviour. The study applies the exact dynamic stiffness method (DSM) with the Floquet-Bloch theorem to predict wave propagation and band gaps in idealised zero-thickness models. Results are compared with those obtained by applying a Wave Finite Element (WFE) method to consider full 1D, 2D and 3D models, [2]. See Figure 1.

As an example, Fig. 2 shows the comparison between the dispersion curves of a folded beam modelled using the exact DSM formulation for an Euler-Bernoulli beam and the WFE method applied to a full 3D FE model of the unit cell using 8-noded brick elements (three degrees of freedom per node: displacements u_x, u_y, u_z in the X, Y, Z directions). Waves propagating

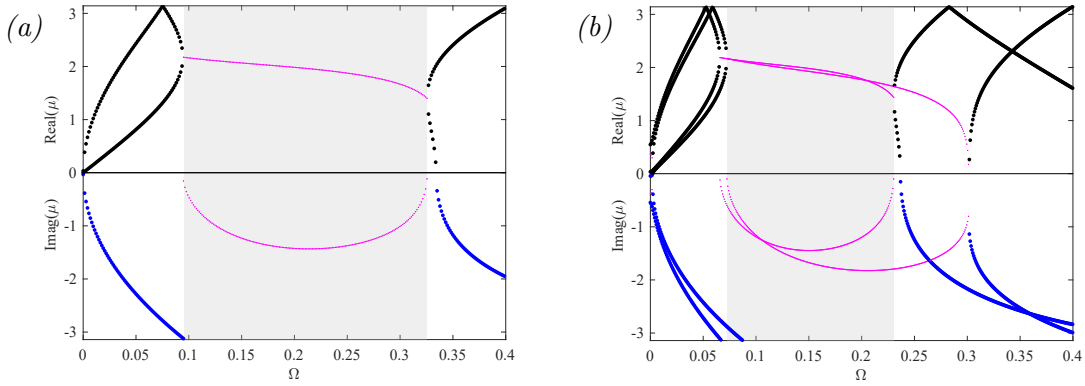

Figure 2: Complex dispersion curves for waves propagating in the positive X direction in two models of the same folded 1D waveguides: (a) exact beam formulation (DSM formulation); (b) 3D FE model using 8-nodes solid elements (WFE method). Black solid lines: pure propagating Bloch waves; blue lines: evanescent waves; magenta lines: complex propagation constants. The grey area shows the first complete band gap.

in the positive direction are assumed. In this figure, the dimensionless frequency $\Omega = \frac{\omega\Delta}{c_L}$ is introduced, where $c_L = \sqrt{\frac{E}{\rho}}$ is the propagation velocity of longitudinal waves in the material, while μ is the propagation constant (real μ representing the propagating waves). The grey area shows the complete stop band formation, where the propagation constants are complex conjugate solutions. In this area, no real branches corresponding to propagating waves are allowed. For finite structures, this implies that all types of vibrations are attenuated in this zone. It can be seen that this first complete band gap starts at the frequency where contradirection coupling (locking) of two propagating Bloch waves occurs, viz. where two pure-real propagation constants intersect, becoming a complex conjugate pair. [3]. The figure also indicates the effect of the modelling choices on wave dispersion and band gap edge frequencies.

Conclusions.

Wave propagation and band gap formation in periodically folded waveguides were studied. Wave coupling due to folding was investigated, and the effects of changes in fold thickness and modelling were analysed. The results showed that incorporating fold thickness and smooth modelling affects both wave propagation and band gap predictions.

Abstract: We study the sensitivity of non-Hermitian quasiperiodic lattices in terms of their corresponding pseudospectra. In particular, we investigate $\mathcal{PT}$-symmetry transitions, and the dependence of the spectral sensitivity around the underlying multiple exceptional points. Nonlinear effects that stem from the gain saturation, are also examined.

Localization arises from inherent randomness, making disordered systems difficult, if not impossible, to study them analytically. The Aubry-André-Harper (AAH) model [1–3] provides a framework for analyzing one-dimensional quasicrystals with a metal-insulator transition [2, 3]. We extend this model to a non-Hermitian quasiperiodic AAH lattice with onsite gain and loss (NHAAH) [4–6], revealing $\mathcal{PT}$-symmetry transitions and multiple exceptional points (EPs). Using pseudospectra [7, 8], we investigate the spectral properties and the sensitivity of the corresponding even and odd lattices. More over, we explore the linear diffraction dynamics, that exhibits quantized jumps [9–11] between non-orthogonal eigenstates and examine the impact of the saturable nonlinearity of the optical gain.

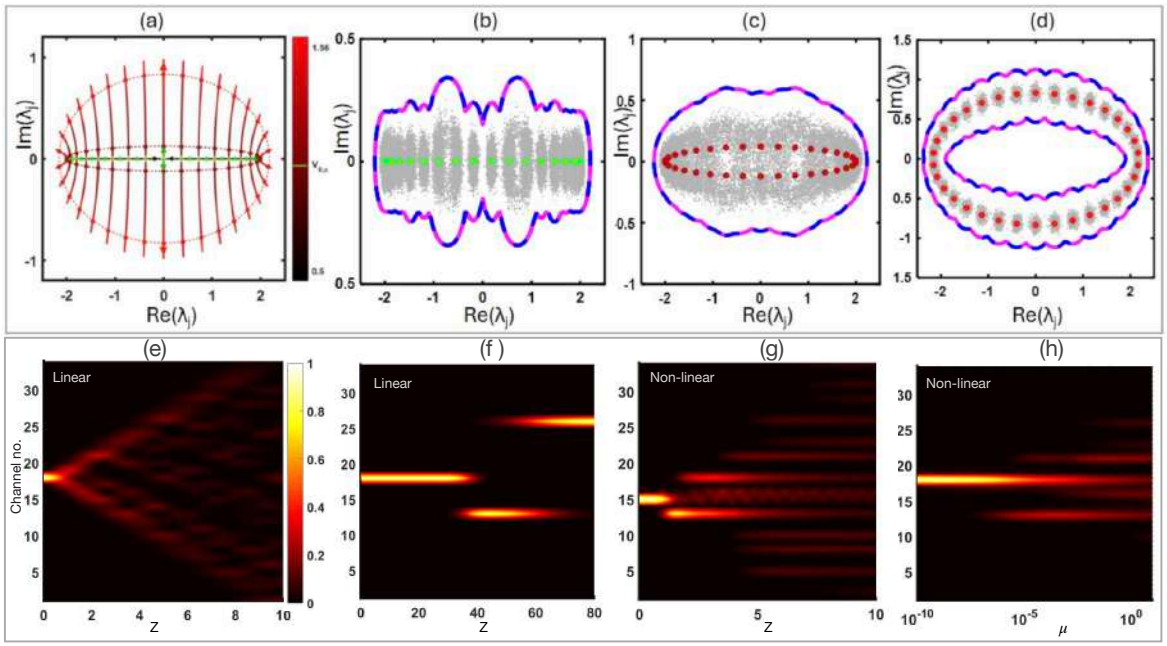

Fig. 1 (a) Spectral flows of the system ($N = 34$) in the complex plane as potential strength V_0

varies for coupling strength $J = 1$ (see colorbar). Green, maroon, and red dots represent spectra before, near, and after the $\mathcal{PT}$-phase transition, with arrows indicating eigenvalue trajectories. (b)-(d) Pseudospectra before, at, and after the $\mathcal{PT}$-phase transition, using three different methods (gray dots, blue, and pink lines). Eigenspectra from (a) are marked in green, maroon, and red. (e), (f) Dynamical evolution under single-channel excitation in the linear case, where (f) highlights three modes involved in sudden jumps. (g) Nonlinearity prevents jumps despite loalized eigenstates, in contrast to the linear case. (h) Increasing nonlinearity induces an insulator-to-metallic transition.

Our results are shown in Fig. 1. In particular, the spectral flows of the associated eigenvalues are presented, along with the corresponding pseudospectra in the complex plane (by using three different methods). The bottom panel shows how the waves diffracts in terms of quantized jumps due to eigenstate localization. The last two figures (g), (h) demonstrate the effect of saturable gain, namely that nonlinearity suppress the jumps. On other words, unbroken $\mathcal{PT}$-symmetry enables wavepacket spreading, whereas broken $\mathcal{PT}$-symmetry induces localization.

In conclusion, we have analyzed the $\mathcal{PT}$-symmetric NHAAH model's sensitivity using pseudospectra, and determined the conditions under which quantized jumps occur. The detrimnetla role of gain saturation was also examined.

Abstract: Focusing of surface water waves is investigated using an analog of a Luneburg lens constructed by submerged pillars. Efficient focusing is observed on a wide range of frequencies. The results may find application in the ocean-human interaction, such as coastal protection.

In recent years, advances in acoustic metamaterials and photonic/phononic crystals have spurred growing interest in the manipulation of surface water waves (SWWs). Among the various phenomena studied, wave focusing has received considerable attention, particularly through the use of artificial structures with gradient refractive indices [1]. One notable example is the Luneburg lens, originally developed for electromagnetic waves and later adapted for acoustic applications [2]. Its refractive index varies with the radial distance r from the center according to $n_L = \sqrt{2 - r^2/R^2}$, where R is the radius of the lens.

The primary objective of this work is to demonstrate the feasibility of extending the Luneburg lens concept to the realm of surface water waves, a direction that, to the best of our knowledge, has not yet been explored. The analogue of a Luneburg lens is constructed using submerged pillars with varying radii r_c and equal height h. We first study the periodic arrangement of the pillars of the same radii (with period $L = 25$ mm) and retrieve their dispersion relation $f(k_x)$. Taking into account that $kh << 1$ we introduce the wavenumber by $f = \sqrt{gH}k/2\pi$, where H is the depth of the water. Then in the linear part of the curve the Bloch wave vector is $k_b = nk$ with n being the refractive index [3].

Assuming that water is an inviscid and incompressible fluid, the velocity potential satisfies the Laplace equation $\Delta\phi = 0$ subject to the following boundary conditions: on the free surface at $z = 0$, $\frac{\partial\phi}{\partial z} = \frac{\omega^2}{g}\phi$ and on the non-flat bottom $\nabla\phi \cdot \vec{n} = 0$ [4]. The corresponding dispersion curves are presented in Fig. 1(a) for the maximum and minimum filling fraction ($r_c = 0$ and $r_c = 0.5L$), while the recovered refractive index is reported in Fig. 1(b) for different heights as a function of r_c.

We construct the lens by placing the pillars of different radii in the form of a square lattice approximating n_L. We choose the radius of the lens to be $R = 10L$ and divide its area into circles with a step equal to L as shown in Fig. 2. From the function $n_L(r)$ we define the refractive index at every circumference $r_i = i \cdot a$ and calculate the filling fraction ff_i of the corresponding square lattice utilizing the Fig. 1(b). Then we fill the circles in such a way that if the coordinates of the pillar satisfy $x^2 + y^2 \in [r_i, r_{i+1})$, then the pillar has the radius $r_i = a\sqrt{ff_i/\pi}$. This allows us to gradually change n from the maximum $\sqrt{2}$ in the center to the minimum 1 in the corner

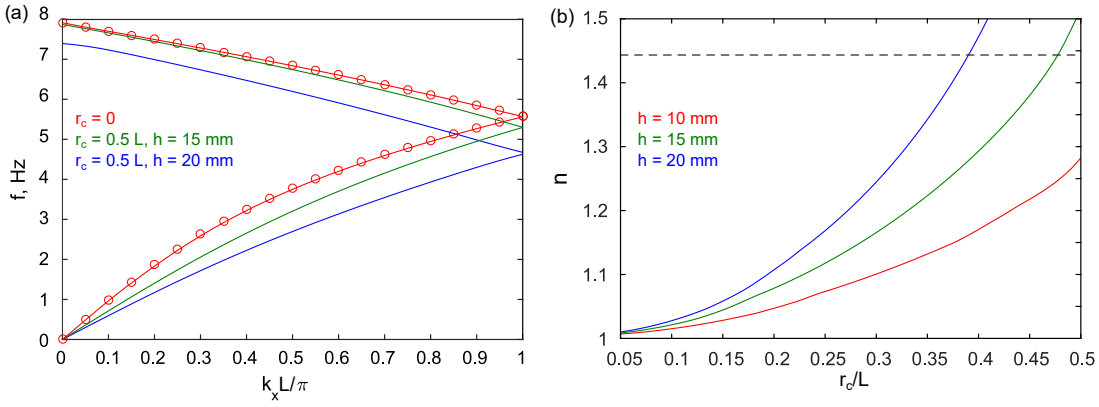

Figure 1: **Dispersion diagram and refractive index**. Dispersion diagram for minimal and maximal filling fraction (a) and refractive index as a function of r_c for different heights (b).

of the lens. The resulting structure is sketched in Fig. 2.

The perspective of this study is to consider focusing in terms of the full equation for the velocity potential in order to take into account the near-field effects occurring between the interacting pillar.

Design of underwater noise reduction ultra-thin metabarriers

V. F. Dal Poggetto [1] and M. Miniaci[1*]

[1]Univ. Lille, CNRS, Centrale Lille, Junia, Univ. Polytechnique Hauts-de-France,

Abstract: In this work, we propose a metabarrier with a tailored elastic anisotropy for efficient underwater noise reduction. The constitutive unit cell of the metabarrier is optimized to enhance wave mode coupling to effectively operate in the sub-wavelength regime and also exhibit high sound transmission loss at higher frequencies.

Effective noise reduction at low frequencies with structures much thinner than the wavelength of incident waves (sub-wavelength behavior) remains a significant scientific and technological challenge. This is particularly true in underwater acoustics, where wavelengths are much longer than in air, and solid-structure interactions play a crucial role. Mitigation strategies typically involve a careful adjustment of the impedance match or mismatch between barriers and water, resulting in (i) absorptive or (ii) reflective behavior [1]. However, reducing underwater noise at very low frequencies (below 1000 Hz) and over a broadband frequency range remains a challenge.

We address this problem by introducing a periodic metamaterial with an optimized unit cell designed to facilitate coupled normal-shear behavior along predefined directions. An initially homogeneous two-dimensional structure is considered whose constitutive matrix $\mathbf{C}$ presents components so that the ratio $C_{33}/C_{11} = 0.9$ is satisfied. We also assume the relationship between the speed of the acoustic waves and the mass densities in the fluid (subscript $_0$) and the solid (without subscripts) to be $c_0/\sqrt{C_{11}/\rho} = 0.9$ and $\rho_0/\rho = 0.9$, respectively. The effect of the dimensionless coupling factor $\delta = C_{13}/\sqrt{C_{11}C_{33}}$ on STL curves is then investigated numerically by considering, as an illustrative example, the following material properties for the metabarrier: density $\rho = 1000$ kg/m^3, stiffness coefficient $C_{11} = 1$ GPa, and thickness $\overline{h} = 10^{-2}$ m. Figure 1**a** (top panel) reports STL curves computed using a transfer matrix method, adopting a thickness $h = \overline{h}$ and $\delta = \{0.9, 0.95, 0.995\}$. The results indicate that increasing δ leads to (i) a five-fold amplification of the first STL peak and (ii) a reduction of 80% in its corresponding frequency. Alternatively, for $\delta = 0.999$ and $h/\overline{h} \in [10^{-2}, 10^{0}]$, Fig. 1**a** (bottom panel) indicates (i) a monotonic behavior for $h/\overline{h} < 10^{-2}$ and (ii) a red shift of STL peaks for increasing h, suggesting that the first STL peak can be tuned using the thickness of the metabarrier. These results are used to design the metabarrier unit cell through topology optimization as follows: (i) we divide a square unit cell into $2q \times 2q$ pixels (Fig. 1**b**, top panel), with matching boundaries to ensure continuity and $\pi/2$-rotational interior symmetry to ensure $\delta \neq 0$; (ii) we set an optimization objective to maximize $|\delta|$ while ensuring connectivity. The unit cell obtained is reported in Fig. 1**b** (bottom panel), with a geometry smoothed for manufacturing reasons, resulting in $\delta = 0.9582$. The dispersion curves of this unit cell in the ΓX direction are reported in Fig. 1**c**, adopting a unit cell length $a = 10$ mm and material properties $E = 3$ GPa, $\nu = 0.3$, $\rho = 1150$ kg/m^3.

Dispersion curves are reported following the polarization metric: $p = \int_S |u_y|^2 \, dS / \int_S |u_x|^2 + |u_y|^2 \, dS$, where u_x (u_y) is the displacement in the x- (y)-direction and S the unit cell domain. This polarization implies that $p = 0$ ($p = 1$) indicates a purely longitudinal (transverse) motion. The band diagram is shown for $[0, 5]$ kHz using continuous lines, with dashed lines representing the dispersion diagram for the equivalent homogeneous medium. The polarization factor of the first branch ranges from 0.403 to 0.414, suggesting a high degree of hybridization of the mode, with a slight tendency toward longitudinal polarization of the deformation. The wave mode at point X at 2.67 kHz is reported for the sake of clarity. The second branch presents $p \in [0.585, 0.589]$, also suggesting a high degree of hybridization, although this time with a slight tendency toward transverse polarization of the deformation. The wave mode shown at 5 kHz (wavenumber $k \approx 0.14\pi/a$) displays a rigid body-like transverse motion. Although the coupling

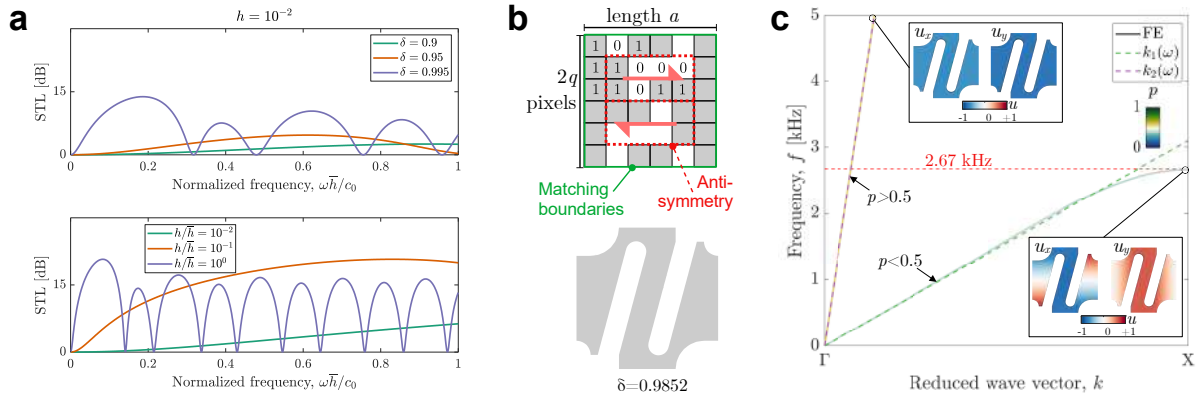

Figure 1: Metabarrier design strategy. **a**. STL curves for non-dimensional thickness $h = 10^0$ and coupling factor $\delta = \{0.9, 0.95, 0.995\}$ (top panel); $\delta = 0.999$ and $h = \{10^{-2}, 10^{-1}, 10^0\}$ (bottom panel). **b**. Unit cell ($2q \times 2q$ pixels) with internal $\pi/2$-rotational symmetry (top panel). Result of optimization procedure after smoothing (bottom panel). **c**. Dispersion diagram (continuous lines) with polarization values p. Dashed lines represent dispersion curves with effective homogenized properties.

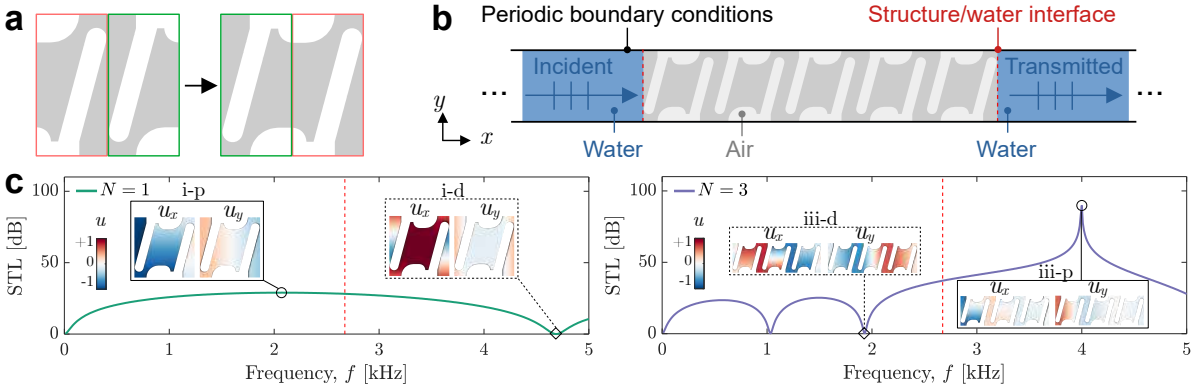

Figure 2: Finite metabarrier and STL curves. **a**. Swapping left/right halves to obtain unit cells without gaps at edges. **b**. Arrangement of unit cells filled with air and submerged into water. The medium is periodic in the y-direction. **c**. STL curves obtained for $N = 1$ and $N = 3$ unit cells.

between normal/shear stresses/strains was optimized in the static regime (ie, $\omega = 0$), dynamic coupling in longitudinal-transverse motion has been observed.

To evaluate the STL properties of a metabarrier made up of a finite number of unit cells, the left and right halves of the optimized unit cell have been swapped (Fig. 2**a**). This operation maintains the periodicity of the system. The unit cell is then repeated along the x-direction using N unit cells, obtaining finite structures with thickness $h = Na$. The STL curve of this structure immersed in water (Fig. 2**b**) considers a periodic medium in the y direction, and is calculated using a FE-based method [2]. These results are shown considering $N = 1$ and $N = 3$ unit cells (Fig. 2**c**). When $N = 1$, the metabarrier presents a maximum STL of 29.0 dB at 2.07 kHz (inset i-p) with deep sub-wavelength performance ($h/\lambda \approx 1/70$). The STL curve reaches a dip at 4.7 kHz, with a symmetric displacement profile (inset i-d). When $N = 3$, three STL peaks are found: attenuation of 23.5, 25.2, and 89.8 dB at 0.57, 1.49, and 4.00 kHz, respectively.

Ultrathin architected plates and their applications

Igor Bargatin

[1]University of Pennsylvania, USA
[*]corresponding author: bargatin@seas.upenn.edu

Abstract: Ultralight architected plates, like nanocardboard, offer unprecedented stiffness-to-weight ratios and shape recovery. Made from nanometer-thick films, these metamaterials enable macroscopic photophoretic levitation via thermal transpiration. They also inform designs for relativistic lightsails, where high bending stiffness and engineered curvature (billowing) are crucial for managing intense photon pressure stresses.

For centuries, engineers have sought plates that are simultaneously lightweight and stiff. Traditional approaches often involve solid materials or macroscale composites like corrugated cardboard or honeycomb panels, with applications ranging from doors to aerospace structures. However, fundamental limits in material density and manufacturing constraints cap the achievable performance, especially when extreme lightness is paramount. Recent advances in nanofabrication have unlocked a new approach: plate mechanical metamaterials, where carefully designed micro- and nano-architectures, rather than just material composition, dictate mechanical properties. This overview focuses on a class of *plate* mechanical metamaterials—ultrathin, architected films—and explores their potential to revolutionize two disparate propulsion concepts: photophoretic levitation and extreme laser-driven acceleration for relativistic lightsails.

We began by creating continuous, free-standing corrugated plates from ultrathin (~25-100 nm) films of materials like alumina using atomic layer deposition (ALD) on patterned silicon molds [1]. Initial designs, using honeycomb patterns, demonstrated that microscale 3D architecture could impart significant bending stiffness and flatness to films otherwise prone to warping, enabling centimeter-scale plates weighing as little as 0.1g/cm^{-2}. We also developed nanoscale analogs of sandwich plates, initially demonstrating ultrathin corrugated plates and later "nanocardboard," a monolithic material composed of nanometer-thick (25-400 nm) face sheets connected by micrometer-height tubular webbing, *i.e.* microchannels [2]. A remarkable property emerged: these brittle

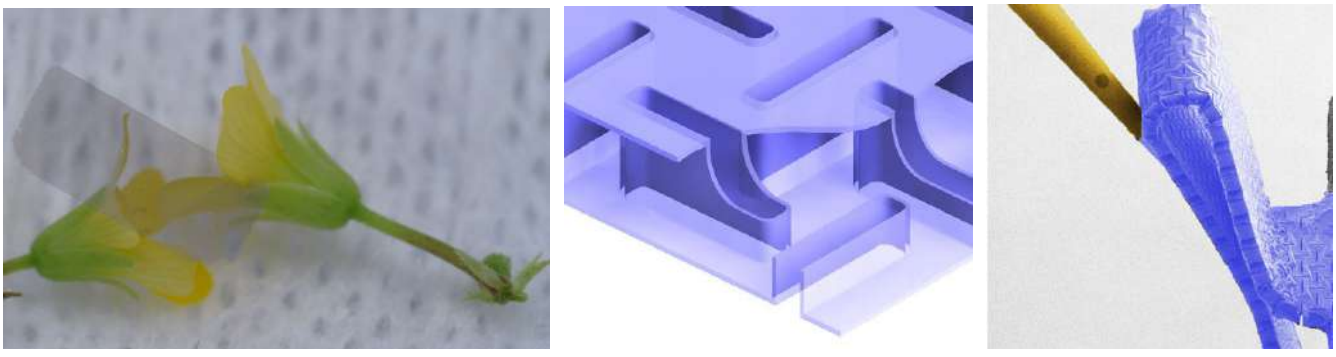

Fig. 1: (left) An architected plate with 50-nm-thickness and cm-scale lateral dimensions resting upon a flower. (center) A schematic of the hollow structure of nanocardboard, a nanoscale analog of sandwich plates. (right) Artificially colored scanning electron micrograph showing the sharp bending of nanocardboard with a micromanipulator probe, which surprisingly does not damage the structure, leading to full shape recovery.

ceramic plates could undergo sharp bends, folding over 90 degrees, yet recovering their original shape without damage (Fig. 1), a feat we attributed to the nanoscale thickness limiting strain to less than ~1% during sharp bending and local buckling.

The unique combination of ultralow mass and low thermal conductivity in nanocardboard enables macroscopic **photophoretic levitation**. Photophoresis, the force exerted on an object immersed in a gas due to light-induced temperature gradients, is typically significant only for micrometer-sized particles but can also be maximized for carefully engineered architected plates. By coating the bottom side of the nanocardboard with an absorbing layer (e.g., carbon nanotubes), incident light creates a temperature difference across the plate thickness. This drives thermal transpiration flow through the internal microchannels. At atmospheric pressure, this flow creates an air cushion beneath the plate, allowing it to hover stably at heights of ≈ 0.5 mm above a substrate [3]. At low pressures (10-200 Pa, relevant to Mars or Earth's mesosphere), the enhanced flow generates a jet enabling mid-air levitation and payload carriage (e.g., 0.33 mg payload on a 0.1 mg plate) [3]. Extending this idea, we proposed meter-scale, 3D hollow structures using Knudsen pumping through porous walls to create high-speed jets, potentially enabling kilogram-scale payloads at mesospheric altitudes (55-80 km) [4].

The extreme lightness and potential for high-temperature resistance make nanostructured plates candidates for **relativistic lightsails**, envisioned for interstellar missions like Breakthrough Starshot. Such sails require acceleration to a significant fraction of the speed of light (e.g., 0.2c) using high-power lasers. However, the intense photon pressure required poses a significant mechanical challenge. Our analysis shows flat sails would likely tear; sails must billow (curve significantly) to reduce stress can also benefit from architected plate geometry to maintain this shape. Optimal meter-scale designs balance curvature, thickness, optical properties, and thermo-mechanical limits. Sufficient laser power allows curved architected sails to achieve shorter acceleration distances, highlighting the necessity of curvature for both integrity and potential performance.

Architected plates therefore represent a class of ultralight metamaterials with unique mechanical properties enabling novel flight via photophoresis and offering structural solutions for relativistic lightsails, paving the way for exploration in previously inaccessible regimes of gas flow and related applications.

Abstract: We design an optomechanical nanobeam cavity based on the Su–Schrieffer–Heeger (SSH) model, created via alternating two mechanical/optical domains at the interface through controlled holes and stubs spacing. The system provides topologically protected photon–phonon coupling ($g/2\pi$ = 782 KHz) and a high optical quality factor ($Q = 3.77\times10^5$).

Phoxonic crystals offer a compelling platform for controlling light and sound at the nanoscale, enabling coherent photon–phonon interactions through the simultaneous confinement of optical and mechanical modes. While substantial progress has been made in one-dimensional (1D) optomechanical systems—most notably nanobeam cavities—recent advances point to the possibility of achieving vacuum coupling rates on the order of $g/2\pi\sim1$ MHz in more complex geometries[1]. These structures not only allow precise control over phonon-mediated photon dynamics but also open new avenues for integrated quantum transduction, nonreciprocal photonics, and ultra-sensitive metrology[2].

cavity. The silicon nanobeam is anchored at both ends to a thick substrate via an intermediate SiO_2 layer. Optical excitation is provided by a telecom-frequency waveguide coupled to the SSH-cavity, while paired interdigital transducers (IDTs) enable mechanical actuation and elastic energy detection.

Here, we present a 1D phoxonic nanobeam cavity inspired by the Su–Schrieffer–Heeger (SSH) model, designed to host topological modes in both the photonic and phononic domains. Figure 2 (a,b) illustrate the dimerized unit cell designs, with symmetrically placed holes and stubs that give rise to Dirac-like dispersion at $k_y = \pi/2a_y$. By systematically breaking this symmetry—displacing holes and stubs either inward or outward from the center—we induce topological phase transitions in both the optical and acoustic spectra, as shown in Figure 2(g–j).

To analyze the system, we simulate a finite nanobeam composed of 40 unit cells—20 on each side of a central interface—using finite element analysis. The left half of the beam features unit cells with a larger separation between holes and stubs, while the right half contains a more compact configuration. The topological gaps are preserved across the structure by finely tuning an anti-symmetric design parameter σ. Mode profiles in Figure 2 (marked by letters A-H) show the topological transition resulting from the unit cell changes at the interface, analogous to the behavior observed in mechanical SSH chains composed of identical masses connected by alternating spring constants. The resulting cavity exhibits strong electromagnetic field confinement within a single optical cycle—comparable to that observed in higher-dimensional phoxonic crystals (Figure 3a)—and achieves high photon-phonon coupling rate of $g/2\pi$ =782 KHz in air.

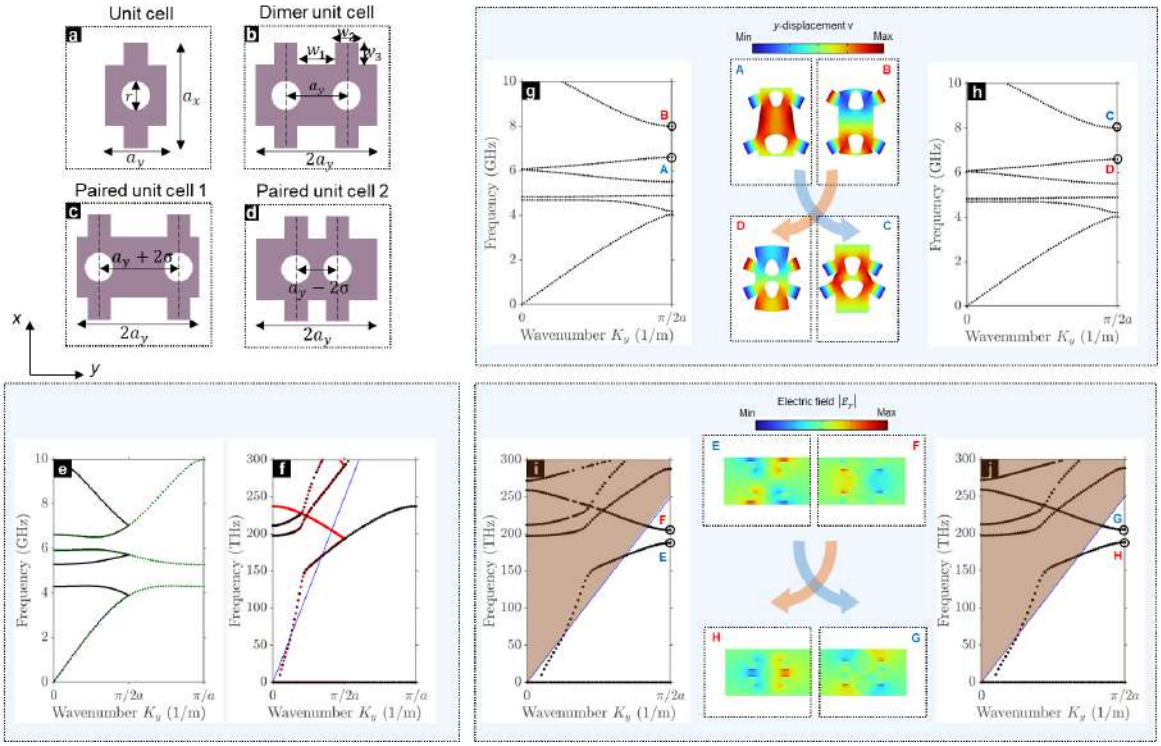

Figure 2 **Unit cell configurations and Energy bands**. (a-b) Single and double unit cell(s) with centered holes and stubs. (c-d) Asymmetric variants with holes and stubs shifts (σ∈[-100, 100] nm), used to build the graded nanobeam. All designs maintain fixed periodicity ($a_x = a_y$ 300 nm), nanobeam thickness (220 nm) and stub lengths ($w_1 = w_2$ = 100 nm). (e-f) Phononic and photonic dispersion bands for (a) and (b), showing Dirac points at ky = $\pi/2a_y$ for symmetric cases. (g-j) Topological gaps (σ≠0) with edge modes (A-H) demonstrating topological band inversion.

This coupling strength is comparable to that reported in more complex two-dimensional phoxonic systems, yet it is realized here with significantly reduced fabrication complexity. These findings highlight the potential of SSH-inspired optomechanical nanobeams as a scalable and robust architecture for advancing next-generation integrated photonic and phononic technologies.

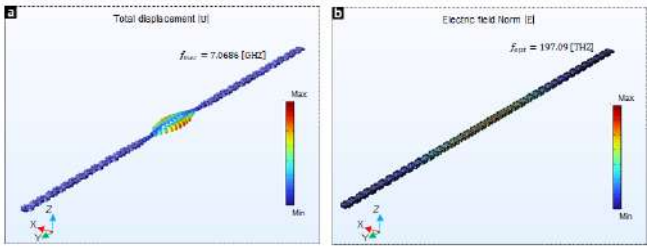

Figure 3 **Phononic and photonic interfacial modes**. (a–b) A non-trivial optomechanical interface featuring a smooth transition, demonstrating a high-quality photonic Q-factor of 3.77×10^5 and an optimized coupling rate $g/2\pi$ = 782 KHz. Normalized displacement is shown in false color, with exaggerated deformation for clarity.

Springtronics: Towards advanced information processing in elastic metamaterials

F. Bohte, S. Zahedi Fard*, P. Omidvar, T. Louvet, S. Zohoori and M. Serra-Garcia[2]

[1]AMOLF, Netherlands
*corresponding author: m.serragarcia@amolf.nl

Abstract: We introduce a design framework for information-processing phononic metamaterials. The key idea consists in encoding the desired functionality as a mass-spring network, that is then translated into a metamaterial geometry and, eventually, into an experimental realization. The talk will discuss mass-spring and geometry design strategies, as well as example applications.

Elastic systems are an exciting platform for information processing. They can, for example, compute with very low power dissipation [1], directly process mechanical signals such as speech [2], steps [3] or building vibrations without transducers, and embody intelligence in robotic structures [4]—thus, they present the tantalizing prospect of having internet-of-things devices powered by speech, and soft robots that are agile and safe to interact with. However, designing an elastic metamaterial that performs a desired computation is challenging: It means solving an elastic inverse problem—that can be potentially high-dimensional, nonlinear, and transient.

Our approach to the design of intelligent elastic systems draws inspiration from electrical engineering. In this field, it is customary to start the design process by drawing a lumped model—a circuit schematic—that performs the required task. During this initial phase, little attention is placed on the specific geometry and materials that will define the final system. The circuit schematic is subsequently converted into a device geometry (such as a printed circuit board or integrated circuit) either manually or via automated software tools, and eventually fabricated. This stands in contrast with the geometry-first approach that is usually taken in the design of metamaterials, highly focused on specific realizations, and dominated by tools such as topological and parametric optimization. In analogy with electrical engineering, we refer to our approach as *springtronics* [5].

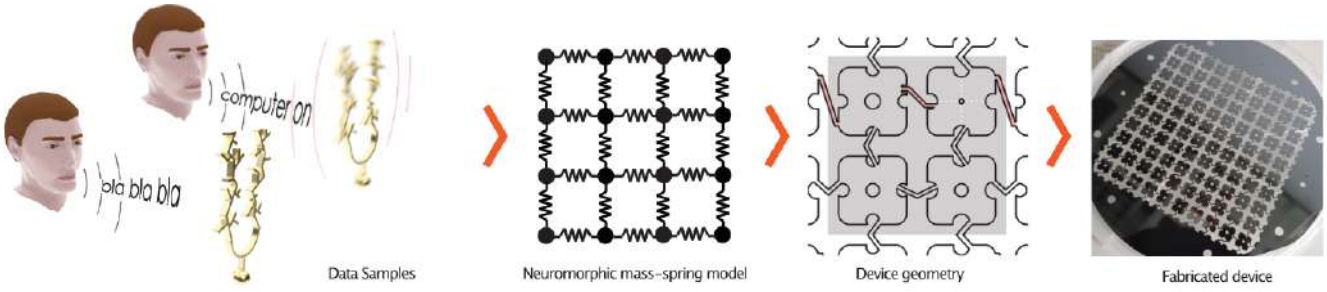

Figure 1. In *springtronics*, functionalities such as speech recognition are first encoded in a mass-spring model, that is then translated into a geometry, and, eventually, fabricated.

In this talk, I will start by discussing our fundamental building blocks. Remarkably, we conclude that a small number of interactions (three types of conservative springs, plus a local damper) suffice to express an extreme variety of tasks, from digital computers that perform operations on signals encoded either as static displacements or as amplitudes [6], to nonvolatile memories, and including speech-recognizing mass-spring networks [5], that

achieve accuracy comparable to low-power electronic alternatives. I will show a few examples of springtronic models that perform interesting tasks.

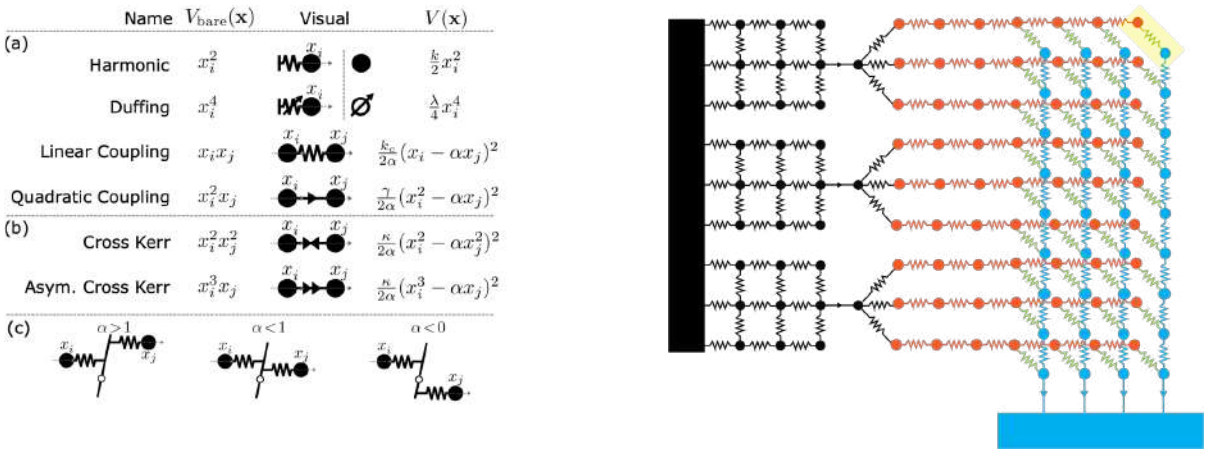

Figure 2. Springtronic models are constructed by combining elementary potentials (left). These potentials can be combined into complex functionalities, such as speech-classifying systems (right).

Then, I will discuss how these mass-spring models can be translated into geometries. We do so within the perturbative metamaterial framework [7], where the masses correspond to degrees of freedom localized at each metamaterial site, and interaction potentials are constructed as geometric perturbations to the design. Although the original perturbative metamaterial work was only applicable to linear systems, we have developed a nonlinear coordinate transformation that allows for a similar principle to be applied to the design of nonlinear metamaterials. Finally, I will show some examples of experimental realizations of springtronic systems.

This work is supported by the ERC grant 101040117 (INFOPASS).

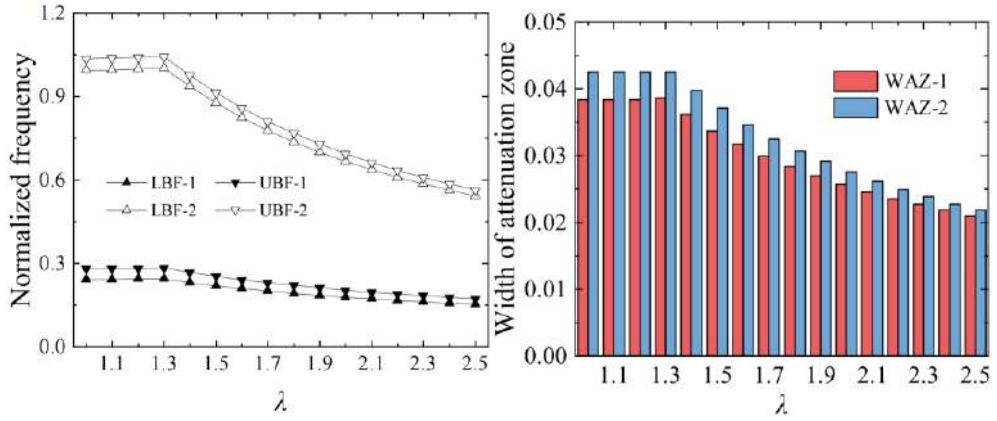
Abstract: Introducing the periodic structure theory developed in the field of solid-state physics into the field of civil engineering, this paper investigates the wave dispersion properties of frame-shear wall building structure, a typical structural system for high-rise building structure, through theoretical and numerical analysis.

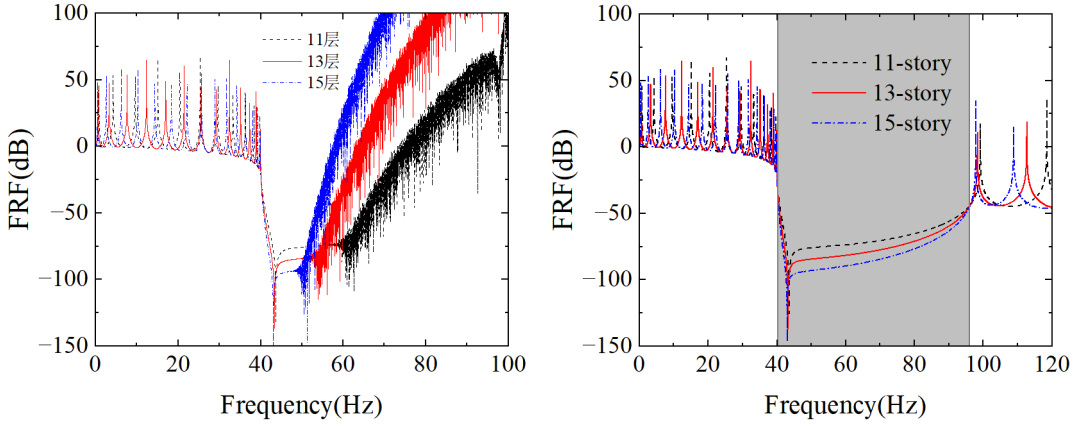
The frame-shear wall structure is widely recognized as a typical design for high-rise buildings. In the vertical direction, these structures can be seen as periodic systems created by the repetitive arrangement of standard floors. As a result, similar to phononic crystals, this periodic arrangement affects certain dispersion characteristics of frame-shear wall structures. Although many researchers have applied periodic structure theory to civil engineering, there is limited research specifically focused on high-rise building structures.



In this work, we first propose a theoretical infinite periodic model suitable for frame-shear wall structures. Using this model, we solve the dispersion equation of the infinite periodic system by combining the Bloch-Floquet theorem with the state space transfer matrix method (SSTMM). We investigate the dispersion curve of a reinforced concrete frame-shear wall building structure by solving the dispersion equation. It is important to note that the dispersion curve includes a region of complex solutions, which represents the attenuation domain, even though the wave vector in this region has a real component.

(a) (b)

Figure 1. Dispersion curve (a) X-Z plane (b) Y-Z plane.



Further, a parametric analysis is conducted on the influences of the anti-lateral stiffness, stiffness characteristic values, material parameters, theoretical simplified parameters and damping parameter of the frame-shear wall building structures on the dispersion properties.

(a) (b)

Figure 2. Stiffness characteristic values versus the first two attenuation zones (a) edge frequency (b) width.

A numerical analysis is conducted on the frame-shear wall structure. The results of the numerical analysis indicate that when the frequency of external excitation is within the passband, the dynamic response of the frame-shear wall structure will experience amplification. However, when the frequency of external excitation is within the attenuation zones, the dynamic response will significantly decrease.

Transforming room acoustics with causality-driven dual-function passive metamaterials

Abstract

A dual-function passive acoustic metamaterial is proposed that effectively balances absorption and diffusion within the same structure by leveraging causality principle.

1 Introduction

Most existing acoustic metamaterial solutions remain configuration-dependent, addressing either sound absorption or diffusion, but rarely both. Hybrid solutions attempting to integrate these functions have often been constrained by physical and spatial trade-offs, leading to suboptimal performance.

In this work, we adopt a causality-driven approach to design a Dual-Function Passive Acoustic Metamaterial (DFPAM) that optimizes both absorption and diffusion within a single structure.

2 Design principle

Absorption and diffusion of acoustic waves are contrastive effects as the former needs to dissipate the acoustic energy and the latter needs to scatter the waves with minimal dissipation. In the present case, we intend to use a strategy based on rigidly-backed slits loaded by an array of Helmholtz resonators as shown in Fig. 1(a).

By analyzing the sum rule given by the passivity/causality conditions of the acoustic system accounted for in this work, it is possible to evaluate the optimal value of the absorption-to-diffusion surface area ratio, $\phi_{\alpha|\delta}$, with a given target absorption spectrum. A depth of 12 cm is chosen in order to provide a solution that fits within dimensions similar to other metamaterial designs reported in the literature. It follows that $\min\left(\phi_{\alpha|\delta}\right) \approx 0.33$. Starting from a 3×3 square grid for the quarter of unit-cell with a combinatorial ratio of absorption cells to overall cells $\phi_\alpha = 1/3$, there are a total of 84 possible combinations. Due to mirror symmetries and further physical considerations regarding the choice of tesselation pattern and diffusion optimality, the rhombus depicted in Fig. 1(a) happens to be one of the best candidates available for sound diffusion. We finally make use of non-linear constrained minimization algorithms for maximizing both absorption and diffusion as well as determining their respective geometries. Figures 1(b-c) display the analytical, numerical and experimental sound diffusion and absorption coefficients obtained throughout this study. The DFPAM achieves high broadband sound absorption (<

$\alpha >\approx 0.85$) and diffusion ($< \delta >\approx 0.8$), covering more than one octave in each configuration. For more details, the reader can refer to [1].

Nonreciprocal Acoustic Wave Control with Field-Transforming Metasurface

Xinhua Wen[1*], Choonlae Cho[2], Xinghong Zhu[1], Namkyoo Park[2] and Jensen Li [1*]

Abstract: Manipulating nonreciprocal wave propagation using the transformation approach is highly desirable for important applications like nonreciprocal cloaking and sensing. However, the conventional framework of transformation optics based on coordinate transformation poses substantial challenges to practical experimental realization [1,2]. Field transformation, as an extension of the transformation optics, provides a possible means for nonreciprocal field manipulation [3]. Nonetheless, due to the stringent constraint on material parameters for this approach, the experimental realization of nonreciprocal field transformation is still elusive. Here we experimentally realize a field-transforming acoustic metasurface, which enables tailor-made field distribution manipulation and nonreciprocal wave control.

Field-transforming metasurface: Firstly, we discuss the design of the field-transforming acoustic metasurface. We start from the desired field distribution using a ring-shaped field-transforming metasurface with inner and outer radii R_1 and R_2, as illustrated in Fig. 1**A**. For an external incident wave outside the metasurface, the metasurface transforms the pressure field by a transformation function $f(\boldsymbol{r})$, resulting that the pressure field within the region enclosed by the metasurface (dark blue region) is amplified by a factor of $1+s$, i.e., $p(\boldsymbol{r}) = (1+s)p_0(\boldsymbol{r})$, where $p_0(\boldsymbol{r})$ represents the propagating pressure field in the background, and a positive s denotes field amplification. Outside the metasurface (cyan region), the pressure field remains unaffected, i.e. $p(\boldsymbol{r}) = p_0(\boldsymbol{r})$, by eliminating the scattered field outside the metasurface. To achieve such a field manipulation, we design a metasurface based on field transformation approach, in which the pressure and velocity fields are transformed by

$$p = f(r)p_0, \qquad v_{\mathrm{r}} = f(r)v_{\mathrm{r0}}, \qquad v_{\theta} = f(r)v_{\theta 0} \tag{1}$$

where v_{r} and v_{θ} are the radial and azimuthal components of the velocity field in the cylindrical coordinates (r,θ). $f(r)$ is a transformation function (only in terms) of r to relate the original (without the presence of the field-transforming metasurface) and the transformed fields. By substituting Eq. (1) into the acoustic wave equation and performing the necessary calculations, we can get the required compressibility and density $\beta = \rho = 1$ and the Willis couplings in the radius direction $\tau = \tau' = -f'(r)/\big(k_0 f(r)\big)$. By choosing a transformation function $\ln f(r)$ to be linear in r, nonreciprocal Willis coupling τ can be a constant value (facilitating the experimental implementation):

$$\tau = -\frac{f'(r)}{k_0 f(r)} = -\frac{\ln f_2 - \ln f_1}{k_0(R_2 - R_1)} \tag{2}$$

where $f_1 = f(R_1)$ and $f_2 = f(R_2)$ are different scaling factors at inner and outer boundaries, respectively. Therefore, the local field amplification ratio can be expressed as

$$f_1/f_2 = e^{\tau k_0 (R_2 - R_1)} = 1 + s \tag{3}$$

Therefore, a constant positive real nonreciprocal Willis coupling τ enables filed amplitude amplification, as illustrated in the lower panel in Fig.1 (**A**).

To implement the field-transforming metasurface with required material parameters, we use 24 active meta-atoms to construct the ring-shaped metasurface, as shown in Fig. 1(**B**). The active meta-atom (shown in Fig. 1(**C**)), enables to independently control all constitutive parameters by controlling the convolution kernels relating the microphones signals

(denoted as D_1, D_2) to speaker signals (denoted as S_1, S_2) [4]. Particularly, the meta-atom enables the realization of purely nonreciprocal Willis coupling, overcoming the limitations inherent in conventional metamaterials [5,6].

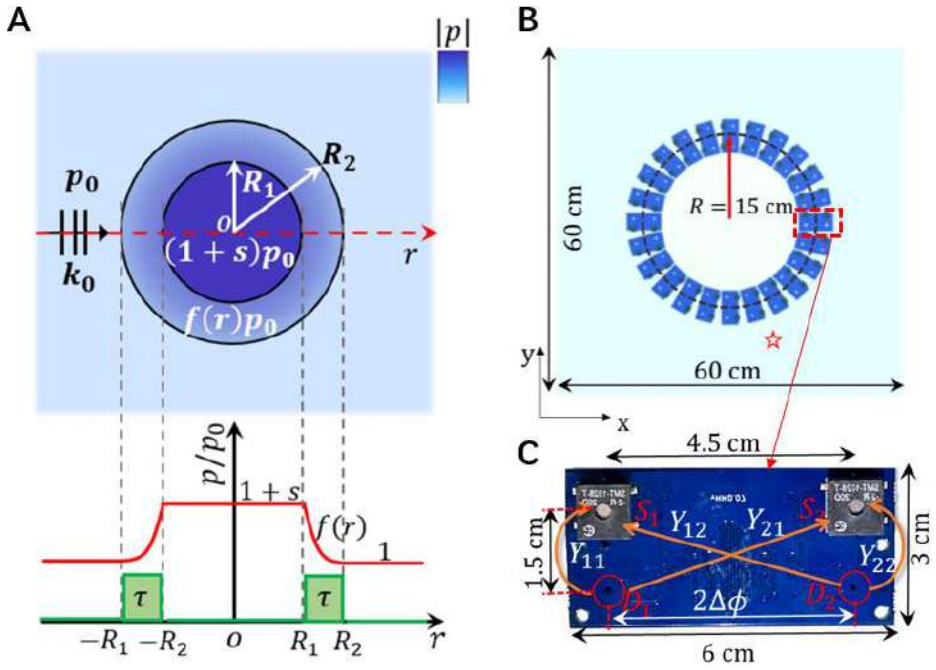

Figure 1: (**A**) Schematic of the localized field amplification by a ring-shaped metasurface with inner and outer radii R_1 and R_2 (upper panel). Lower panel: the line mapping of the pressure field along the red dashed line, in which the transformation function is associated with the Willis coupling τ (green line). (**B**) The constructed metasurface using 24 active meta-atoms. (**C**) A photograph of the meta-atom.

The field-transforming metasurface enables nonreciprocal wave manipulation. As shown in Fig. 2(**A**), when sound comes from outside at point source A, the metasurface increases the sound pressure inside by a factor of 1.5 times, but the sound pressure outside stays the same. On the other hand, when sound comes from inside at point source B, the sound pressure outside is reduced by the same factor, while the inside sound pressure stays the same (shown in Fig. 2(**B**)). Therefore, the active metasurface works like a one-way diode for sound now in two dimensions: people inside hear louder, amplified sounds coming from outside, but people outside hear quieter, attenuated sounds from inside. In addition, the metasurface demonstrates the self-adaptive capability, allowing to automatically adjust to different sound excitations without needing any changes to the metasurface itself.

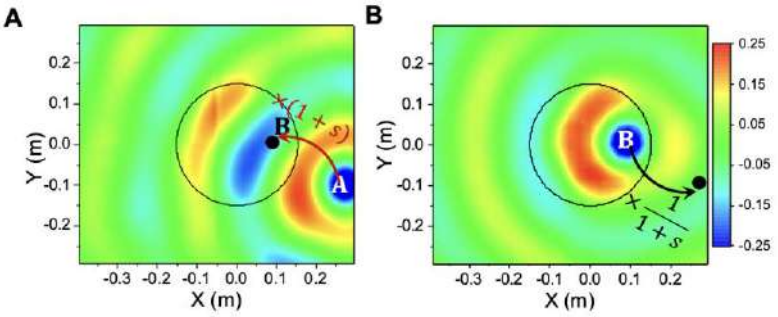

Figure 2: The measured field patterns for (**A**) an external excitation at location A and (**B**) an internal excitation at location B. The transmission wave for A → B (B → A) is scaled by a ratio of 1.5 (1/1.5). The experimental results presented herein exemplify a scenario of $s = 0.5$.

Conclusions: We have developed and demonstrated nonreciprocal field transformation in a 2D acoustic system. The field-transforming metasurface, constructed using active meta-atoms, enables tailor-made field manipulation and nonreciprocal wave control. The nonreciprocal field transformation significantly extends the framework of TO toward nonreciprocal wave manipulation, and is expected to trigger further design of nonreciprocal devices using transformation approaches, such as nonreciprocal cloaking.

Abstract: We perform momentum-resolved studies of acoustic phonons in an acoustoplasmonic metamaterial (APM) using Brillouin light scattering and finite-element-method calculations. The APM is a square lattice of nanoholes on a gold-covered SiO_2-on-Si wafer. For certain modes, the acoustic and plasmonic fields are localized in the nanoholes leading to plasmon-enhanced optomechanical interactions.

Various signal-processing operations require the transduction of electromagnetic waves (light) to mechanical vibrations (acoustic phonons) and vice versa. The transport properties of acoustic phonons can be controlled with the so-called phononic metamaterials[1]. For many modern applications, the acoustic phonons need to couple to electromagnetic radiation at optical frequencies[2]. Potentially, the coupling between acoustic phonons and optical radiation can be enhanced with plasmonic nanostructures[3]. The relevant artificial structures combining phononic and plasmonic functionalities are termed acoustoplasmonic metamaterials (APM). So far, the bulk of studies on plasmon-enhanced optomechanics were devoted to Surface Enhanced Raman Scattering (SERS), while recent works demonstrated plasmon-enhanced Brillouin Light Scattering (BLS) by acoustic vibrations in metallic nanoparticles[3]. Here, we explore the interactions of plasmons with propagating acoustic phonons in an APM structure using BLS spectroscopy and finite-element-method (FEM) calculations. Following a top-down approach, we prepared a square lattice of nanoholes on a gold-covered thermal-oxide-on-silicon wafer (30 nm Au / 300 nm SiO_2 / bulk Si).

The BLS measurements were performed in the backscattering geometry using two continuous wave (CW) lasers with wavelengths 532 nm or 660 nm. The angle of incidence (θ) of light is used to select the wavevector of the probed phonons parallel to the surface ($k_{\parallel}$) through the relationship: $k_{\parallel} = 4\pi \sin\theta / \lambda$. In this way, we recorded the phononic band structure, while the vibrational density of states (VDOS) was found by averaging the spectra for different $k_{\parallel}$-values. The obtained VDOS was of course modulated by the mode-dependent optomechanical coupling that gives rise to the BLS signal. In the presence of nanoholes, the Rayleigh and Sezawa modes of the homogenous flat film transformed into a rich phononic band structure. The distribution of the BLS intensity in reciprocal space varied strongly with the used wavelength of light (532 or 660 nm). On the one hand, the 532 nm radiation gave strong BLS for low-frequency modes (~2-4 GHz range) and revealed phenomena like avoided crossing and partial Bragg gaps. On the other hand, the 660 nm radiation gave the strongest BLS signal for high-frequency modes at ≥7 GHz. The photon-energy dependent optomechanical coupling strength is evident in the VDOS spectra of **Figure 1a**. The FEM calculations revealed that as the wavelength of light increases, the electromagnetic field is enhanced near the nanoholes (**Figure 1b**). The displacement fields and the elastic energy density of high-frequency modes (≥7 GHz) are also localized near the nanoholes (**Figure 1c**) leading to enhanced BLS signal for 660 nm light. Generally, the optomechanical interactions between photons (/plasmons) and acoustic phonons are mediated by two mechanisms: the photoelastic (PE) effect in the volume and the moving interface (MI) effect on the surface of materials[3]. The FEM calculations of the PE and MI effects were

used to visualize the coupling strength between plasmons and acoustic phonons in reciprocal space (**Figure 1d**). Our work paves the way for tailoring plasmon-enhanced optomechanics in the GHz range using acoustoplasmonic metamaterials and metasurfaces.

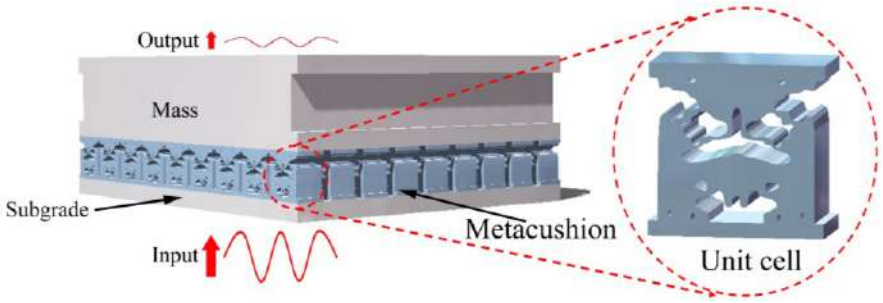
Customized inverse design of quasi-zero-stiffness metamaterials by topology optimization



Chao Ma1[1], Kun Wu2[1*]

[1]Tianjin University, China
[*]corresponding author: kunwu@tju.edu.cn

Abstract: This work presents an inverse design approach for metamaterials with customized quasi-zero-stiffness property. Finite element simulations and experiments are performed on the optimized topological configuration to validate the QZS feature. The proposed inverse-design methodology may pave a new way for low-frequency vibration isolation using compact single-phase solid structure without assembly.

This study develops an approach for inverse design of periodic QZS metacushion on the basis of topology optimization, as shown in Figure 1. The combination of coded modelling and finite element method is employed in iterative calculations so as to obtain periodic QZS metamaterials with objective static properties. Customized QZS metacushions with different porosity values and sizes are investigated on terms of weight and space arrangement, as shown respectively in Figure 2. In terms of dynamics, QZS metacushion exhibits excellent performance in low-frequency vibration isolation with confirmation by both experiments and simulations. The selection of payload has significant influence on the vibration responses which is necessary to approach the restoring force for a better performance of low-frequency vibration isolation.

Realization of Weyl elastic metamaterials with spin skyrmions

Yuang Pan[1], **Yihao Yang**[*]

[1]Zhejiang University, China

[2] Zhejiang University, China

[*]corresponding author: yangyihao@zju.edu.cn

Abstract: Topological elastic metamaterials provide a topologically robust way to manipulate the phononic energy and information beyond the conventional approaches. Among various topological elastic metamaterials, Weyl elastic metamaterials stand out. Here, we realize an ideal, 3D printed, all-metallic Weyl elastic metamaterial with low dissipation losses.

Topological elastic metamaterials provide a topologically robust way to manipulate the phononic energy and information beyond the conventional approaches. Among various topological elastic metamaterials, Weyl elastic metamaterials stand out, as they are unique to three dimensions and exhibit numerous intriguing phenomena and potential applications. To date, however, the realization of Weyl elastic metamaterials remains elusive, primarily due to the full-vectoral nature of elastic waves and the complicated couplings between polarizations, leading to complicated and tangled three-dimensional (3D) bandstructures that unfavorable for experimental demonstration. Here, we overcome the challenge and realize an ideal, 3D printed, all-metallic Weyl elastic metamaterial with low dissipation losses. Notably, the elastic spin of the excitations around the Weyl points exhibits skyrmion textures, a topologically stable structure in real space. Utilizing 3D laser vibrometry, we reveal the projection of the Weyl points, the Fermi arcs and the unique spin characteristics of the topological surface states. Our work extends the Weyl metamaterials to elastic waves and paves a topological way to robust manipulation of elastic waves in 3D space.

Numerical and Experimental Investigation of Multi-Stable Metastructures Endowed with Free-Standing Bistable Locally Resonant Unit Cells

Tugberk Guner[1*], Oreste S. Bursi[1] and Hasan N. Olmez [1]

[1]University of Trento, Dept. of Civil, Environmental and Mechanical Eng., Via Mesiano, 38123, Trento, Italy

Abstract

We have conceived new multi-stable metastructures endowed with free-standing bistable locally resonant unit cells for passive vibration attenuation. Notably, bistability is introduced into each main cell, using novel slender pre-buckled beams. It is demonstrated how the presence of resonators can enhance the elastodynamic response of metastructures both numerically and experimentally.

1. Introduction

Multi-stable systems exhibit rich static and dynamic behaviours, driven by transitions between discrete equilibrium states [1]. This results in rich dynamics and underscores the importance of further research to harness their potential. A frequently studied category of multi-stable systems, bistability is attracting attention, due to the potential revealed by recent research [2]. The rich and advantageous functionalities inherent in bistable mechanisms make them viable candidates for applications spanning diverse fields such as engineering, physics, biology, materials science, and beyond [3]. Bistable mechanisms are increasingly used in vibration and impact protection devices such as isolators [4] and structural dampers [5]. In energy harvesting, bistability enhances power output by leveraging large-amplitude, high-velocity snap-through motions and generating subharmonic responses, thus overcoming the limitations of resonance-based systems [6; 7].

Recent advances have also integrated bistability into metamaterials, giving rise to novel functionalities such as chirality [8], deployability [9], foldability [10], and so on. More specifically, [11], investigated the dynamics of the locally resonant (LR) metamaterial beam with bistable attachments and produced an attenuation frequency range that is 350% wider than the corresponding linear LR bandgap. Several studies have investigated the nonlinear dynamics of 1D bistable lattices. Nadkarni et al. [12] analyzed snap-through instabilities and provided closed-form analytical solutions. Frazier et al. [13] demonstrated supratransmission with dual amplitude thresholds, enabling energy transmission through band gaps. Deng et al. [14] explored the behaviour of transition waves considering the nearest-neighbour spring interactions. A simple and effective way to realize multi-stable systems is by connecting bistable springs in series. This concept underlies free-standing bistable lattices, where unit cells are interconnected through bistable elements, forming a multi-stable metastructure (Fig. 1). These lattices have been shown to either trap input energy or transmit it as solitary waves, depending on the system's dynamic response [15]. Advances in additive manufacturing have further enabled the rapid and precise fabrication of such complex metastructures, facilitating experimental validation. Based upon the gap in the literature, this study undertakes a numerical and experimental investigation of multi-stable 1D metastructures made up of locally resonant bistable unit cells. Notably, bistability is introduced into the main springs as elastodynamic slender beams under buckling, as illustrated in Fig. 1. Consequently, metastructures consisting of six cells were experimentally tested and compared against numerical results.

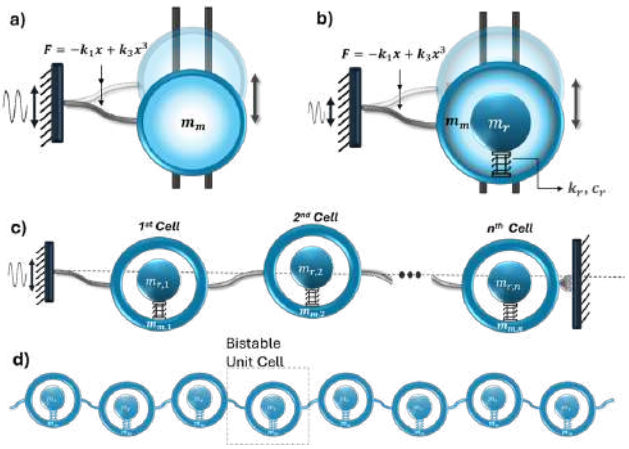

Figure 1: A bistable oscillator (a) standalone, (b) coupled with a resonator, (c) a multistable metastructure composed of locally resonant unit cells (MLRM), (d) metamaterial made up of locally resonant bistable unit cells (BLRM)

2. Dynamics of Bistable LR Metamaterials

In basics, metamaterials can be constructed by arranging unit cells in a repeating pattern; importantly, their properties are also influenced by their designed structure. Accordingly, herein, two metamaterials that were made of a periodic arrangement of: (i) bistable oscillators; and (ii) bistable oscillators coupled with linear resonators were examined. Respectively, these metastructures are called bistable metamaterials (BM) and bistable locally resonant metamaterials (BLRM). Here, the locally resonant (LR) property governs from the anti-resonance of attached resonators in a periodic medium. The schematic representations of these metamaterials are given in Fig. 1(d), where i represents the i-th cell in the lattice. The non-dimensionalised EoMs of the i-th cell of the BLRM can be written as follows:

$$\begin{aligned}&\hat{x}''_{m,n}+\eta(2\hat{x}'_{m,n} \in \hat{x}'_{m,n-1} \in \hat{x}'_{m,n+1})\\ &\quad \in (2\hat{x}_{m,n} \in \hat{x}_{m,n-1} \in \hat{x}_{m,n+1})\\ &\quad +\varepsilon(\hat{x}_{m,n} \in \hat{x}_{m,n-1})^3+\varepsilon(\hat{x}_{m,n} \in \hat{x}_{m,n+1})^3 \quad (1a)\\ &\quad +\varphi\eta_r(\hat{x}'_{m,n} \in \hat{x}'_{r,n})+\varphi\lambda^2(\hat{x}_{m,n} \in \hat{x}_{r,n})\\ &\quad =f_{ext}(\alpha,\Omega,\tau)\\ &\hat{x}''_{r,n}+\eta_{r,n}(\hat{x}'_{r,n} \in \hat{x}'_{m,n})+\lambda^2(\hat{x}_{r,n} \in \hat{x}_{m,n})=0 \quad (1b)\end{aligned}$$

where $\hat{x}=x/\delta_s$, $\tau=t\omega_n$, $\omega_n=\sqrt{k_1/m_m}$, $\eta=c(m_m\omega_n)^{-1}$, $\varepsilon=k_3\delta_s^2(m_m\omega_n^2)^{-1}$, $\Omega=\omega_0/\omega_n$, $\alpha=A_0/\delta_s$, $\eta_r=c_r(m_r\omega_n)^{-1}$, $\omega_r=\sqrt{k_r/m_r}=\lambda\omega_n$ and $m_r=m_m\varphi$

The dispersion relation and wave solutions of the system can be obtained analytically or numerically under the assumption of periodic response. However, as highlighted by Van Belle [16] and Aloschi et al. [17], the presence of damping introduces amplitude-dependent effects due to nonlinearity, causing the dispersion characteristics of each unit cell to differ. This variation breaks the fundamental assumption of uniform periodicity required by Floquet-Bloch theory. Despite numerical methods remaining effective in approximating *band-gap-like behaviours* and capturing key wave propagation characteristics. Following the methodology of [18], a BLRM composed of 500 bistable unit cells was modelled, with an additional 1000 perfectly matched layer (PML) cells at the free end to eliminate reflections. The system was subjected to sinusoidal excitation with varying amplitudes ($0<\alpha<5$) and frequencies up to 3Ω. Each simulation was run for 500 seconds to ensure steady-state behaviour, with a smooth ramp-up over the first 20 seconds to suppress transient impact effects. The resulting wave field was analysed using a 2D Fast Fourier Transform (FFT), and the dispersion characteristics are shown in Fig. 2. In Fig. 2, it is evident that at each frequency, a peak point emerges, corresponding to the wavenumber

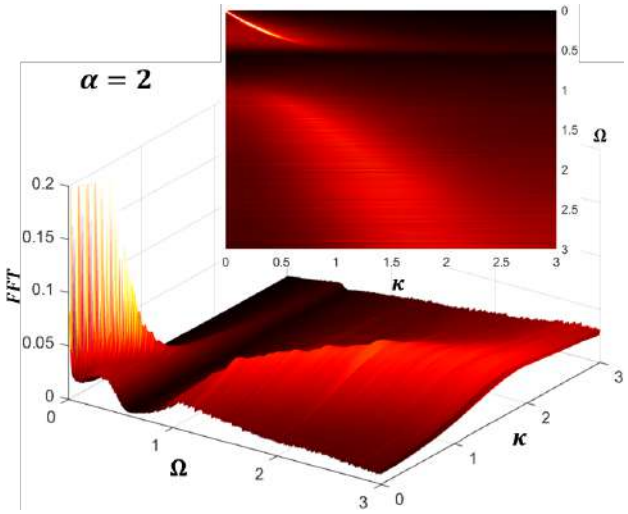

Figure 2: Frequency–wavenumber relation obtained using 2D Fast Fourier Transform (FFT) for $\alpha=1.0$.

of the predominant wave propagating through the chain. Consequently, at each frequency, the peak can be isolated, and the dispersion relation can be plotted. For comparison, the results of the BM were also examined and plotted alongside the BLRM results in Fig. 3. Moreover, as illustrated in Fig. 4, the wave amplitude varies across the cells of the BLRM. When the input amplitude α is small, the long-wavelength waves propagate over a longer distance, reaching up to the 100th cell. In contrast, for higher input amplitudes, wave attenuation becomes significant, with noticeable energy confinement within the first 10 cells. At high amplitudes and shorter wavelengths, the initial cells exhibit higher displacement ratios, followed by a rapid decay, indicating that the wave energy is effectively trapped within the first few cells.

3. Dynamics of Multi-stable Metastructures

In practical applications of low-frequency metamaterials, implementing structures with as many as 500 unit cells is often infeasible due to physical size and spatial limitations. The experimental study presented in the following sections demonstrates that even assembling six cells posed significant challenges. Consequently, this research also focusses on finite lattice metastructures with a limited number of cells, where periodicity is inherently constrained and boundary effects, such as wave reflections, must be carefully considered.

To investigate these effects, numerical simulations were conducted on finite BM and BLRM, composed of 3, 6, and 9 unit cells. These correspond to multi-stable metastructures (MM) and their locally resonant counterparts

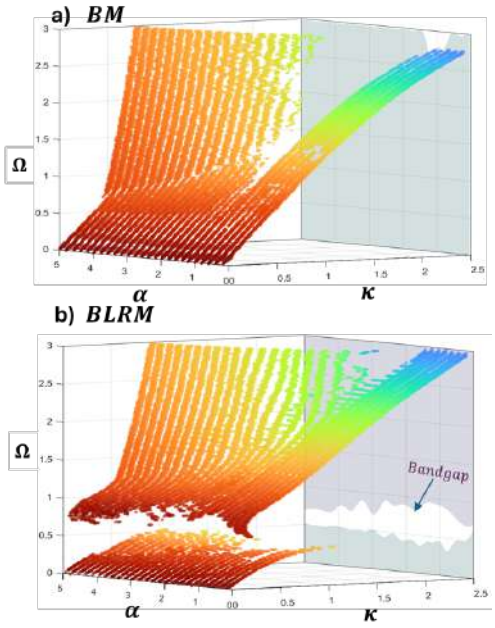

Figure 3: Dispersion relations obtained for varying input amplitudes, highlighting the influence of excitation magnitude on wave propagation characteristics.

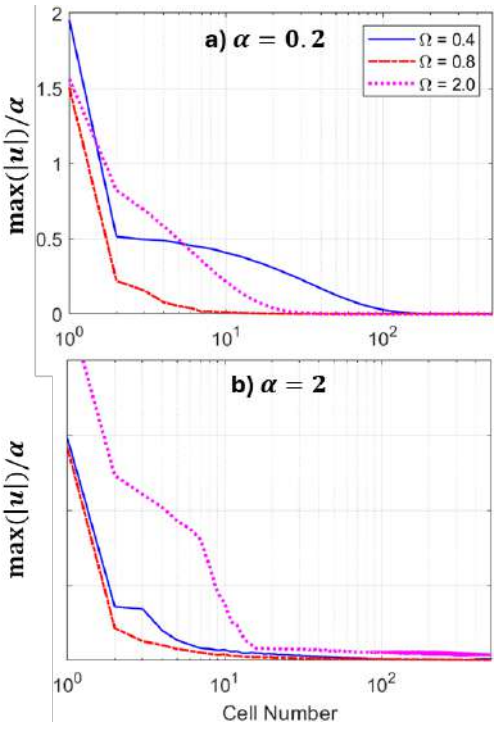

Figure 4: Variation of peak steady-state displacement amplitudes across the unit cells of the BLRM under sinusoidal excitation with amplitude: (a) $\alpha = 0.2$ and (b) $\alpha = 2.0$

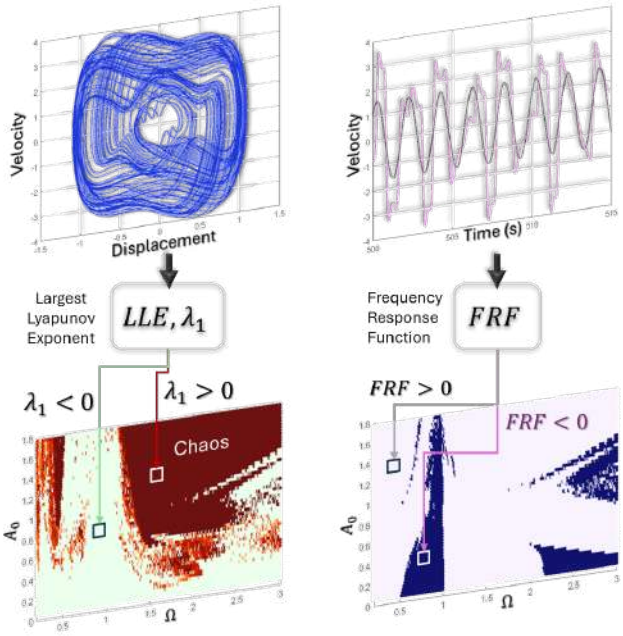

Figure 5: Numerical tools adopted and typical outcomes to characterise the response of MMs and MLRMs

(MLRM), respectively. The analysis methodology is illustrated in Fig. 5. Specifically, regions of chaotic response were identified using Lyapunov exponent analysis, with the largest Lyapunov exponent (LLE) computed via the algorithm proposed by Rosenstein et al.[19]. Additionally, the frequency response function (FRF) was calculated as:

$$FRF(\omega_0) = 20log_{10}\left(\frac{max|\dot{x}_{out}|}{max|\dot{x}_{in}|}\right) \tag{2}$$

where velocities are used instead of displacements, as they are more reliable in capturing inter-well motions. The FRF characterises the regions of amplification (FRF > 0) or attenuation (FRF < 0). Simulations were performed for a range of input amplitudes $\alpha \leq 3$ and excitation frequencies, i.e. $\Omega \leq 3$.

For MMs, as shown in Fig. 6, increasing the number of cells enhances the presence of chaotic behavior, particularly in the low-amplitude regime. However, more cells also extend the range of amplitude and frequency where attenuation occurs. In contrast, the behavior of MLRMs, depicted in Fig. 7, reveals the influence of local resonances. As the number of cells increases, the band gap widens, suppressing chaotic responses not only within the attenuation band but also in surrounding propagation zones. Furthermore, larger cell counts allow for attenuation of higher-amplitude excitations.

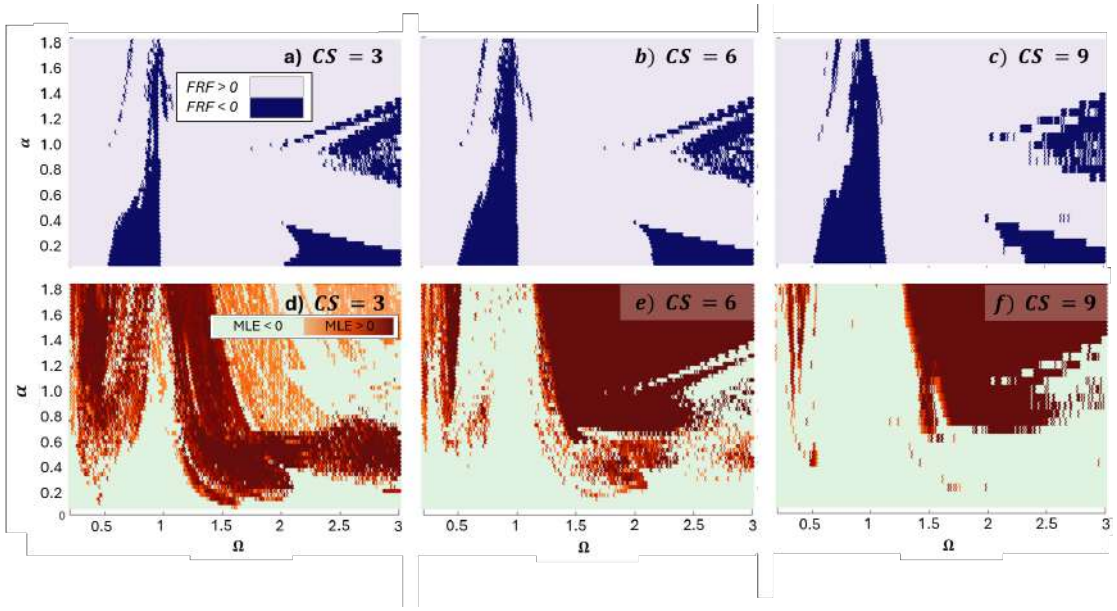

Figure 7: The effect of increasing the number of cells in the MLRM. The top row presents attenuation/propagation zones, whilst the bottom row presents chaotic behaviour.

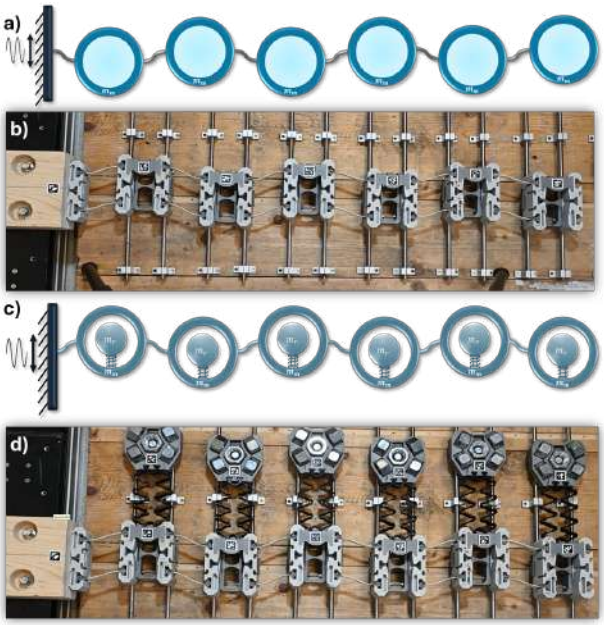

Figure 8: MM and MLRM configurations with six unit cells: (a, c) equivalent spring–mass–damper models; (b, d) corresponding realizations using 3D-printed experimental setups.

Table 1: Properties of materials used for 3D FFF printing

Material	Components	Density kg/m^3	Elastic Modulus MPa	Tensile Strength MPa
ABS+PC	Main beams	1.02	2100	40
TPU	Res. beams	1.16	150	50
ABS	Others	1.10	2030	43.6

4. Experimental Setup and Unit Cell Design

For the experiment, six cell MM and MLRM were created using bistable unit cells as depicted in Fig. 8. The input was provided as a driven boundary that is given a compact shake table with a maximum velocity of 0.5m/s and 2g under 50 kgf payload. Overall, in connection with previous studies, the objective was to create a metastructure aiming band gap in the low-frequency range, i.e. 1-5 Hz, also within the limits of the shake table. Consequently, the unit cells were manufactured using, Fused Filament Fabrication (FFF) 3D printing. As a result, commonly available filaments, such as ABS, TPU, were used, and their technical details provided by the manufacturer are given in the Table 1.

A schematic illustrating the correspondence between the LR unit cell and its 3D-printable counterpart is shown in Fig. 9. In this design, beams subjected to shear are modelled as spring-damper elements. When unloaded axially, these beams behave as mono-stable spring-dampers, with damping arising from internal deformation and material viscosity. However, when an axial load exceeding the critical buckling threshold is applied, the beams buckle (Fig. 10), and their lateral force–displacement behaviour exhibits bistability. This enables the creation of simple, easily manufactured bistable springs. To ensure repeatable performance, the beam ends were designed with rotational constraints and each unit cell was guided by circular aluminium rails.

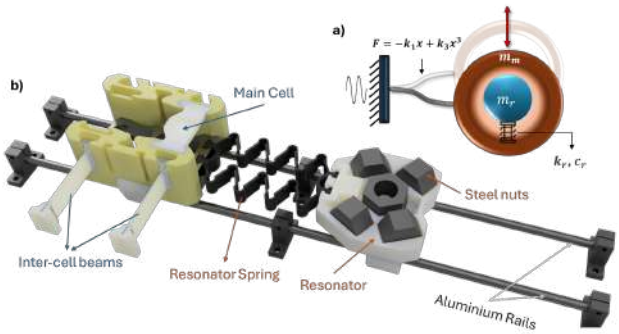

Figure 9: Schematic of the unit cell design and its equivalent spring–mass–damper model.

For experimental data acquisition, Digital Image Correlation (DIC) was employed. High-speed videos (1920×1080 pixels at 120 fps) were captured and processed in MATLAB. Multi-object tracking was achieved using AprilTags [20].

5. Experimental Results

Six-cell MM and MLRM configurations were initially analyzed through separate frequency sweeps with two input amplitudes: $A_0 = 8\,\text{mm}$ with ω ranging from 0 to 10 Hz, and $A_0 = 15\,\text{mm}$ with ω_0 spanning from 0 to 5 Hz. The displacement responses of the cell farthest from the shake table are illustrated in Fig. 11. For both scenarios, the attenuation effect caused by the locally resonant resonators is notably apparent. Under low-amplitude input, MM exhibited propagation peaks at 2.5 Hz and 8.4 Hz, with noticeable attenuation between the 4.3-7 Hz range. In contrast, MLRM showed a complete attenuation range starting from 0 Hz and extending up to 8.5 Hz. With $A_0 = 15\,\text{mm}$, MM displayed an aperiodic response with a pronounced amplification at 1 Hz, whereas MLRM's response remained below 10 mm and non-chaotic throughout the range considered, validating the numerical predictions.

For a more detailed examination, Fig. 12 displays the displacement responses of the MLRM resonators under the condition of $A_0 = 15\,\text{mm}$. The greatest displacement was

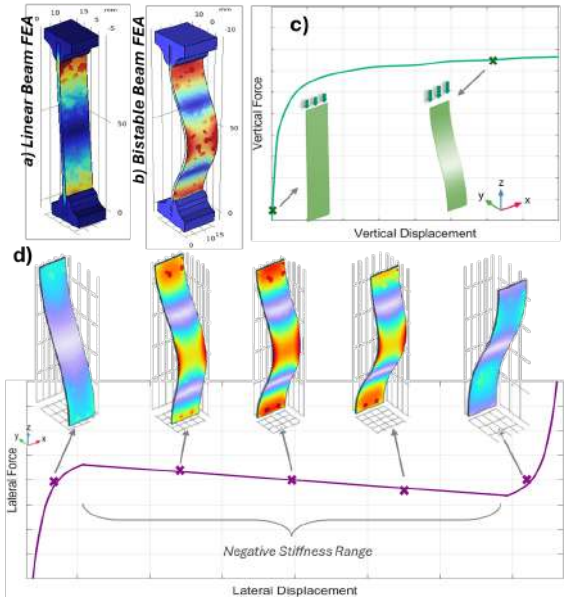

Figure 10: Stress distribution in a beam under axial load; (a) below and (b) exceeding the critical buckling load; (c) vertical force–vertical displacement response; (d) lateral force–displacement response under sustained axial load greater than the critical buckling load.

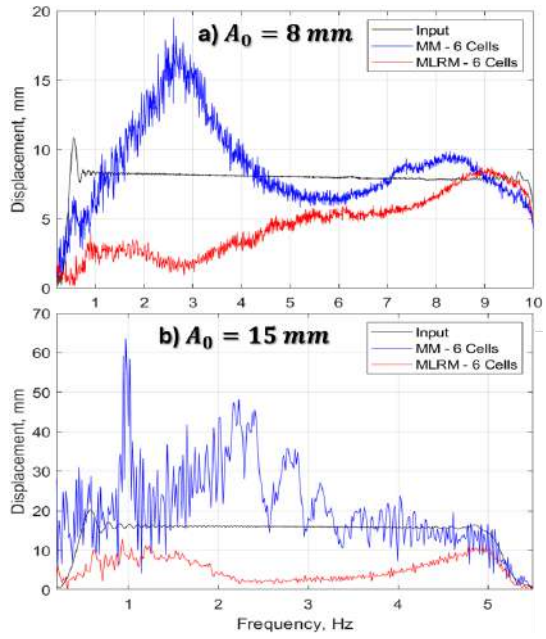

Figure 11: Six-cell MM and MLRM tested for frequency sweeps with: (a) $A_0 = 8\,\text{mm}, \omega = 0 \in 10Hz$, and (b)$A_0 = 15\,\text{mm}, \omega_0 = 0 \in 5Hz$. The displacement responses of the cells farthest from the shake table are presented.

found in the resonator nearest to the input source, namely the shake table, occurring at 2.2 Hz. As the distance from the input increases, both the displacement and the resonant frequency of the resonators diminish. Notably, the resonator furthest from the input showed an equivalent displacement to that of the main mass. Finally, configurations with three cells and six cells were evaluated under a high input amplitude of $A_0 = 20\,\text{mm}$, with the results presented in Fig. 13. For MMs, using fewer cells led to an aperiodic amplified response within the 1-2.5 Hz range, followed by an attenuation zone beyond 2.6 Hz. With a six-cell setup, the amplified response was diminished, but the attenuation zone also vanished. In the case of MLRMs, a three-cell configuration produced chaotic responses below the 1 Hz range, which is beyond the resonators' operating range. With six cells, there was a marked reduction in performance above 1 Hz. Thus, in MLRMs, increasing the number of cells improved dynamic responses and enhanced vibration isolation. However, when the number of cells is restricted, it is essential to focus on the lower frequency ranges and non-periodic reactions. Displacement responses of the MLRM resonators. The MRLM is subjected to frequency sweep with $A_0 = 15\,\text{mm}$

6. Conclusions and Future Perspectives

This study investigated the dynamic behaviour of periodic metamaterials composed of bistable locally resonant unit cells, BLRM, and finite lattice metastructures, specifically multi-stable metastructures (MM) and their locally resonant counterparts (MLRM) with a limited number of unit cells. Through numerical simulations, the propagation characteristics of the waves in the BLRMs were investigated. In finite MM and MLRMs, using Lyapunov exponent analysis and frequency response functions, we identified regions of chaotic response and assessed the influence of unit cell count and excitation amplitude. Experimental results demonstrate that increasing the number of unit cells generally enhances vibration attenuation and reduces chaotic behaviour, particularly in MLRMs, as a result of the widening of the locally resonant band gap. MMs, while capable of attenuation, were more prone to chaotic amplification under high excitation. MLRMs exhibited superior performance in mitigating vibrations in a broader frequency range, even with high input amplitudes. However, when constrained to fewer cells, MLRMs showed sensitivity to excitation frequencies outside the resonator's effective range, resulting in diminished isolation capability.

These findings emphasise the importance of finite boundaries, unit cell count, input amplitude, and frequency in the design of finite nonlinear metastructures, especially when aiming for robust performance in compact systems. Future work may focus on optimising the placement and

tuning strategies of the resonator with varying frequencies to further improve energy absorption in short, finite configurations.

Multimode phonon lasing in a self-modulated silicon optomechanical crystal cavity

Abstract: We theoretically and experimentally investigate an optically self-modulated multimode optomechanical platform. The self-induced modulation adapts to optomechanical feedback from multiple modes, enabling synchronous pumping and driving them into high-amplitude coherent mechanical motion despite strong mode competition. These findings advance the generation of multi-phonon coherent sources in chip-integrated silicon platforms.

Cavity optomechanics [1] has enabled the realization of coherent phonon sources ("phonon lasers"), but extending this phenomenon to multimode systems remains challenging due to mode competition, which typically suppresses simultaneous oscillations in multiple mechanical modes [2]. Previous approaches rely on externally modulated laser inputs to induce parametric coupling [3] or use widely separated mechanical frequencies to mitigate competition [4], both of which constrain scalability and integration.

Here, we experimentally demonstrate a stable multimode phonon lasing regime in a silicon nanobeam optomechanical cavity, where two flexural mechanical modes achieve high-amplitude, self-sustained oscillations despite strong mode competition.

Using a simple setup (Fig. 1a), we characterize the optical (Fig. 1b) and mechanical (Fig. 1c) modes of the structure. Under strong blue-detuned optical drives (sweeping from lower to higher laser wavelengths), the interplay between thermo-optic (TO) and free-carrier dispersion (FCD) effects induces cyclic modulation of the refractive index (Fig. 1d), known as self-pulsing (SP). This SP cycle [5] features a tunable repetition rate in the 10–100 MHz range, where several flexural modes of the nanobeam exhibit large optomechanical coupling.

Counterintuitively, we demonstrate that the adaptive capabilities of SP enable simultaneous, synchronous, radiation-pressure-driven amplification of oscillations in two strongly competing mechanical modes. This adaptation persists even when the mechanical frequencies are incommensurable, leading to transitions between periodic (Fig. 1e), quasi-periodic (Fig. 1f), and chaotic intra-cavity power dynamics, while maintaining coherent, high-amplitude mechanical oscillations.

Supported by a predictive macroscopic model, these findings provide a novel strategy for engineering coherent multimode phonon sources and pave the way for optomechanical frequency comb generation with low repetition rates and advanced nonlinear phononic systems.

A reconfigurable coding acoustic metasurface based on coiling units

Jie Hu *, Hao Zhou, Haoxiang Li

Nanjing Forestry University, China
*corresponding author: hujie@njfu.edu.cn

Abstract: In this paper we design a reconfigurable coding metasurface comprising two types of encoding coiling units that can manipulates the acoustic waves arbitrarily over a certain frequency. The multi-functional performance of our scheme is numerically verified via the demonstration of two distinctive examples of beam splitting and acoustic focusing.

The key to constructing a binary encoding metasurface lies in selecting two coding units with a consistent transmission amplitude and a relative phase difference of π. To achieve this, we employ a coiling unit that effectively manipulates the phase modulation of acoustic waves. Through the adjustment of the internal crossbars, the output acoustic phase difference of units changes by π and the units can be encoded as "0" and "1" in digital format. Figure 1(a, b) illustrates a schematic of the 1-bit encoding units representing "1" and "0", allowing for various functionalities through the combination of these units. Here we select 2 kHz as the operational frequency, and the relationship between the unit phase and the length of the movable crossbar is plotted in Fig. 1(c). The length *l* of "0" and "1" coding units are chosen as 7 mm and 19 mm respectively to ensure the phase and amplitude requirements for the "0" and "1" units being simultaneously satisfied at 2kHz.

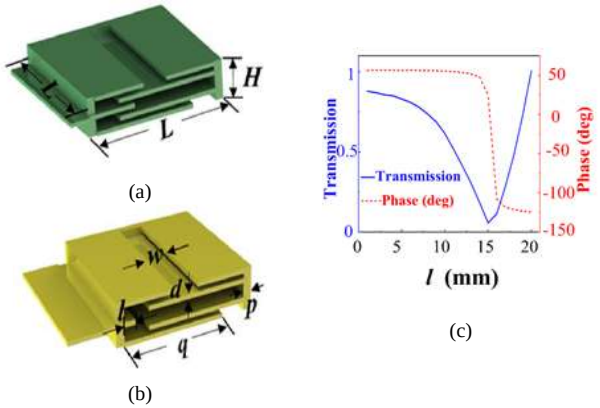

Figure 1 Schematic diagram of "1" coding unit (a) and "0" coding unit(b); (c) Relationship between unit phase, amplitude, and movable plate *l* at a frequency of 2 kHz

In this study, we exhibit two examples to verify the outstanding performance of multi-functional manipulation of our structure: beam splitting and acoustic focusing.

When incident plane waves penetrate perpendicularly into a programmable metasurface composed of *M*×*N* "0" or "1" units, the far-field function can be expressed as follows[1]:

$$f(\theta,\beta)=f_e(\theta,\beta)\sum_{m=1}^{M}\sum_{n=1}^{N}\exp\left\{-i\left\{\varphi(m,n)+kL\sin\theta\left[\left(m-\frac{1}{2}\right)\cos\beta+\left(n-\frac{1}{2}\right)\sin\beta\right]\right\}\right\} \quad (1)$$

where θ and β are the elevation and azimuth angles, respectively, and $f_e(\theta, \beta)$ is the pattern function of a unit; k is the wave number; $\varphi(m, n)$ is the scattering phase of the unit at (m, n), which is either 0 or π. From Eq. (1), it can be concluded how to achieve maximum scattering in different directions by adjusting θ and β.

For simplicity but without losing generality, we construct a programmable metasurface using a 2×2 units configuration for illustration purpose. Simulations are conducted at 2kHz to investigate the beamforming effect with single beam, binary beam and quad-beam in the transmitted field.

Additionally, we conduct further research by utilizing 12 tunable units to create a reconfigurable acoustic encoding lens which not only demonstrates excellent focusing capabilities but also allows for arbitrary control of the focal point's position.

The diagram of our design and simulation results of beam splitting with different encoding sequences are shown in Figs. 2(a-c). Figs. 2(d) illustrates the principle of adjustable acoustic focusing via acoustic waves passing through the encoded metasurface lens and Figs. 2(e) display the focusing performance at different spots.

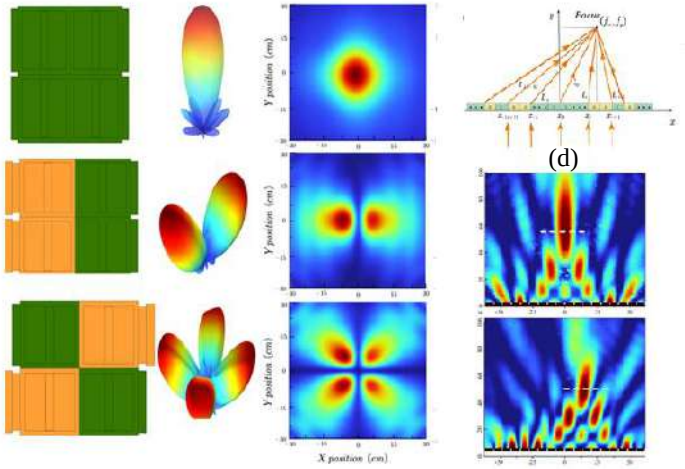

Figure 2. (a) diagram of the 2×2 structure with different arrangement 00/00, 01/01, 01/10. (b)3D structure and far-field sound pressure distribution of the 00/00, 01/01, 01/10 coded metasurface, respectively. (c) Simulation of the sound pressure distribution with 00/00, 01/01, 01/10 coded metasurface, respectively. (d) Schematic diagram of tunable focusing. (e) Simulated acoustic pressure distribution with arbitrary focusing

Here we design a reconfigurable coding acoustic metasurface that comprises the minimized types of building blocks with compactness and manipulates the transmitting waves arbitrarily. In our design, each individual unit cell of metasurface has a coiled configuration that can be divided into two types of encoding units: 0 and 1. The multi-functional performance of our scheme is numerically verified via the demonstration of beam splitting and acoustic focusing. The simulated results agree well with the theoretical predictions, showing the designed coding metasurface efficiently and flexibly manipulates the wavefront of the outcoming waves to form the desired specific patterns. With advantages in terms of easy fabrication, ultrathin thickness, our design opens route to the design of novel acoustic functional devices based on active space-coiling metasurfaces and holds significant application potential in diverse fields such as acoustic imaging and communication, etc.

Abstract: We experimentally demonstrate unconventional oriented Landau levels in acoustic Berry dipole systems, wherein by reversing the orientation of the pseudomagnetic field, the system exhibits distinct Landau spectra. Remarkably, we observe a new type of helical zero modes whose existence critically depends on the magnetic field's orientation.

Band crossing plays an important role in condensed matter theory, serving as the origin for various topological semimetals and insulators [1,2]. A well-known example is Weyl point, which can be regarded as a source or sink of Berry curvature field in the momentum space, characterized by integer Chern numbers [3–7]. When a magnetic field couples with a Weyl point, resulting in isotropic discrete Landau levels independent of the orientation of the magnetic field and a chiral zero mode unidirectionally propagating along the direction of the magnetic field [8–11].

Very recently, band crossing beyond the above paradigm was predicted and studied theoretically [12-14]. These band crossing points, referred to as “Berry dipoles”, carry a dipolar Berry curvature field, resulting in zero Chern number but nonzero Berry dipole moment. Interestingly, it was recently proposed that oriented Landau levels are formed when a Berry dipole is subject to an external magnetic field [15-17].

In this work, we experimentally realize oriented Landau levels and helical zero modes in Berry dipole semimetals constructed by engineering an inhomogeneous acoustic crystal to introduce pseudomagnetic fields. We demonstrate dramatically different Landau level spectra when the pseudomagnetic field is parallel or antiparallel to the Berry dipole moment. Specifically, when the pseudomagnetic field is parallel to the Berry dipole moment, there exist a pair of helical zero modes propagating respectively along and opposite to the pseudomagnetic field. Remarkably, the helical zero modes vanish and Landau levels are gapped when the pseudomagnetic field is reversed. Our work offers a platform to study topological matter beyond Chern class, such as Berry multipoles, four-dimensional tensor monopoles.

Abstract: We propose and experimentally validate the concept of a vibroacoustic metasurface to enhance sound transmission across the water-air interface. Furthermore, we explore the potential application of encapsulating airborne loudspeakers with optimized vibroacoustic metasurfaces to function as sound sources underwater.

Modulation of waves for cross-media transmission has garnered widespread attention due to its extensive applications in various engineering fields [1]. However, the transmission efficiency at the interface is rather low due to impedance mismatch between different media. A prominent example is the transmission of sound through the water-air interface [2]. Given the substantial contrast in acoustic impedance (approximately 3600 times), only 0.1% of sound energy naturally propagates between water and air [3]. Here, we propose a vibroacoustic metasurface to enhance water-to-air sound transmission and further explore its potential applications [4].

The photograph of the fabricated sample of vibroacoustic metasurface with a partially enlarged view of the cross-section is shown in Figure 1A. By taking advantage of fluid-solid interaction, specific vibration modes are induced for the inverse-design solid metasurface. Figure 1B plots the measured transmission enhancement of the sample varying with frequency compared with the bare water-air interface. It can be observed that the sample exhibits above 20 dB (ten times) amplitude enhancement from 9.84 to 11.53 kHz. The measured peak frequency is found to be around 10.45 kHz with approximately 25.9 dB (nearly 20 times) transmission enhancement, close to the perfect transmission of 30 dB. The measured time-domain sound signals at a test point are presented in Figure 1C. The sharp contrast between sound pressure amplitudes transmitted by the sample and the bare water-air interface further confirms the excellent performance of the sample of vibroacoustic metasurface for sound transmission enhancement through the water-air interface.

In addition, we measure the sound pressure fields transmitted through the sample and bare water–air interface at the peak frequency, as shown in Figure 1D and 1E, respectively. It can be clearly observed that the sound waves emitted from underwater transducer are converted into uniform plane waves after passing through the sample, and the transmission amplitudes through the sample over the entire measurement area are greatly improved compared to the bare water-air interface.

To reveal the mechanism of enhanced sound transmission, we performed the vibration test for the fabricated sample. Figure 1F shows the experimental setup. The normal displacement component was measured by using the PSV scanning vibrometer. Figure 1G presents the measured vibrations of sample at different frequencies, and the corresponding simulated results of a single unit cell are given for comparison. Vibrations at the notch are more pronounced than on both sides when the frequency is close to the peak one. An anti-phase vibration mode is clearly observed. In contrast, when the incident frequency is away from the peak one, the collaborative vibration at the notch becomes unapparent. The enhanced water-to-air sound transmission is mainly attributed to the unique flexural vibrations of the solid unit cell, which gives rise to the required sound impedance by inducing compression and expansion of the inner air cavity. More details can be seen in reference [4].

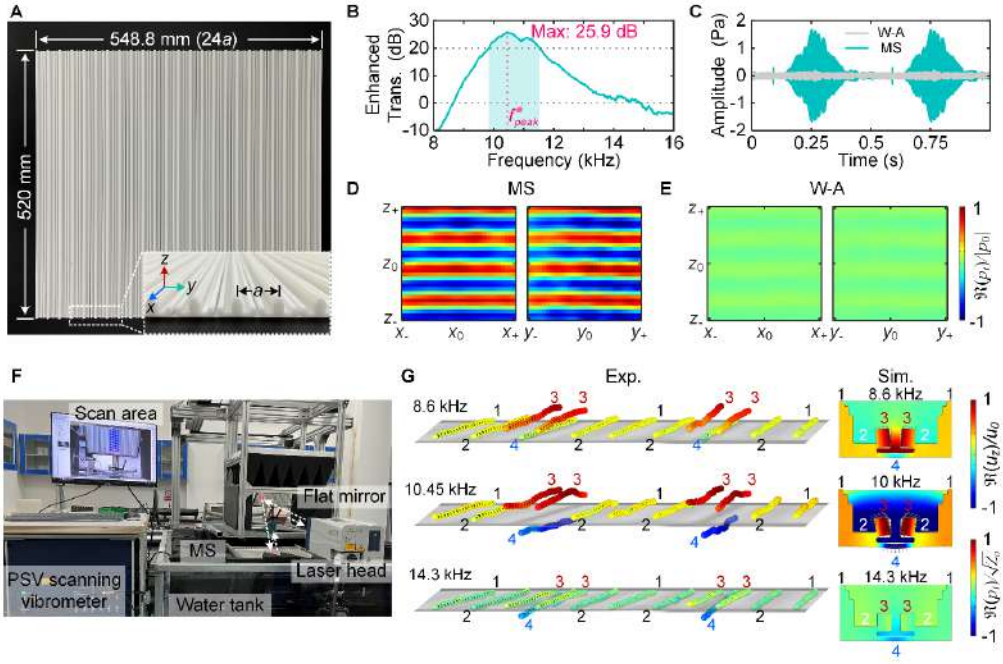

Figure 1: Vibroacoustic metasurface for sound transmission enhancement through the water-air interface [4]. (A) Photograph of sample of vibroacoustic metasurface. (B) Measured sound amplitude enhancement (dB) of sample compared to the bare water–air interface. (C) Measured time-domain sound signals from water to air through the sample and water–air interface. (D) Measured real parts of transmitted sound fields through the sample and (E) water–air interface. (F) Photograph of the experimental set-up for vibration measurements of sample. (G) Measured vibration at different locations of sample for different frequencies, and the corresponding simulated results are given for comparison.

Furthermore, we explore the application scenario by encapsulating airborne loudspeakers with optimized vibroacoustic metasurfaces, using them as a sound source underwater. In this configuration, the vibroacoustic metasurfaces function as a sealed shell, enclosing the airborne loudspeakers inside. Numerical simulations were conducted to evaluate the air-to-water sound transmission performance. The results show that the designed sound source significantly outperforms a solid cavity without the metasurface in terms of sound emission. Furthermore, effective air-to-water transmission was maintained, even when accounting for solid viscosity losses. Overall, the proposed vibroacoustic metasurfaces not only opens a new avenue for realizing water-air communication but also holds promise for applications in high signal-to-noise ratio sensing devices.

Vibration and sound radiation reduction in broadband by meta-plate with rainbow reflection effect

Feng Liu[1*], Yan-Feng Wang[1], and Yue-Sheng Wang[1,2]

[1]Department of Mechanics, Tianjin University, China
[2]Department of Mechanics, Beijing Jiaotong University, China
[*]corresponding author: liu_feng@tju.edu.cn

Abstract: A meta-plate with a rainbow reflection effect is proposed to suppress vibration and sound radiation. Results show significant broadband suppression with extremely low structural damping. The suppression mechanism is attributed to vibration redistribution and systematic reduction, driven by the slowing-down velocity and energy enhancement effects of the rainbow reflection phenomenon.

In this work, we propose a meta-plate with radial trapping effect [1], which is realized by sixteen rings with gradient heights, attached on the host plate with a side length a and thickness h_0, as shown in Figure 1. Here, the rings are made of photosensitive resin by utilizing its extreme-low inherent loss instead of introducing additional damping materials.

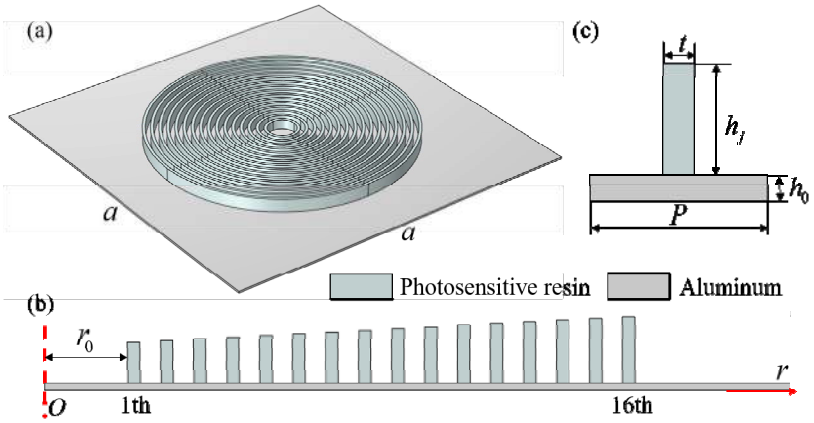

Figure 1 (a) Sketch of square meta-plate with unit-cells of gradient rings; (b) Sketch of two-dimensional axis-symmetrical rainbow reflection structure; (c) Sketch of the unit-cell.

To demonstrate the rainbow reflection effect of the designed meta-plate, the wave propagation for the infinite two-dimensional meta-plate under a point load applied at the center is analyzed without considering the reflection from the outmost boundary. The wavefields at different frequencies are shown in Figure 2. The incident flexural waves are stopped at corresponding unit-cell and cannot propagate into the host plate. The wave energy within the rings where the wave stopped is obviously lager than other regions, demonstrating the energy enhancement of the rainbow reflection effect.

The normal mean square velocities of the bare plate and meta-plate are shown in Figure 3(a). For frequency larger than 1880 Hz (marked by the dashed line), near the first-order locally resonant frequency 1920 Hz of the 16th unit-cell, the rainbow reflection effect is emerged. Therefore, for most of the frequencies from 1880 Hz to 3500 Hz, the mean square velocity of the meta-plate is reduced compared with that of the bare plate, leading to a

substantial reduction of sound power (reference: 10^{-12} W) at these frequencies, as shown in Figure 3(b). The significantly reduction of mean square velocity and sound power is owing to the slowing-down of the wave velocity and energy enhancement of the rainbow effect, profited from which, the waves can be effectively absorbed only relying on an extreme-low inherent loss of the gradient rings. As further evidence, the modal loss factor of the lossy meta-plate is calculated, as shown in Figure 3(c). The modal loss factors of the meta-plate suddenly increase significantly when the frequency is larger than 1880 Hz. The results of modal loss factors further demonstrate that the substantial reduction of mean square velocity and sound power of the lossy meta-plate is attributed to the bandgap and slowing-down wave effects simultaneously possessed by rainbow trapping structures, which is quite different from previous studies based only on bandgaps.

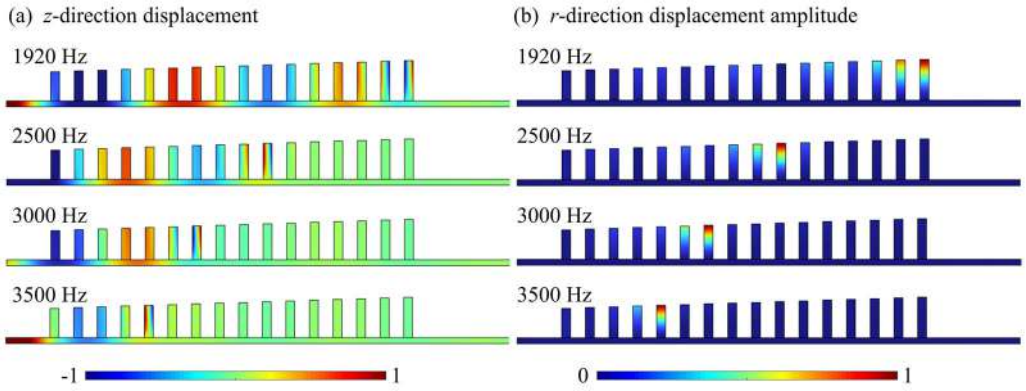

Figure 2 (a) *z*-direction displacement and (b) *r*-direction displacement amplitude of the meta-plate at different frequencies to demonstrate rainbow reflection effect.

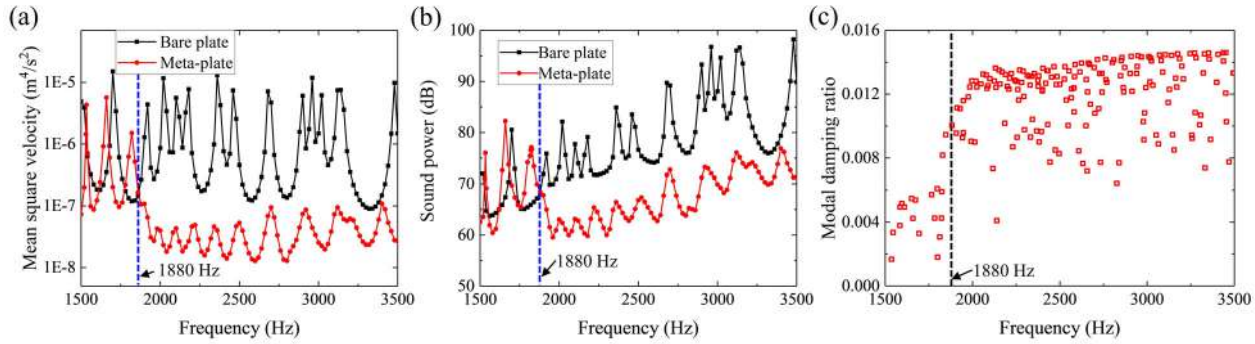

Figure 3 (a) Mean square velocity and (b) sound power for meta-plate and bare plate. (c) Modal loss factor of meta-plate.

The proposed meta-plate is similar to a plate with several circular reinforcement ribs, which enhances the structural stiffness while significantly suppressing the vibration and sound radiation in broadband without additional damping materials. The present design provides a novel approach for vibration and noise reduction in engineering, such as for the cabins of high-speed trains and aircraft.

Quadratic Weyl semimetal and topological double negative refraction in phononic crystals

Y. T. Yang[1*]

[1]Beijing University of Chemical Technology, China
[*]corresponding author: yangyating@buct.edu

Abstract: We report the realization of an acoustic quadratic Weyl semimetal, which hosts a pair of quadratic Weyl points with opposite charges ±2. Nonzero charges of the quadrative Weyl points give rise to the Fermi-arc boundary states. We further achieve the double negative refraction of the boundary acoustic waves without reflection.

Weyl semimetals, featured with nontrivial band crossing in three-dimensional momentum space dubbed as the Weyl point (WP), have been studied extensively [1-4]. We design a bilayer PC with chiral interlayer interactions to realize a quadratic Weyl semimetal, which hosts only a pair of quadratic WPs at the M and A points. D4 and time-reversal symmetries protect the existence of the quadratic WPs, which carry topological charges ±2, and possess quadratic dispersions along the kx and ky directions and linear one along the kz direction. Interestingly, we construct an interface formed by two different Weyl semimetals with opposite chirality of the interlayer interactions. Double negative refraction is observed in experiment. Different from the conventional negative refraction, which means that only one transmitted wave and the incident wave are located on the same side of the interface normal, double negative refraction manifests that two transmitted waves satisfy the negative refraction condition at the same time. Moreover, the refraction fields are distributed in two separate planes, which will facilitate wave manipulation.

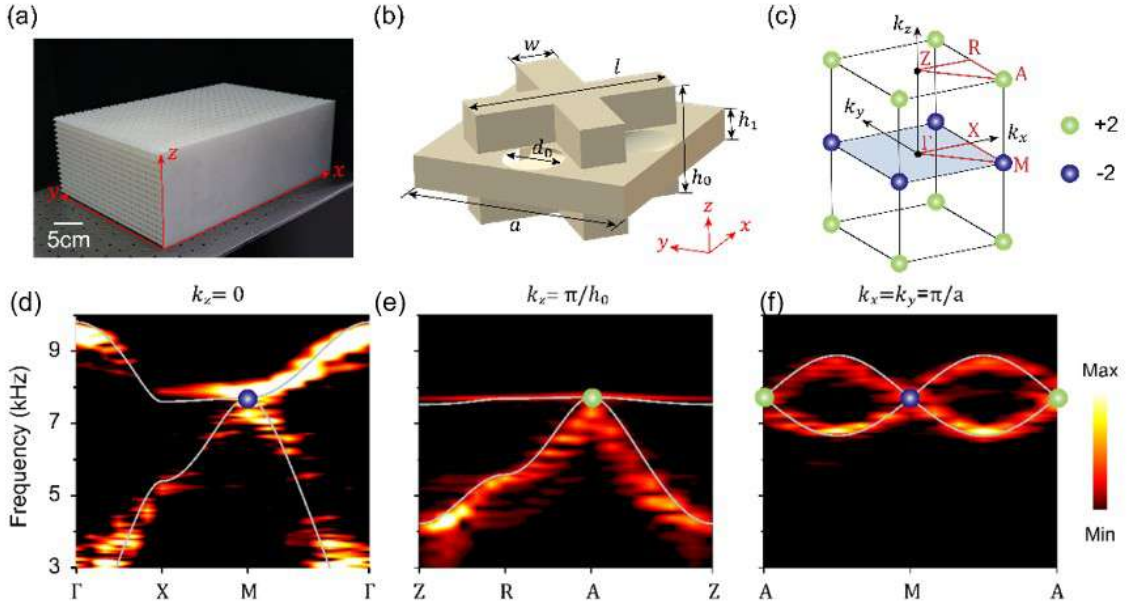

FIG. 1. PC with a pair of quadratic WPs and the bulk band dispersions. (a) Photo of the sample fabricated by 3D printing technology. (b) Unit cell of the PC, composed of vertical crossed scatterers in each layer and four chiral tubes connecting the two layers. (c) First Brillouin zone with quadratic WPs labelled by green (topological charge of +2) and blue (topological charge of -2) spheres. (d) and (e) for kz=0 and kz=π/h0. (f) Along the kz direction for kx=ky=π/a. Color maps and gray lines denote the experimental and simulated results, respectively.

Abstract: This study integrates an acoustic metamaterial absorber, springs, and triboelectric nanogenerators to convert urban noise into electricity. By tuning absorber and spring resonance, the system achieves maximum displacement, enabling effective energy harvesting for low-power devices, offering a sustainable solution for noise pollution and green energy.

Noise pollution, particularly low-frequency noise, poses a significant challenge as traditional sound-absorbing materials struggle to attenuate it effectively. Helmholtz resonators (HRs) have emerged as a promising solution due to their local resonance effect, enabling efficient low-frequency absorption within a compact structure. However, a single HR typically produces only one absorption peak, limiting its effectiveness in multi-frequency noise reduction. To address this limitation, researchers have developed multi-layer Helmholtz resonator (MHR) structures, which combine multiple resonator units to achieve multiple absorption peaks across different frequencies.The design of MHRs leverages several key strategies. By tuning the geometric parameters of multiple HR units, researchers have successfully introduced multiple narrowband absorption peaks. Additionally, stacking multiple HR layers further expands the absorption bandwidth, while embedded aperture modifications allow for precise control over resonance frequencies and impedance matching. Studies have demonstrated that even with a thickness as small as 1/30th of the working wavelength, MHRs can achieve near-perfect absorption at specific low-frequency targets, such as 100 Hz and 400 Hz. Experimental results from 3D-printed samples, validated against finite element simulations, confirm the effectiveness of these structures in multi-frequency noise mitigation.Future research directions could explore adaptive MHR designs with tunable properties, advanced material optimization, and large-scale implementations in architectural acoustics, transportation, and defense applications. This study addresses the current energy shortage and growing environmental awareness by proposing an innovative solution to convert urban noise into electrical energy. As green energy research progresses, researchers worldwide are striving to find eco-friendly and sustainable power generation devices. Among them, the triboelectric nanogenerator, which can convert weak mechanical energy into electrical energy, has garnered significant attention. This technology offers advantages such as simplicity, high energy density, and low cost, making it an ideal candidate for alternative energy sources. However, urban areas face increasing noise pollution, leading to irritability and health issues among residents. To address this problem, the introduction of acoustic metamaterials has enabled researchers to design an absorber that can perfectly absorb incident sound waves with sub-wavelength thickness. In this study, we integrate an acoustic metamaterial absorber, springs, and triboelectric nanogenerators to design a system that converts noise pollution into electrical energy to power low-energy devices. As shown in Fig. 1(a), we designed a quasi-Helmholtz resonator as the acoustic metamaterial absorber, incorporating a spring within it. Both the absorber and spring are made from 3D-printed resin. Considering that general traffic noise has a frequency of about 2000 Hz and a decibel level of approximately 90 dB, we set the sound pressure of the incident sound wave to 1×10^{6}. Next, we

placed two different materials for triboelectric generation at the position of maximum displacement between the spring and the sidewalls of the absorber. As shown in Fig. 1(b), the absorption spectrum and spring displacement diagram demonstrated that by fine-tuning the dimensions of the absorber and spring, we align the absorption frequency with the spring's resonance frequency to achieve maximum displacement. In the simulation, the relative displacement between the spring and absorber is approximately 1.8 mm. This system shows potential for converting noise into energy, providing a new direction for green energy development in urban environments.

Abstract: We investigate the emergence of topological interface states in a silicon-based crystal supporting both photonic and phononic modes. Our results demonstrate that these modes are robust and immune to certain defects, such as bends, ensuring stable wave propagation.

Topological insulators exhibit exceptional properties that enable low-loss wave transport along topological waveguides, even in the presence of impurities. Originally associated with the Quantum Hall Effect (QHE) in condensed matter physics, this phenomenon has been extended to photonic and phononic regimes, leading to the development of topological photonic [1, 2] and phononic crystals [4, 5].

Designing a single crystal that simultaneously supports topological photonic and phononic modes is particularly challenging due to the intrinsic differences between electromagnetic (photonic) and mechanical (phononic) waves. Achieving such a structure could unlock promising applications in optomechanics and telecommunications. In this work, we propose a periodic silicon-based two-dimensional membrane to realize an analog of the quantum valley Hall effect (QVHE) [3, 6] (Fig. 1 (a)). Careful optimization of the geometric parameters leads to the emergence of two isolated Dirac cones in both photonic and phononic band diagrams. Breaking spatial inversion symmetry lifts these degeneracies, opening two Dirac gaps at approximately 0.332

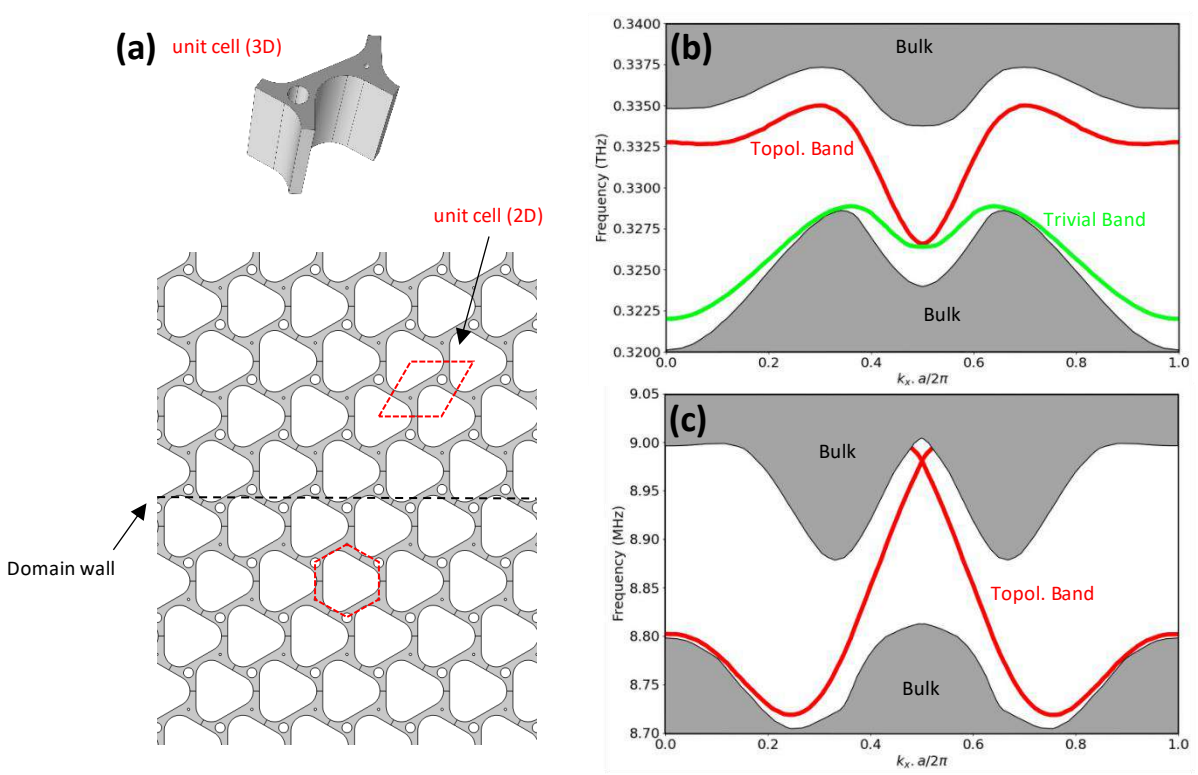

Fig. 1 (a) Unit cell of the honeycomb phononic crystal (top) and representation of the interface between two topologically distinct crystals (bottom). **(b)** and **(c)** show the photonic and phononic band diagrams for supercells, respectively, where topological branches are highlighted in red (Topol. Band). In the photonic case, a non-topological (Trivial) branch is also present, shown in green.

THz and 8.85 MHz for TE-polarized photonic and symmetric phononic modes, respectively. Introducing a domain wall with a zigzag interface results in the emergence of two topological branches in both the photonic and phononic regimes (Fig. 1 (b) and Fig. 1 (c)).

Figures 2 (a) and 2 (b) illustrate the magnetic field and the z-component of the displacement field amplitudes of topological interface modes propagating through a Z-shaped waveguide at frequencies of 0.3318 THz and 8.86 MHz for photonic and phononic crystals, respectively. The slight intensity decay observed in the photonic case after the bending is due to the radiative nature of these modes in the air medium, as the band diagram lies above the light cone. This is confirmed by our analysis techniques, such as Laplace transform, and is clearly visible in Fig. 2 (a), where the field remains uniform along the entire path, with no visible standing wave.

Those results highlight the robustness and immunity of these topological interface modes (both optical and mechanical) while maintaining the same structural characteristics. These insights pave the way for significant advancements in optomechanical and telecommunication technologies.

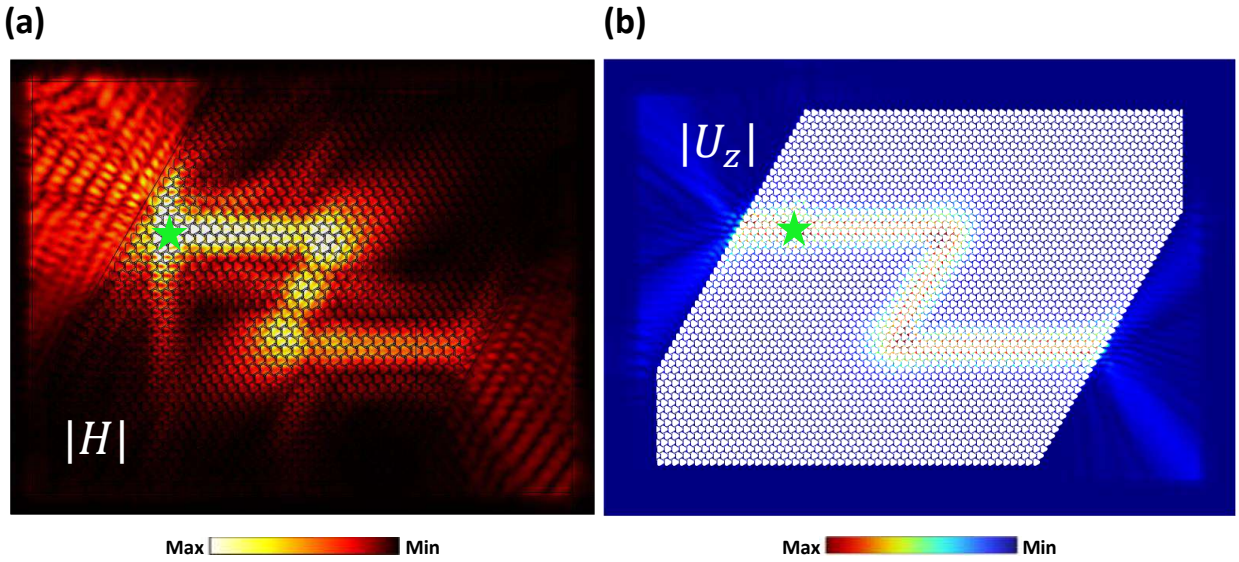

Fig. 2. (a) Photonic topological interface mode propagating along a zigzag path. **(b)** Same as **(a)** for the phononic interface mode. The green stars in **(a)** and **(b)** indicate the positions of the photonic/phononic sources.

Phononic Quantum State Preparation and Ultrafast Coherent Control via Pulsed Excitation of Quantum Emitters

S. S. Ffrench[1], D. D. A. Clarke[1], D. Wigger[1] and O. Hess[1*]
[1]School of Physics and CRANN Institute, Trinity College Dublin, College Green, Dublin 2, Ireland

Abstract: Phonons are quintessential for emerging solid-state quantum technologies, yet coherent control is challenging. Using the independent boson model, we derive the pulse area condition for selective phononic quantum state preparation via optical excitation of quantum emitters. Optimized ultrashort pulses enable high-fidelity multiphonon generation despite dephasing and phonon decay.

Introduction: As ubiquitous quasiparticle excitations in crystalline solids, phonons are poised to play a vital role in emerging solid-state quantum technologies, with prospective applications extending from the coherent manipulation of spin qubits and modulating the photonic performance of quantum emitters (QEs) to the realization of universal quantum interfaces at the nanoscale. Nevertheless, achieving the full potential of phononic quantum information science relies on extending concepts and strategies for ultrafast, coherent quantum control to systems of interacting QEs and lattice vibrational modes [1]. Whilst the preparation of phononic coherent and Schrödinger cat states via optical excitation of QEs has been reported, few studies have emerged surrounding the selective preparation of single- and multiphonon Fock states, despite their fundamental and quantum technological importance.

In this contribution, we explore the practical limits of schemes for selective multiphonon quantum state preparation via ultrafast optical excitation of solid-state QEs. Adopting the example of color centers in two-dimensional hexagonal boron nitride (hBN), we explore via time-dependent density matrix techniques the relative performance and intricacies of single- and multipulse excitation protocols, demonstrating that suitably optimized, ultrashort pulse sequences enable high-fidelity multiphonon generation despite dephasing and phonon decay.

Phononic quantum state preparation: Our analysis is based on the optically-driven independent boson model (IBM) for a two-level QE coupled to a phonon mode in the presence of a laser field [2, 3]. Analytical diagonalization of the field-free IBM Hamiltonian via a polaron transformation yields the spectrum shown in Fig. 1(a). Assuming that the system is prepared in some initial state $|n\rangle_G$ at time $t = 0$, an exact treatment of the time evolution operator establishes that the requisite pulse area for a total population inversion to the excited state $|m\rangle_X$ is given by $\Theta^n_{m,k} = (2k + 1)\pi R^n_m$, where k is a non-negative integer, $R^n_m = 1/|M^n_m|$ and M^n_m is the Franck-Condon factor pertaining to the specific vibrational transition of interest.

Adopting parameters appropriate to visible region color centers and longitudinal optical phonon modes in hBN [3], Fig. 1(b) demonstrates the achievable population inversion. Assuming the coupled system to be prepared initially in the ground state $|0\rangle_G$, irradiation by an ultrashort, resonant Gaussian pulse with appropriate area excites the system to the target state $|0\rangle_X$ (upper) or $|1\rangle_X$ (lower). To circumvent the requirement of exponentially scaling pulse areas for populating higher multiphonon states (stemming from the Franck-Condon factors), we also explore optimized sequences of ultrashort laser pulses, whereby the coupled system is driven to

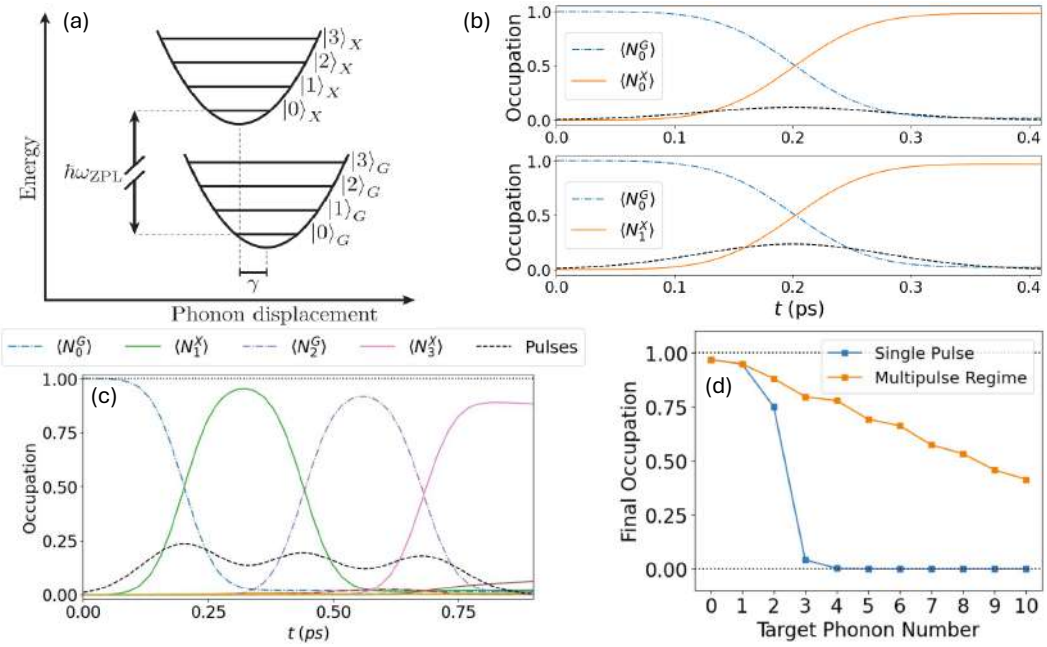

Figure 1: (a) Schematic representation of the spectrum of the IBM Hamiltonian, comprising two harmonic oscillator spectra displaced in energy according to the zero phonon line energy $\hbar\omega_{\mathrm{ZPL}}$ and in configuration coordinate by the polaron shift γ (adapted from Ref. [2]). (b) Time-dependent populations of the initial (ground) state $|0\rangle_G$ and the target excited states $|0\rangle_X$ (upper) and $|1\rangle_X$ (lower), under resonant excitation by Gaussian laser pulses with renormalized pulse area and width $\sigma = 80$ fs. (c) Optimized three-pulse sequence to populate $|3\rangle_X$ via intermediate states. (d) Comparison of the attainable populations in the n-phonon states $|n\rangle_{G/X}$ via single-pulse and optimized multipulse excitation schemes. Occupations are recorded 2σ after the peak of the final pulse in the sequence. See Ref. [3] for numerical parameters.

some target phononic state along a transition pathway that minimizes the total required pulse area. Such a scheme is exemplified for the three-phonon state $|3\rangle_X$ in Fig. 1(c), where an occupation probability exceeding 85% is attained in spite of phonon decay and QE pure dephasing. Finally, Fig. 1(d) compares the achievable population transfers from the ground state $|0\rangle_G$ to various n-phonon states $|n\rangle_{G/X}$ under both renormalized single-pulse and optimized multipulse excitation. Notably, while the single-pulse approach already fails beyond $n = 2$, the use of multiple pulses allows the generation of states with up to $n = 6$ phonons at occupation probabilities above 75%, and even up to $n = 8$ phonons with occupation probabilities above 50%.

Abstract: Investigation of the interaction between elastic surface waves and nano-cylinder scatterers to identify resonant regimes and thereby extract crucial transport parameters in multiple scattering experiments aimed at exploring two-dimensional sub-diffusive Anderson localization. Using a Ti:Sapphire pump-probe setup we recorded spatial maps of the displacement.

1) Introduction

Understanding scattering resonances by a single object is essential for calculating scattering cross sections σ_s and, consequently, the key transport parameters in disordered media -the mean free path l_s and the diffusion constant D. Single-scatterer measurements also enable exploration of two-dimensional localized sub-diffusive states where the power spread $\langle r^2 \rangle \propto t^{\alpha}$ with $0 < \alpha < 1$, and Anderson localization where elastic waves remain trapped in a region of the medium. Pump-probe interferometry has long been used to image surface elastic waves and give the advantage of non-contact methods. Previous observations of localized, multiple scattering states observed on nano-structures have left open whether confinement arises from weak-localization (reciprocal-path interference) or from volume-wave leakage into the substrate. Here the scattered displacement field of (A_0,S_0) Lamb waves by Au discs of 2μm diameter and variable heights of 50-100nm placed over a 50nm Au film over Si_3N_4 membrane and the scattered displacement field of Rayleigh waves by the same discs on 50nm Au film on Si_3N_4, Si substrate, were measured.

2) Experimental setup

We employ a Coherent Chameleon Ultra II Ti:Sapphire laser delivering >3 W average power at 800 nm in ~140 fs pulses at an 80 MHz repetition rate. A half-wave plate (λ/2) and polarizing beamsplitter (PBS) split the beam into pump and probe arms. The pump arm is amplitude-modulated at 1.5 MHz using an acousto-optic modulator (AOM) and only the first diffracted order is selected for excitation. To reduce optical penetration depth and generate higher-frequency acoustic components, the 800 nm pump is frequency-doubled to 400 nm via second-harmonic generation in a β-BaB_2O_4 (BBO) crystal.

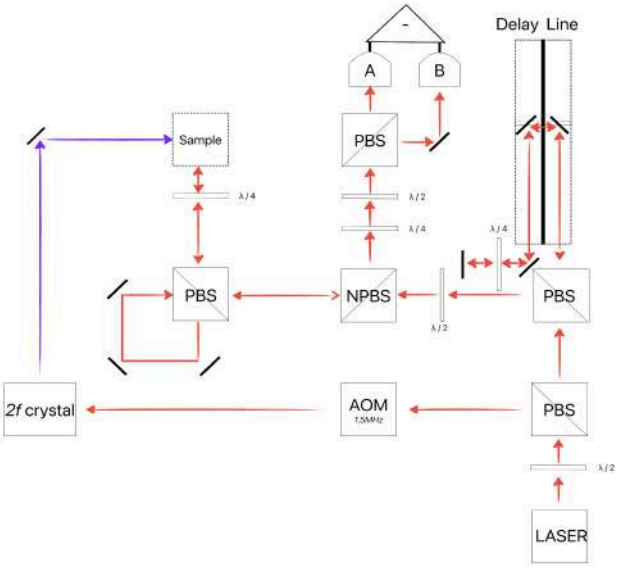

Figure 1: Pump probe setup

The probe arm traverses a 12.5 ns optical delay line before entering a Sagnac interferometer, which splits it into two counter-propagating pulses that interrogate the sample at times t and $t+\Delta t$. Upon reflection, the complex reflection coefficient

$$r(t) = |r|e^{i\varphi(t)} \qquad (1)$$

is modulated by both the strain-induced refractive index change (photoelastic effect) and the surface displacement Δz(t). After recombination, the two probe pulses interfere at photodiodes A and B; subtracting their outputs yields

$$I \propto \varphi(t + \Delta t) - \varphi(t) \qquad (2)$$

which, when demodulated at 1.5 MHz by a Stanford Research Systems SR830 lock-in amplifier, provides sensitivity to surface displacements in the 100 MHz–5 GHz band.

3) **Results**

We conducted spatial mappings on the substrates and obtained

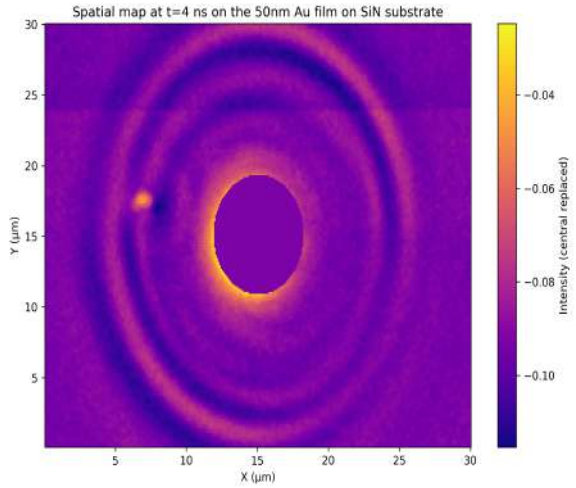

Figure 2*: A (30 by 30µm) spatial scan of a Rayleigh wave with a lateral precision of 125nm at t= 4ns.*

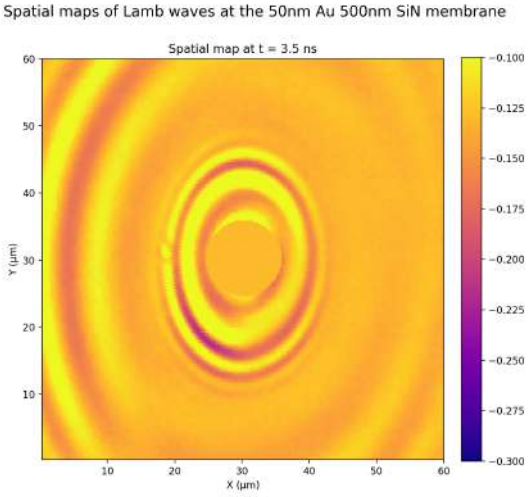

Figure 3*: A 60 by 60 µn spatial scan of Lamb waves with a lateral precision of 250nm at different t.*

Figure 2 shows the spatial map of the out-of-plane displacement on the Si_3N_4/Si substrate. The gold cylinder appears as a bright yellow spot on the left, due to its locally enhanced reflectivity. From that point, a circular scattered wave-front propagates outward. To improve visibility of the weak scattered signal, we digitally masked the central specular reflection (static background) using a mean-value subtraction, which enhances the contrast of the propagating wave. In contrast, the membrane sample (Figure 3) supports highly dispersive Lamb modes (A_0 and S_0), therefore the scattered wave is difficult to spot in the spatial scan. Quantitative analysis of the scattered field was done with frequency-filtered reconstructions.

4) Conclusion

We have demonstrated that spatially resolved pump–probe interferometry can quantitatively map the scattering of surface and guided elastic waves by isolated Au nano-cylinders. On rigid Si_3N_4/Si substrates, Rayleigh-wave scattering produces clear circular wave fronts, enabling direct extraction of the angular cross-section and hence the elastic mean free path ls. In contrast, on freestanding Si_3N_4 membranes the dispersive Lamb modes (A_0, S_0) smear out the scattered field, reducing peak amplitudes of the incident wave and necessitating frequency-filtered analysis. Future work will extend this approach to denser scatterer arrays and to time-resolved studies of sub-diffusive transport.

Metamaterial-based Dielectric Elastomers for Enhanced Energy Harvesting

A. Dutta[1*], Y. Pennec[1], G. Leveque[1], B. Djafari-Rouhani[1], M. Miniaci[1]**

Abstract: This work investigates the integration of mechanical metamaterials into dielectric elastomer generators (DEGs) to enhance energy harvesting performance. By introducing auxetic and multi-stable geometries in both two-dimensional (2D) and three-dimensional (3D) DEGs, we demonstrate enhanced capacitance variation and broadband response, leveraging metamaterial-induced nonlinearities and deformations to improve energy conversion efficiency.

Introduction: Dielectric elastomers (DEs) are a class of soft electroactive materials capable of converting mechanical deformation into electrical energy, and vice versa. Often referred to as stretchable capacitors, their performance is strongly influenced by their geometric and topological properties [1].
Mechanical metamaterials are artificially engineered structures designed to exhibit unusual quasi-static (and dynamic) behaviors, including auxeticity, multi-stability, frequency band gaps, which make them promising candidates for enhancing energy harvesting performances of DEs.
While the operation of DEs in actuator mode (DEA) has been extensively studied, especially in soft robotics [2], their application in generator mode for energy harvesting remains comparatively underexplored [3], [4].
In this work, we aim to exploit the unique mechanical properties of metamaterials to enhance the performance of DEGs. As a demonstration, we integrate metamaterial architectures into both 2D and 3D DEGs [3] [5], and investigate how their distinctive behaviors affect energy harvesting efficiency.

Modeling: A DE consists of an elastomer sandwiched between two compliant electrodes. When mechanical input, usually tensile force, is applied, the elastomer's area increases while its thickness decreases, resulting in a change in capacitance [3]. As illustrated in Fig 1., if the structure is electrically charged in a low-capacitance state and then stretched, the stored electrical energy increases as mechanical work is done on the system. When the elastomer returns to its original, unstretched state, this energy can be recovered as electrical output in the form of current.

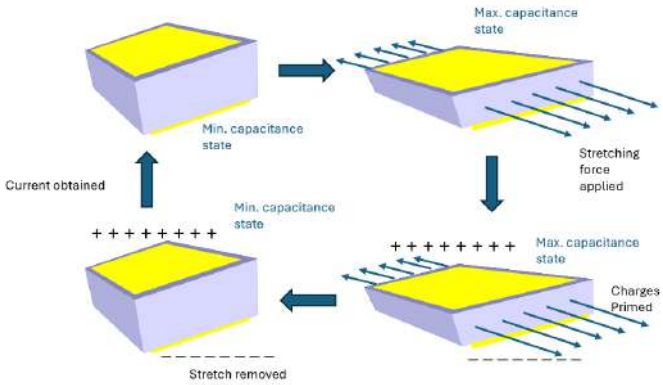

Figure 1: Typical energy harvesting cycle with a DEG.

Moretti et al. [3] investigated the effects of different strain modes on the capacitance variation of DEs. While uniform biaxial strain yields the highest capacitance change, real-world applications involve a wide range of non-uniform and complex deformation inputs. To accommodate such conditions, alternative configurations have been proposed, such as the diamond configuration in 2D [6], and the conical and bubble configurations in 3D.

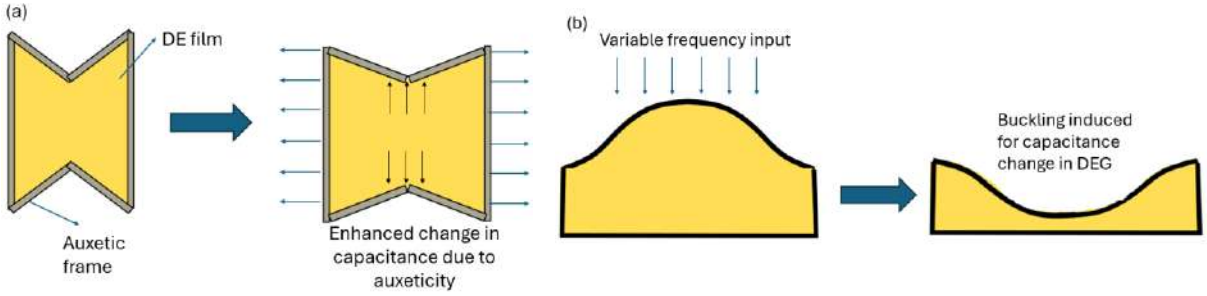

Figure 2: (a) Auxetic frame DEG, (b) buckling frame DEG.

In this work, we first modify the geometry of 2D DEs to include auxetic behavior upon deformation [7], as shown in Fig 2 (a), building upon the approach introduced in [5]. We then compare the change in capacitance with the base geometry. Next we extend the 2D metamaterial design to incorporate snap-through buckling – Fig. 2 (b), and investigate its response under variable-frequency excitation to demonstrate broadband energy harvesting behavior. Finally, we explore more complex 3D metamaterial architectures, including origami-inspired structures, to assess their potential for enhanced energy conversion.

Acknowledgments: This project has received funding from the European Union's Horizon Europe research and innovation programme under grant agreement MetacMed (GA No 101119738).

Abstract: We introduce "variational optical processors," self-configuring photonic networks that learn modal representations of partially coherent or quantum optical fields through optimization, applicable to diverse classical and quantum optical processing tasks.

Classical and quantum light fields can be described in terms of modes. Modal decompositions play a central role in our understanding of multimode light field generation, propagation, and measurement. Some important examples include the decomposition of partially coherent light into so-called "natural modes" (a form of Karhunen-Loeve expansion [1]), coherency and density matrix eigendecomposition [1, 2], Schmidt decomposition of pure quantum bipartite states [2], and the Bloch-Messiah decomposition of multimode Gaussian states [3]. Methods relying on tomographic projection of the fields onto an *ad hoc* basis, usually requiring prior knowledge of the modes' geometry, have been realized to perform modal decomposition of multimode quantum and classical fields [4, 5].

Networks of Mach-Zehnder interferometers (MZIs) have proven highly effective in manipulating [6] and measuring [7] coherent multimode light. We now propose that these self-configuring meshes can be used to measure, process, and generate multimode light fields that exhibit some degree of partial (classical or quantum) coherence.

Here, we introduce a general framework for modal decomposition of partially coherent or quantum multimode light fields using a new class of optical devices coined "variational optical processors (VOP)." These networks consist of self-configuring MZI arrays whose parameters are optimized sequentially to e.g., maximize a function of the detected output signal. We find that in various cases – including Karhunen-Loeve expansions of classical and quantum light, Schmidt decomposition of bipartite states, and Bloch-Messiah decomposition of multimode squeezed vacuum – the modal decomposition can be mapped to a sequential output optimization by variational principles. Once trained, the resulting device physically separates the input light fields into mutually orthogonal components that have the properties of the modal decomposition of interest (e.g., mutually incoherent, separable quantum states, supermodes, etc.). Furthermore, by sequentially learning the modes associated with the largest eigenvalues or singular values, our framework achieves favorable scaling in both physical hardware and required measurements compared to traditional tomographic techniques. Our method therefore paves the way to full characterization of multimode classical and quantum light fields in various use cases such as spatially partially coherent light [8], single photon mixtures [8], entangled photon pairs [9], and multimode squeezed vacuum [10].

A gain route to reversed Cherenkov radiation

Abstract: We find precise conditions to enable reversed Cherenkov radiation from a positive-index gain isotropic slab under which the backward-propagating Cherenkov radiation is maintained while the forward-propagating one is suppressed. Counterintuitively, the intensity and the angular spread of reversed Cherenkov radiation can be made robust to the slab thickness.

When a charged particle moves with a velocity larger than the phase velocity of light in a surrounding material, that particle emits light into a highly directional cone. This exotic light emission process, known as Cherenkov radiation [1], was experimentally observed by Cherenkov under the guidance of Vavilov and later theoretically explained by Frank and Tamm. The many variants of Cherenkov radiation phenomena are now a common sight in modern physics (e.g. the bluish glow of an underwater nuclear reactor). According to the famous Frank-Tamm formula $cos\theta = \frac{c}{nv}$, the angle θ of light emission (also known as the Cherenkov angle) is related in a unique way to the particle velocity $v = |\bar{v}|$, where n is the refractive index of the surrounding material and c is the speed of light in vacuum. Enabled by this unique feature, the Cherenkov radiation is crucial to many practical applications, ranging from particle detectors/counters and light sources to bio-medical imaging and photodynamic therapy.

Upon close inspection of the Frank-Tamm formula, the Cherenkov angle inside the conventional material with $n > 0$ has $\theta < 90°$. That is, conventional Cherenkov radiation in positive-index materials is emitted in the forward direction relative to the direction of the particle motion. The forward direction is often undesirable. For example, Cherenkov detectors that rely on measuring Cherenkov radiation must cope with the energetic charged particles that cause radiation damage. This radiation damage limits the performance of particle identification and counting. Radiation emission in the backward direction is desired for both practical applications that rely on the Cherenkov effect (e.g. the development of advanced Cherenkov detectors with improved performance) and for fundamental reasons that relate to the nature of radiation emission in optical materials.

The most famous way to create such unconventional Cherenkov radiation is using exotic materials with $n < 0$, for which $\theta > 90°$ in the Frank-Tamm formula. In this case, the emitted photons and the emitting charged particles are spatially well-separated in opposite directions. This unconventional phenomenon, as first proposed by Veselago in 1968 [2], is the so-called reversed Cherenkov radiation [3]. In addition to negative-index materials, people later found that reversed Cherenkov radiation could also occur in anisotropic materials (e.g. hyperbolic materials) and photonic crystals. Essentially, the occurrence of reversed Cherenkov radiation requires the surrounding material — such as negative-index materials, hyperbolic materials, and photonic crystals — to support a judiciously-designed photonic eigenmodes, whose group velocity $\bar{v}_g$ has the antiparallel component with respect to the particle velocity $\bar{v}$, namely $\bar{v} \cdot \bar{v}_g < 0$. In contrast, conventional Cherenkov radiation inside any isotropic positive-index material has $\bar{v} \cdot \bar{v}_g > 0$. Whether reversed

Cherenkov radiation can emerge for $\bar{v} \cdot \bar{v}_g > 0$ remains elusive.

Here we reveal a mechanism for creating the effective reversed Cherenkov radiation from a positive-index isotropic slab, by exploiting the optical gain. This finding breaks the long-standing belief that the reversed Cherenkov radiation occurs only under the scenario of $\bar{v} \cdot \bar{v}_g < 0$. We show in Fig. 1 that a judiciously-designed gain medium can not only maintain backward-propagating radiation emission, but even suppress the forward-propagating emission. This way, while the initially-induced Cherenkov radiation inside the gain material still has $\bar{v} \cdot \bar{v}_g > 0$, the modified Cherenkov radiation after the interaction with the gain slab could transmit only into the backward vacuum region, leading to effective reversed Cherenkov radiation. We highlight that the connection between the reversed Cherenkov radiation and the optical gain has never been explored before, despite the long research history of free-electron radiation and optical gain. Meanwhile, whereas the pseudo-Brewster effect of gain materials was recently reported possible to simultaneously enhance the radiation intensity and directionality of transition radiation [4] (another typical type of free-electron radiation that occurs when an electron moves across an optical interface), the influence of optical gain on the performance of Cherenkov radiation remains under-explored.

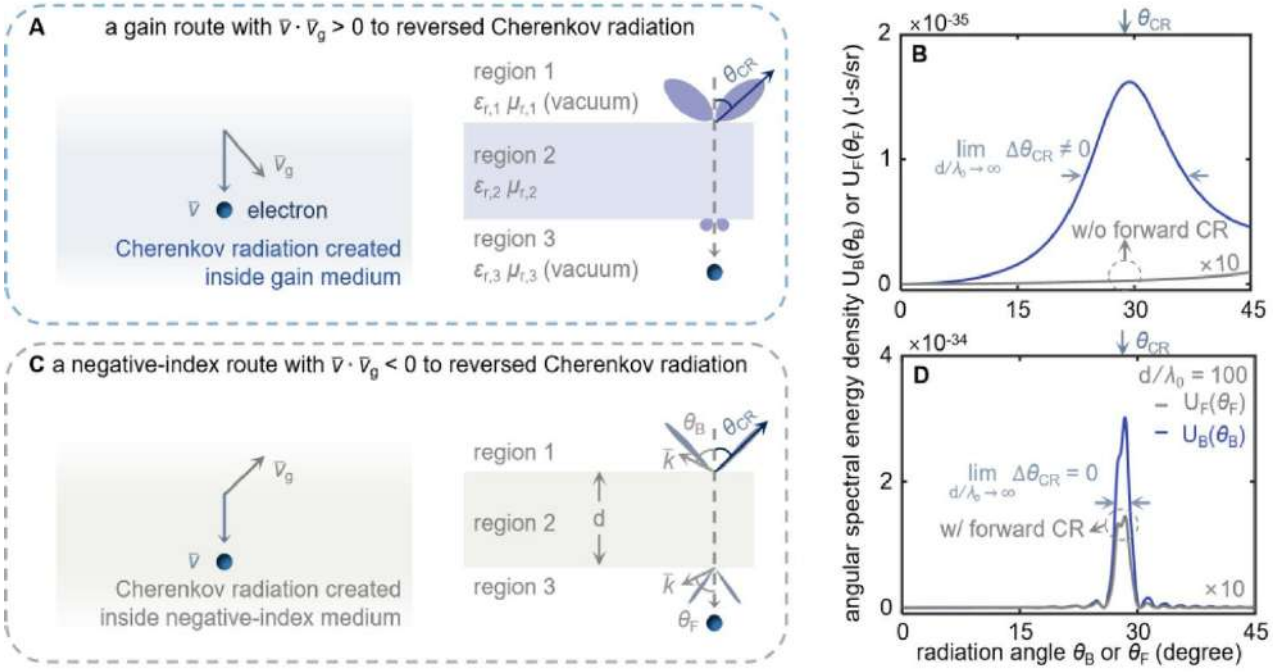

Fig. 1 Conceptual demonstration of a gain route to reversed Cherenkov radiation.

Near-field shaping by ray-caustic synthesis at microwaves and millimeter waves

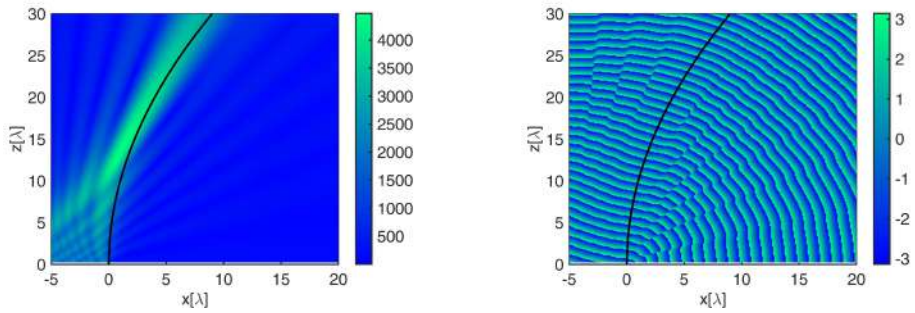
Federica Anfuso[1], Ahsan Ullah Khan[1], Gino Sorbello[1] and Santi C. Pavone[1*]
[1]DIEEI, University of Catania, Via S. Sofia 64, 95123 Catania, Italy.
santi.pavone@unict.it (corresponding author)

Abstract

We present a method for synthesizing focused electromagnetic beams by manipulating ray caustics at microwave and millimeter wave frequencies. In ray optics, caustics are high-intensity ray trajectories where rays converge, allowing for precise near-field beam focusing. This approach has significant potential for advanced communication systems and near-field launcher design.

1 Introduction

Caustic theory finds applications in optics [1, 2] and electrical engineering, especially for near-field focusing. In the context of ray optics, caustics represent the envelope of the tangents to rays, which are adopted – under the high-frequency approximation – to describe the propagation of electromagnetic waves through a general medium. In this sense, caustics result in localized increase in field intensity. By controlling the position and shape of a target ray-caustic, it is possible to manipulate the radiated beam along specific trajectories in the near-field region. This contribution aims at introducing at microwaves and millimeter waves a useful near-field shaping technique based on ray-caustic synthesis [1], thus proving a physics-based approach that surpasses, in principle, more conventional non-diffractive beams, thanks to the interesting possibility to radiate almost-arbitrary curved beams in space.



2 Formulation and Numerical Results

For simplicity, we consider a 2-D environment, where a phase gradient surface along the x-axis is designed to synthesize a phase function $\phi = \phi(x)$. Ray-caustic shaping in such an equivalent 2-D environment has been proven to be effective, as shown in [3–6]. This concept is based on the determination of a spatial phase profile $\phi(x)$ at the plane $z = 0$, which enables the synthesis of the desired curved caustic. The trajectory of the target ray is defined by the curve $z = f(x)$, with the tangent slope $\theta_t(x) = \frac{df(x)}{dx}$, which enables direct computation of the phase function. By appropriately designing $\phi(x)$, the electric field can be focused to follow the prescribed ray-caustic path. The 2-D radiated electric field by the n-th elementary radiator, placed at $x = x_n$ and phased as $e^{j\phi(x_n)}$, can be evaluated as

$$\mathbf{E}_n(\mathbf{r}) = -\hat{\mathbf{y}} e^{-j\phi(x_n)} G_{2D}(|\mathbf{r} - \mathbf{r}_n|), \tag{1}$$

where $G_{2D}(|\mathbf{r} - \mathbf{r}_n|)$ is the 2-D scalar Green's function of an unbounded medium, and $\mathbf{r}$ is the observation vector.

A numerical example has been developed, based on a caustic described by the function $f(x) = \gamma\sqrt{x}$, with $\gamma = 10$, extending over a prescribed length $L = 10\lambda$ at $z = 0$, being $\lambda = 1$ m. The objective is to demonstrate that the radiated electric field follows the trajectory defined by $f(x)$. The numerical result, shown in Fig. 1, validates the theoretical model by confirming that the field aligns with the intended caustic trajectories. It is important to note that the phase plot in Fig. 1(b) shows the local wave-fronts close to the desired caustic are planar and orthogonal to the caustic trajectory, as dictated by geometrical optics.

(a) (b)

Figure 1: (**a**) Amplitude and (**b**) phase of the radiated field generated by the phase profile described by $\phi(x)$.

3 Conclusions

We presented a new method for near-field curved-beam shaping using caustic synthesis, for innovative applications and microwaves and millimeter waves. Caustics, which are the envelope of tangents to reflected or refracted rays, naturally concentrate field intensity on arbitrary trajectories, making them ideal for focusing beams along curved trajectories. The proposed approach offers additional design parameters for innovative near-field launchers, beyond more traditional non-diffractive beams.

Abstract: (limited to 50 words max) The study reports the theoretical and experimental demonstration of an ultra-compact dielectric metasurface that leverages the topological features of symmetry protected quasi-bound states in the continuum supported by a silicon-based nanostructure. The dual-mode operating regime allows you to select the transmitted polarization without modifying the device orientation.

Manipulation of light polarization is crucial for a variety of applications including quantum communications, sensing, imaging, and material characterization, to name a few[1]. Since resorting to traditional approaches, such as cascading waveplates, is not effective in chip-scale environments, the quest for more compact, integrable solutions has been steadfast and has led to different answers, all aimed at reducing the size of the polarization devices. Some examples are devices based on photonic crystals, metallic gratings and nanoparticles or epsilon-near-zero materials [1,2]. Metasurfaces have emerged as a solution for polarization detection and engineering at the nanoscale. However, current metasurface-based polarizers can convert the incoming light into a single linear polarization state with some degree of flexibility in terms of spectral tunability [3,4]. Here we present two ultracompact all-dielectric metasurfaces that can convert any incoming polarization into either horizontal or vertical polarization without pre-determination of the incoming state of light [5]. This is achieved through the excitation of symmetry-protected quasi-bound states in the continuum (q-BICs) in a properly designed metasurfaces. Our optical modulators are based on silicon, specifically on silicon on insulator (SOI) and amorphous silicon (a-Si) on glass. Silicon has gained a foothold in nonlinear nanoscale photonics thanks to its well-established fabrication processes, high refractive index and strong third-order optical susceptibility. In these metasurfaces the symmetry is broken by changing the width of every other silicon nanobar in the array, supporting several quasi-bound states in the continuum modes (q-BICs), which are otherwise dark bound modes (BIC) in its symmetric counterpart. More specifically, in the SOI metasurface composed of a set of silicon nanobars with periodicity p = 600 nm, widths D1 = 150 nm and D2 = 90 nm (corresponding to an asymmetry factor $\alpha = 0.4$) and height h = 145 nm, placed on top of 1 μm SiO2 substrate we can identify five q-BICs in the near-IR frequency range. Each mode possesses a very high electric field enhancement and topological features that are typical of q-BIC modes. The presence of a finite SiO_2 layer in the fabricated samples introduces some additional Fabry-Perot resonances in the spectra that do not alter the spectral position of the q-BICs. On the contrary, for a-Si metasurface we optimize the following parameters: periodicity p = 650 nm, widths D1 = 130 nm and D2 = 91 nm (corresponding to an asymmetry factor $\alpha = 0.3$) and height h = 140 nm, placed on top of glass substrate. The metasurfaces are fabricated through a top-down process performed by a combination of e-beam lithography and reactive ion etching, paying particular attention to the correct definition of the gap and

to the vertical shape of the nanorods. Transmission spectra from the metasurface have been simulated and experimentally measured for normal incidence conditions and two orthogonally polarized linear waves for different structural asymmetry. The experimental results are in excellent agreement with the predicted spectra and show how the incoming linear polarization can be selectively suppressed whenever a q-BIC resonance is excited. In figure 1 we summarize the results.

(a) Working principle of the frequency selective polarization controller: a silicon-based nanostructure supporting q-BICs converts arbitrarily polarized incoming light into linearly polarized light; b) Transmission spectra for incoming TE (red line – electric field oriented along y) and TM (blue line – electric field oriented along x) polarizations. Abstract

We use Symbolic Regression to recover a closed-form expression that models the dielectric function of one of the materials that make up the wing of the *Morpho helenor* butterfly. This scheme provides a reliable alternative for characterizing the properties of materials from experimentally measured spectral data.

Symbolic Regression (SR) has regained popularity as a powerful tool, for discovering analytical expressions that model a given dataset, without requiring any prior assumptions about the algebraic form of the solution. This capability makes SR particularly valuable for applications in biomimetics [1], where retrieving the optical properties of materials remains an open challenge. In this work, we used SR to retrieve the dielectric function of the high-index layer in the multilayer system of the *Morpho helenor's* wing scale, from its experimentally measured reflectance spectra.

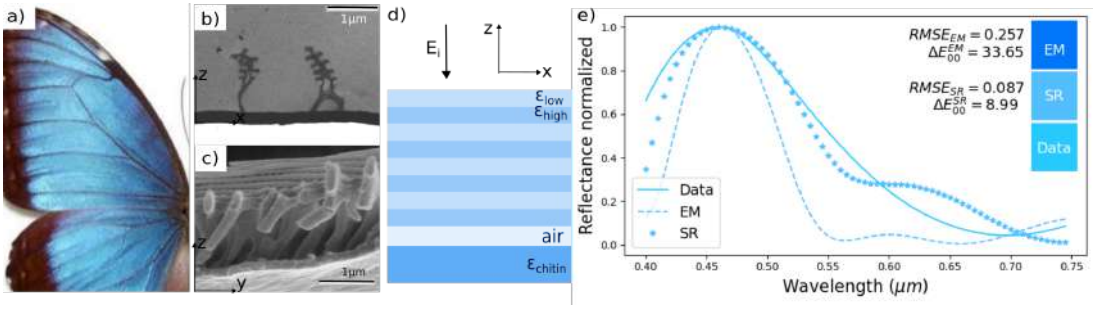

Figure 1: a) Part of a *Morpho helenor's* butterfly wing (adapted from [2]). b,c) TEM front view and SEM side view of a cover scale, revealing its ridge-lamellar multilayer structure and the lower chitin lamina. d) Multilayer system considered in this work. e) Normalized reflectance of the experimentally measured Data, the effective medium EM model, and the SR prediction, with their corresponding RMSE accuracy metric, and their ΔE^*_{00} color difference.

The *Morpho helenor* butterfly Fig. 1-(a), is widely recognized for its brilliant blue structural coloration. In the TEM and SEM images in Fig. 1-(b,c) we can see the two distinct structures responsible for its optical response. The first is a lower lamina of chitin that acts as a thin film, whose reflectance defines the overall spectral shape of the reflectance and is the dominant contributor to the coloration. The second is the ridge-lamellar multilayer configuration, whose geometric parameters are well-tuned with the thin film, enhancing reflectance in the blue wavelength range and intensifying the characteristic brilliant blue appearance [2].

Previous research has modeled the general structure of *Morpho* butterflies using an effective medium (EM) approach [3]. In *Morpho helenor*, the presence of large open windows introduces significant air gaps between consecutive ridges, resulting in at least 75% of air in each effective layer and reducing the accuraccy of the model. In this work, we used SR to model the *Morpho helenor* without the EM approach. We consider the simplified geometry depicted in Fig. 1-(d), a multilayer system composed of alternating high- and low-refractive-index layers. The incident and substrate medium are air, while the low-index layer is approximated as a homogeneous medium with a dielectric function of $\epsilon_l = 1.1$. The final two layers consist of an air layer and a 220 nm chitin film, respectively.

The butterfly's reflectance spectrum $R(\lambda)$ was experimentally measured using a bifurcated optical fiber probe at normal incidence. We used $R(\lambda)$ as input for the SR, and predicted the dielectric function of the high-index material ϵ_h^{SR}. We used the Berreman 4x4 method to compute the reflectance $R^{SR}(\lambda, \epsilon_h^{SR})$ of the multilayer considered in Fig. 1-(d), incorporating the prediction. We used the RMSE metric to quantify the accuracy of R^{SR} to reproduce the input $R(\lambda)$. To provide insights into the stability of the retrieved models, we performed 50 realizations of the SR corresponding to different initialization random seeds. Each realization yields a list of dimensionally homogeneous expressions. To assess the model's reliability we implemented two additional metrics: Presence, which quantifies the number of realizations where the model is retrieved, and Occurrence, which measures the relative frequency of the model compared to all retrieved expressions. The results are summarized in Table 1.

Table 1: Top four models retrieved by SR. Each one is presented with a Presence and Occurrence metric across realizations, and its response accuracy $RMSE$ metric.

Expressions	**Presence**	**Occurrence**	**RMSE**$_R$
$\epsilon_{h1} = \frac{A}{B-\lambda}$	50	59%	0.087
$\epsilon_{h2} = A$	21	11%	0.095
$\epsilon_{h3} = \frac{(A+B\lambda)}{(C-D\lambda)}$	16	8%	0.087
$\epsilon_{h4} = A\lambda$	14	9%	0.080

The best model retrieved by SR is $\epsilon_h^{SR} = \epsilon_{h1}$ of Table 1, with $A = 1.124\mu m$ and $B = 1.124\mu m$. This model is present in the results of all realizations, and it corresponds to 59% of all retrieved expressions. In Fig. 1-(e) we show that the retrieved SR model outperforms the EM model in accuracy, exhibiting a lower $RMSE_R$ value and a lower ΔE_{00}^* color difference when compared to the experimentally measured data. The metrics suggest that this model represents the best approximation for the dielectric function of the high-index layer under the assumed geometry, likely representing a local optimum of the problem. This approach can be extended to cases where the optical properties of the materials are unknown, or to more complex configurations, paving the way for biomimetic photonics applications.

Abstract: First, a novel class of heat engines based on the radiative exchange between hot and cold pin junctions is studied by coupling the drift-diffusion equations for heterostructures to fluctuational electrodynamics. Then we address thermal emission of objects of size smaller than the wavelength, including spheres, nanowires and discs on surface.

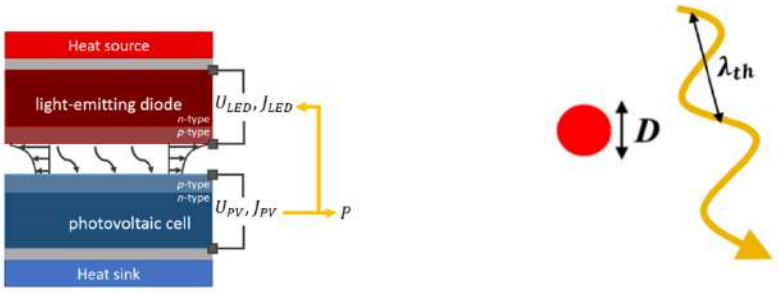

Figure 1. (a) Schematic of a thermophotonic energy harvester, highlighting the LED heat pump and the PV cell heat engine as elements of the dual radiative heat engine. (b) Schematic of an object of subwavelength size.
We report on two different works.

First, we study heat engines based on the radiative exchange between hot and cold bodies. The surface of one or each of the two bodies is covered with a pin junction, leading to electroluminescence (EL) and/or photovoltaic (PV) conversion [1]. For instance, when a passive hot body faces one room-temperature pin junction, thermophotovoltaic energy conversion happens. A device with both hot and cold pin junctions can be termed a dual radiative engine. Interestingly, such configuration allows for exchanging radiation above the Planck blackbody limit in far field since EL is not bounded. Bringing the two bodies in close proximity further allows to increase the radiative exchange by means of near-field tunneling. Thermal-to-electrical conversion or refrigeration by such devices can therefore compete with current state-of-the-art ones such as thermoelectrics [2].

Most of the analyses of these devices performed to date are based on accurate optical computations with fluctuational electrodynamics, i.e. the combination of electromagnetism and statistical physics describing thermal radiation at the wavelength scale. However, electrical charge transport is usually treated with a detail-balance approach [3-4], which does not include the local variation of chemical potential and therefore is unable to capture the fine interplay between the electrical quantities and the light emission. To predict more accurately the effects, we have developed a combined solver of the drift-diffusion equations for charge transport

in heterostructures and the radiation emission and absorption, called CRESCENT-1D [5], available on GitHub [6]. We will report on its capabilities with the example in the case of a near-field thermophotonic converter, which is made of a hot light-emitting diode (LED) and a room-temperature PV cell in the case of waste-heat harvester. If one wants a refrigerating device, the LED is cold and the PV cell is place to the room-temperature side of the device. We discuss also the issues associated with photon recycling and spatial dispersion in these computations.

In a second part, we address thermal radiation involving objects of sub-wavelength size [7]. For these objects, the usual concept of emissivity assumed to be size independent breaks down. An apparent emissivity can be defined based on the absorption cross section, well studied for nanoparticles or antennas. For isolated objects, such as spheres [8] or nanowires, it was found that the apparent emissivity can strongly surpass unity. The results depend on the permittivity of the material and some interplay with the geometry. Interestingly, the power law deviates from the Stefan-Boltzmann law with an exponent that can be way larger than 4. We extend the study to more complex objects, such as disks on surfaces. In [9], the emission of a blackbody by a diffracting hole was computed and found to scale as T^8 following the Bethe-Bouwkamp results. We analyze how this prediction evolves for real materials, in particular those supporting surface polaritons.

The effective refractive index of resonant particulate media depends on the shape of the particule arrangement

Abstract

The effective properties of random particulate media must be extracted on volumes large enough to include all kind of interactions between the scatterers. We show that for resonant interactions, this so-called representative volume element may also depend on the shape of the geometrical boundary of the particle suspensions.

1 Results

The smallest unit of a microstructure that exhibits the same effective refractive index n_{eff} as the entire microstructure sample is referred to as representative volume element (RVE). By performing numerical simulations of RVE one may save considerable computational ressources, in opposition to larger domains. Therefore, it is worth having a hint of the expected RVE before launching numerical simulations.

Usually, the strategy to determine the RVE is to gradually increase the size of the computed unit, until the extracted effective value converges toward a constant value, which is therefore considered as the actual n_{eff} [1,2] of the microstructure at a given wavelength λ. In this context, a legitimate question is whether other parameters than the size can be used to reduce further the computational ressources. For example, the shape of the unit in which the inhomogeneities are arranged may well affect how quickly the extracted value approaches the n_{eff} limit.

In this contribution, we do not address this precise question – which would desserve a study not performed so far in the literature – but a related one, encompassing the cooperative scattering of light in random particulate media. We show that there exist regimes of resonant interactions between the particles where the extracted effective value is biased by the shape of the computed unit. To be specific, while the extracted effective value no longer evolves when the size of the computed unit is increased, it turns out to reach different values when the shape is varied.

We also show that this effect is totally decorrelated from electromagnetic field fluctuations between computed units differing only in the location of the particles (i.e., the different microstates of a statistical ensemble, see section 2). There exist regimes where these fluctuations may be quite large and strongly conditioned by the shape of the computed units while, simultaneously, the same n_{eff} is found irrespective of the shape.

These intriguing phenomena are examined from the vantage point of the eigenmodes of the computed units. Since the systems of particles are absorptive and open, such eigenmodes are actually quasinormal modes (QNMs) and their eigenfrequencies are complex. The analysis of the dispersion of the QNMs in the complex λ-plane reveals striking different behaviors depending

on the permittivity of the particles. We are therefore able to discriminate two types of resonant regimes that we will referred to as (i) the scattering and (ii) the fluctuating regimes. While the modes exhibit a clear tendency to gather in certain regions of the complex plane for the former, the modes are spread out in the whole complex plane for the latter. Another big difference between these two regimes lies in the field structure of the modes. The QNMs of the former are Mie-type modes, while for the latter they are localized modes in the sense that the associated fields are concentrated in specific regions of the particulate medium.

2 Methodogy

The effective refractive index n_{eff} of the random particulate material is extracted from the mean field $\mathbf{E}_{\text{sc}}$ scattered by the computed units, in agreement with the wave equation

$$\nabla \times \nabla \times \langle \mathbf{E}_{\text{sc}} \rangle - n_{\text{eff}}^2 \frac{\omega^2}{c^2} \langle \mathbf{E}_{\text{sc}} \rangle = 0 \tag{1}$$

which links these two quantities [3]. In other words, the computed units can be considered as the constitutive configurations of a statistical ensemble, and they differ from one to another in the position of the particles, all other parameters (fill-factor, size of particles, etc.) being kept constant. The mean field is obtained by averaging the field scattered by all the computed units of the ensemble. Such a mean field is then compared to the field scattered by an homogenous domain of refractive index n_{hmg} (i.e., a closed-form problem), having same size and shape as the computed unit. When the field scattered by the homogeneous domain fits the numerical data, then $n_{\text{eff}} = n_{\text{hmg}}$.

In a nutshell, we operate here on the shape of the ensemble's microstates to investigate the impact on the extracted n_{eff} and, in addtion to that, we study the corresponding evolution of the eigenmodes of these microstates.

Abstract: We study experimentally and theoretically the dynamics of wave packets at exceptional rings stemming from Dirac points in a photonic honeycomb lattice. We demonstrate a new effect: the transverse non-Hermitian drift in the reciprocal space, useful for beam steering. Its description is based on biorthogonal quantum metric.

The control of non-Hermiticity opens new opportunities in photonics. Non-Hermitian systems often exhibit exceptional points, characterized by the coalescence of the eigenvectors and the reduction of the number of eigenvalues. These points have been extensively studied in the past few years, especially in photonics [1]. The square root behavior of the eigenvalues leads to high sensitivity [2]. It can be traced back to the quantum metric, which diverges close to exceptional points [3]. While the properties of the dispersion and the group velocity were analyzed quite extensively [4,5], the dynamic behavior of wavepackets at the exceptional rings has not been deeply studied yet. This dynamics provides a better microscopic understanding of the macroscopic transport phenomena (as for the anomalous Hall effect), and because of the possible practical applications. It is often influenced by the quantum geometric tensor that includes the Berry curvature and the quantum metric [6]. This led to an important question of the choice of the quantum metric for the description of non-Hermitian systems [7]. Despite the hot debate, the question is still open [8].

In this work, we use a honeycomb photonic lattice in rubidium atomic vapors in the regime of electromagnetically-induced transparency (EIT) to unveil the role of the quantum metric. We introduce non-Hermiticity by inducing different losses on A and B lattice sites, which results in the transformation of Dirac points into exceptional rings. This transition is evidenced by the qualitative change in the probe dynamics: we observe a transition from conical diffraction to non-Hermitian spatial broadening. The scaling of the size of the wave packet with the non-Hermiticity magnitude is quantitatively determined by the quantum metric. Next, we demonstrate both experimentally and theoretically the presence of a non-Hermitian counterpart of the anomalous Hall effect. We observe a drift of the probe wavepacket in the reciprocal space. This drift occurs not only in the direction of the gradient of the imaginary part of the energy, but more surprisingly, also in the transverse direction. We call this effect the transverse non-Hermitian drift and demonstrate that it is entirely due to the non-orthogonality of the eigenstates and requires the biorthogonal quantum metric for its description [9]. The resulting non-Hermitian reciprocal-space dynamics can be applicable to beam steering.

Scattering-Matrix-Based Optical Property Analysis and Simulation Acceleration for Periodic Photonic Structures and Metasurfaces

Yijia Cheng[1], Chengnian Huang[1], and Wei E. I. Sha[1*]

[1]College of Information Science and Electronic Engineering, Zhejiang University, Hangzhou 310027, China
[*]corresponding author: 12131036@zju.edu.cn (Y. Cheng); weisha@zju.edu.cn (W. E. I. Sha)

Abstract: The scattering matrix method (SMM) enables spectral/field analysis of periodic photonic structures. Leveraging S-matrix physical properties, finite-difference matrix differentiation accelerates complex pole extraction in band-structure eigenvalue solutions. By decomposing non-periodic metasurfaces into coupled quasi-periodic subunits with parallel computation, SMM extends to large-scale aperiodic simulations bypassing full-wave modeling.

As a widely-used mode matching method as well as a semi-analytical model, scattering matrix (S-matrix) method not only provides excitation solution to accurately predict the behavior of light in photonic structures but also allows for corresponding eigenvalue analysis and band diagram calculation, which makes it an effective solver for some novel photonic structures.

Regarding periodic photonic structures, the S-matrix of a whole structure can be obtained by the Bloch mode expansion and layer-by-layer analysis for generating and cascading S-matrices in all layers, respectively. By giving the input vector, the reflection, transmission, and absorption coefficients can be calculated. Furthermore, the eigenvalue analysis can be implemented through finding poles of the determinant of inverse of S-matrix. To find the complex poles, we calculate the derivatives of complex S-matrix with iterative Newton-like method

$$\omega_{n+1} = \omega_n + 2\frac{\max \operatorname{eig} S'(\omega_n)}{\max \operatorname{eig} S''(\omega_n)} \tag{1}$$

by using the numerical FD stencils [1] instead of matrix decomposition and inverse, which avoids complex matrix operations and is free from the ill-conditioned inverse of large-dimensional S-matrix. A square-lattice photonic crystal slabs (PCS's) which has rich resonant properties (quasiguided modes [2]) is used as a numerical example to calculate the optical coefficients and band structure of the PCS's model (shown in Fig.1).

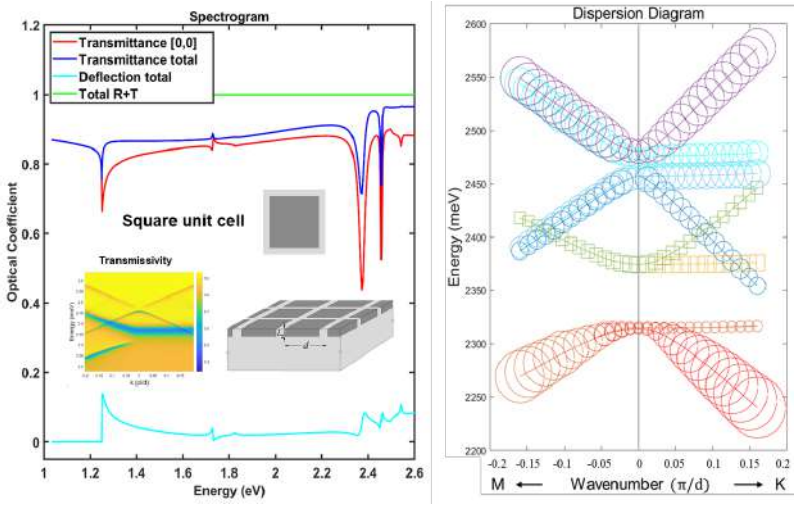

Figure 1. Optical coefficients and dispersion diagram (the imaginary parts of the eigen-energies are denoted by circles or squares with different sizes) of the square-lattice PCS's model.

Building on the SMM's ability to handle periodic structures, it can also be extended to simulate large-area metasurfaces, where electromagnetic simulations remain challenging. For example, metalenses, which are crucial for optical beam manipulation, have large physical dimensions compared to the optical wavelength, complicating accurate simulations. One solution is to apply a locally periodic approximation to aperiodic structures, neglecting the coupling between unit cells. To improve approximation accuracy and account for overlapping domains [3], larger supercells containing multiple unit cells (e.g., 3x3, 5x5, 7x7, etc.) are used to calculate the local field distribution.

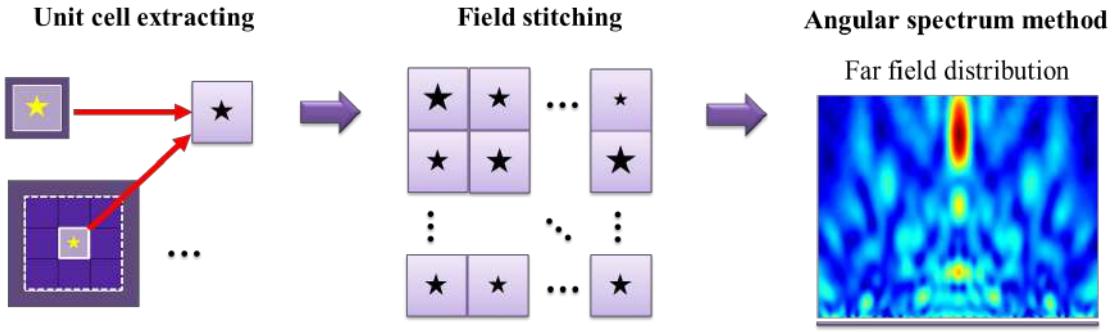

Figure 2. The procedure of the scattering-matrix-based field-stitching technique.

As illustrated in Fig. 2, the scattering-matrix-based field stitching technique developed in this study follows a three-step process. First, supercells of different sizes are employed to simulate the coupling modes of central unit cells. Second, the effective field distributions of these central unit cells are extracted from the supercell simulations and stitched together to reconstruct the complete field of the large-area metalens. To ensure smooth transitions at cell boundaries, a technique involving averaging the phases of fields in overlapping regions is applied. In the final step, the far-field focusing pattern is calculated by angular spectrum method. A 16λ-scale focusing dielectric metasurface consisting of 25x25 silicon disks is used as a numerical example to validate the method, with its far-field focusing pattern shown in Fig. 2. This process helps assess the focusing performance of the metalens, supporting further design and optimization since it substantially lowers time costs in comparison to full-wave simulation, owing to the parallelizability of the unit calculations and the reduced complexity.

Furthermore, the scattering-matrix-based algorithm and its eigenfrequency solver can be further developed to simulate the electromagnetic fields and band structures of emerging photonic structures, such as diffraction gratings with macroscopic moiré patterns and quasi-bound states in the continuum, as well as sources like oscillating point dipoles in addition to plane wave excitations. And the advancements of SMM will facilitate effective mode analysis, contributing to the optimized design of photonic devices.

Abstract: Controlling the directionality of light radiation and scattering is essential to various optical applications. We show that small particles can be employed to generate directional near fields with broad applications in light routing, non-Hermitian sensing, and optical force manipulations.

Controlling the propagation direction of light to achieve directional radiation and coupling is a key objective of light manipulations. Recent studies have uncovered various mechanisms for manipulating the far-field and near-field directionality. In this talk, we show that small metallic particles can be applied to generate intriguing near fields with strong directionality. Specifically, we find that a subwavelength chiral helix particle, under the excitation of linearly polarized plane waves, can give rise to electric and magnetic dipoles with tunable phases and amplitudes [1]. These dipoles can form three types of directional sources—circular dipole, Huygens dipole, and Janus dipole—at the same frequency (such directional sources can also be realized with toroidal dipoles [2]). Therefore, the chiral particle can generate near fields that couple unidirectionally with guided waves. The spin, power flow, and reactive power of the near fields induce unidirectional couplings in three orthogonal directions, i.e., the chiral particle behaves like a “directional dipole dice”.

The circular dipole “face” of the chiral particle can give rise to a lateral optical force perpendicular to the propagation direction of the incident light, if the particle is placed on a substrate [3, 4]. Interestingly, the direction of the lateral force is decided by the spin of the circular dipole and thus the handedness of the chiral particle. For the particles with opposite handedness, the lateral force points in opposite directions. Thus, the mechanism can be applied to sort chiral particles or molecules. In addition, the emergence of the lateral force is accompanied by the directional excitation of surface waves (in the case of metal substrate) or guided waves (in the case of dielectric substrate) due to the property of spin-momentum locking.

Circular dipole can also be induced in small spherical particles under the illumination of circularly polarized light. For two spherical particles sitting on a waveguide, the excited circular dipoles can couple unidirectionally through the waveguide, protected by the spin-momentum locking of the guided wave. This unidirectional coupling naturally leads to a second-order non-Hermitian exceptional point [5], which does not rely on tuning system parameters such as loss or gain. At the exceptional point, the two particles exhibit dramatically different responses—one particle has a typical Lorentzian response, while strong interference happens to the other particle. By arranging multiple spherical particles on the waveguide, we can realize an arbitrary order exceptional point with its order directly decided by the number of the particles. The system exhibits enhanced sensitivity to external small perturbations due to the higher order exceptional point.

Abstract: The exploitation of Bound States in the Continuum (BICs) -resonant eigenmodes with infinite *Q*-factors- promise the implementation of novel devices for many nanophotonic applications, but they are notoriously difficult to excite from the far-field. Here, we report their efficient excitation in periodic arrays of polarizable objects using radially polarized beams.

The last decade has witnessed an effervescent interest in exploiting Bound States in the Continuum (BIC) in both dielectric and plasmonic metasurfaces for many applications [1,2]: lasing, nonlinear optics, electromagnetically induced transparency, polarization conversion, and sensing, among others. These states -which are strongly resonant eigenmodes with eigenfrequencies laying within the radiation continuum- remain perfectly confined and cannot couple to the far-field, thus giving rise to infinite *Q*-factors. Nevertheless, small perturbations, like absorption losses or finite size effects, can destroy pure BICs and result in quasi-BICs, modes with large, but finite, *Q*-factors that can couple to the far field. But the same physical mechanism that gives rise to their diverging *Q*-factors makes their excitation from the far-field notoriously difficult.

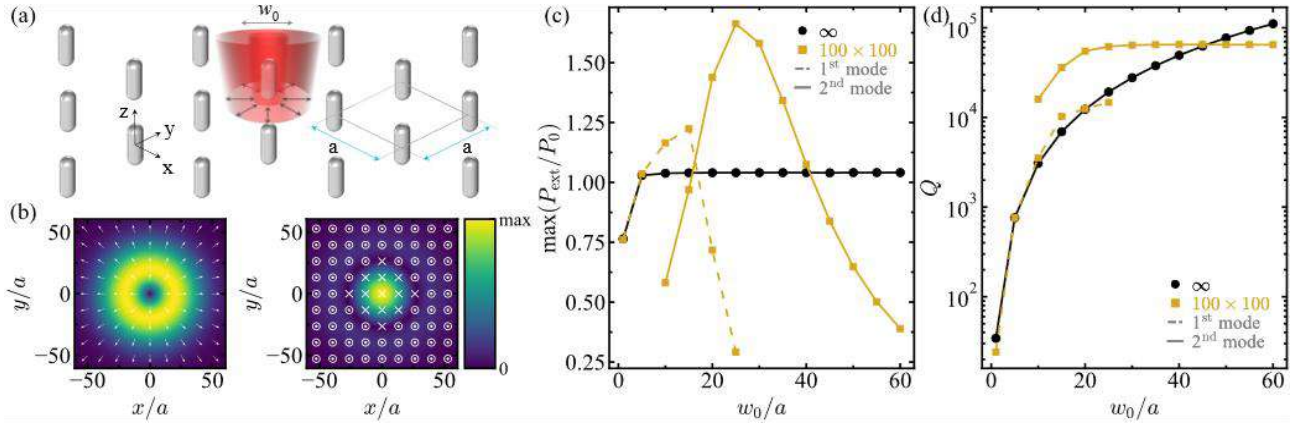

Figure 1. (a) The system under consideration consists of *z*-oriented loss-less elongated polarizable objects arranged in a square array of period *a*, which is excited by a radially polarized beam. (b) Spatial distribution across the array plane for the in-plane (left panel) and out-of-plane (right panel) components of the electric field for a radially polarized beam. (c) Maximum extincted power P_{ext} normalized to the incident power P_0 for infinite and finite arrays as a function of beam width. (d) *Q*-factor for infinite and finite arrays as a function of beam width.

Here, we report the excitation of quasi-BICs in periodic arrays of *z*-oriented elongated polarizable objects using structured beams (Fig. 1a). Exploiting a semianalytical approach based on the combination of the coupled

dipole model and the angular spectrum representation of a light beam [3], we demonstrate that tightly focused radially polarized beams are capable of exciting quasi-BICs more efficiently than any tilted plane wave [4]. For infinite square arrays (lattice period a) of loss-less objects with resonant wavelength $\lambda_r = 1.5a$, we show that increasing w_0 (a variable proportional to the beam width) leads to stronger and spectrally narrower collective resonances (Figs. 1c and 1d). Nevertheless, while the extinction efficiency saturates, the Q-factor increases exponentially with w_0, evidencing the excitation of a quasi-BIC. For finite arrays the behaviour is significantly different (Figs. 1c and 1d). For beam widths smaller than the array size, two different quasi-BICs are excited. The first mode initially follows the behaviour of the infinite array, to later vanish. For the second mode, the extinction efficiency and the Q-factor grow and significantly surpass those of the infinite array. More importantly, these conditions lead to much more efficient quasi-BIC excitation than for any tilted plane wave. For larger beam widths, the Q-factor saturates and the extinction efficiency worsens, eventually vanishing. Our results provide a solid theoretical framework to analyse, understand, and optimize the excitation of quasi-BICs in finite arrays by means of radially polarized beams.

Abstract: Optical anisotropy plays a crucial role in the manipulation of light. Its strength is, however, limited to low values in conventional materials. Transition metal dichalcogenides possess both high refractive index and high birefringence. Here, we investigate optical resonances in nanoplatelets with both geometrical and refractive index anisotropies to control light scattering and emission.

Anisotropy plays a crucial role in manipulating light as the basis for optical components such as polarizers, waveplates, or modulators and phenomena like phase matching in nonlinear optics. The functionality of these devices hinges primarily on the retardance between two orthogonal linear polarizations, which is proportional to both the thickness and the birefringence (Δn) of the material. A large birefringence is thus beneficial for the performance and compactness of such components. Birefringence is a tuning degree of freedom for nanophotonics, for example, in electro-optic modulators, waveguides with reduced cross-talk, and electro-optic polarization conversion. Beyond natural materials, metasurfaces and metamaterials can be constructed to achieve high anisotropy but suffer from losses and fabrication challenges. As a result, natural materials with higher anisotropy than conventional dielectrics or metals are in demand.

Transition metal dichalcogenides are promising birefringent materials due to their layered van der Waals structure, which naturally leads to a large intrinsic birefringence above unity. In particular, molybdenum disulfide (MoS_2) possesses one of the highest birefringences of all natural materials in the near infrared. Such a high birefringence is possible thanks to the presence of strong excitons. They endow MoS_2 with a high in-plane refractive index above 4.5 while making it possible to have higher out-of-plane index contrast than lower index dielectrics. A high refractive index also enables the existence of Mie-type resonances in MoS_2 nanostructures for enhancing and controlling light-matter interaction.

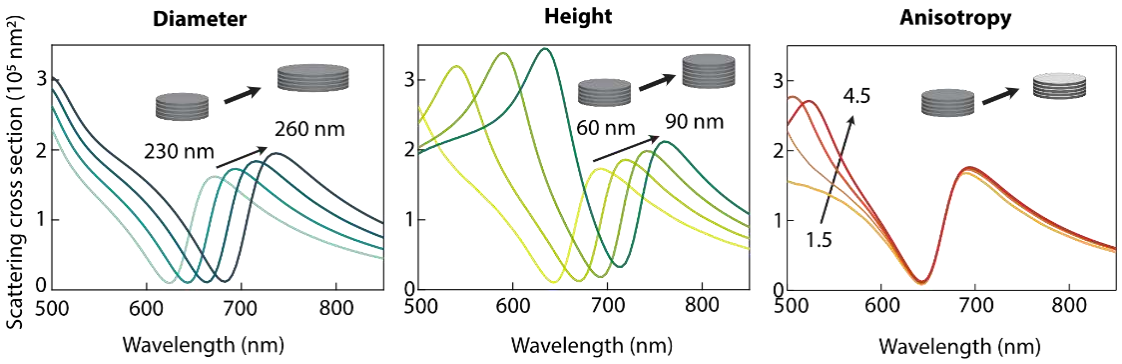

Figure 1. Different dependence of electric and magnetic dipole resonances on geometrical and optical anisotropy.

Here, we study the optical resonances sustained by nanoplatelets made of high refractive index material with high optical anisotropy. These nanoplatelets have both geometrical and refractive index anisotropies. Their high refractive index enables them to sustain electric and magnetic resonances. We find a distinct impact of changing geometric and birefringence on the tunability of electric and magnetic resonances, which we explain using multipolar expansions. Due to their double anisotropy, the optical response of nanoplatelets strongly depends on the direction of illumination, as different illumination conditions can lead to in-plane or out-of-plane electric and magnetic multipoles. We also show that nanoplatelets can control the polarization and directionality of the scattering radiation patterns. Finally, we show preliminary experimental results using MoS_2 nanoplatelets.

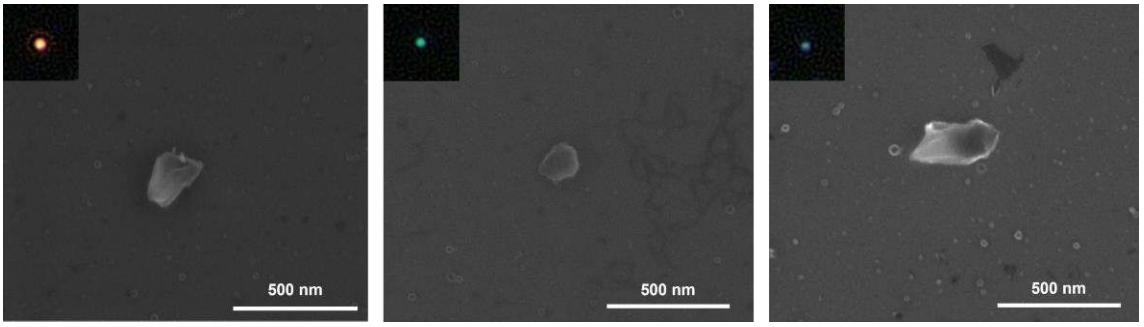

Figure 2. SEM image of MoS_2 nanoplatelets with varying sizes. The insert images are corresponding dark field images, where the nanoplatelet colors indicate different optical resonances.

In summary, high-refractive-index nanoplatelets with intrinsic out-of-plane anisotropy and large birefringence exhibit a wealth of electric and magnetic multipolar resonances that are sensitive to geometry and anisotropy in distinct manners. We envision that nanoplatelets could be used to enhance and direct light scattering and light emission, with applications in light-emitting devices and lasers.

Analysis of a tunable terahertz waveguide using the frequency-dependent HIE-FDTD method

J. Shibayama[1*] and H. Miyao[1]
[1]Hosei University, Japan
shiba@hosei.ac.jp

Abstract

A tunable terahertz waveguide with InAs sidewalls and air buffers is efficiently analyzed using a newly developed frequency-dependent hybrid-implicit-explicit FDTD method based on the trapezoidal recursive convolution technique. The waveguide acts as a TE/TM-pass waveguide, while it acts as a TE-stop/TM-pass waveguide polarizer with the buffer being filled with water.

1 Introduction

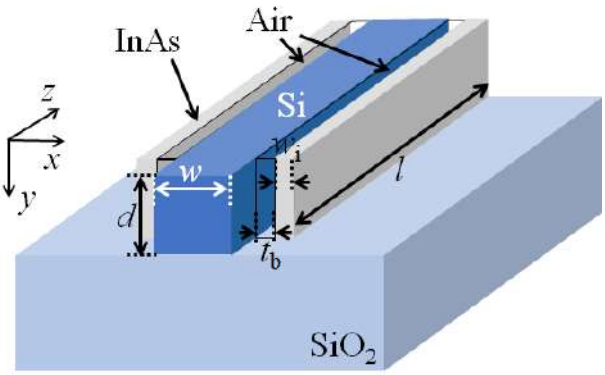
Many devices have been investigated for communication, sensing, and imaging at terahertz (THz) frequencies. We have investigated a surface plasmon resonance (SPR) waveguide sensor in the THz regime [1]. For the sensor, only the TM wave is required as an input source, since the sensor operates on the TM wave. Therefore, we need a waveguide polarizer with TE-stop/TM-pass characteristics. Here we propose a tunable THz waveguide with InAs sidewalls and air buffers. The waveguide acts as a TE/TM-pass waveguide, while it acts as a TE-stop/TM-pass waveguide polarizer with the buffer filled with water. To efficiently analyze the polarizer, we also develop a frequency-dependent hybrid-implicit-explicit (HIE) FDTD method.

2 Discussion

The structure of the waveguide is shown in Fig. 1. The Si core dimension is $w = 50$ μm and $d = 60$ μm. InAs sidewalls with air buffers are placed on both sides of the core, in which $w_{\rm i} = 5$ μm and $t_{\rm b} = 12.5$ μm are used. The temperature is set to $T = 300$ K and the designed frequency is 1.3 THz.

Note that fine meshes should only be used in the horizontal (x) direction for accurate analysis of the thin InAs layer. In addition, InAs is a dispersive material at THz frequencies, which requires the frequency-dependent FDTD formulation [2]. Therefore, we newly formulate a frequency-dependent HIE-FDTD method, in which the implicit scheme is applied only in the x direction. The developed FDTD method greatly relaxes the Courant-Friedrichs-Lewy (CFL) condition, leading to a reduction in computational time with a larger time step size compared to the conventional explicit counterpart (e.g., [3]). In the following analysis, the spatial sampling widths are $\Delta y = \Delta z = 2.5$ μm, $\Delta x = 0.125$ μm. In this case, we can use a time step seize that is fourteen times as large as the explicit counterpart.

Fig. 2 shows the filed distributions where the buffers are filled with water. As can be seen, the TE wave is rapidly attenuated due to surface plasmon excitation, while the TM wave propagates through the waveguide, demonstrating the performance of the TE-stop/TM-pass characteristics. The present field distributions agree quite well with those obtained from the conventional explicit FDTD method (not illustrated) and the computational time is reduced to only 25%. The extinction ratio between the TE and TM modes is calculated to be 20 dB at



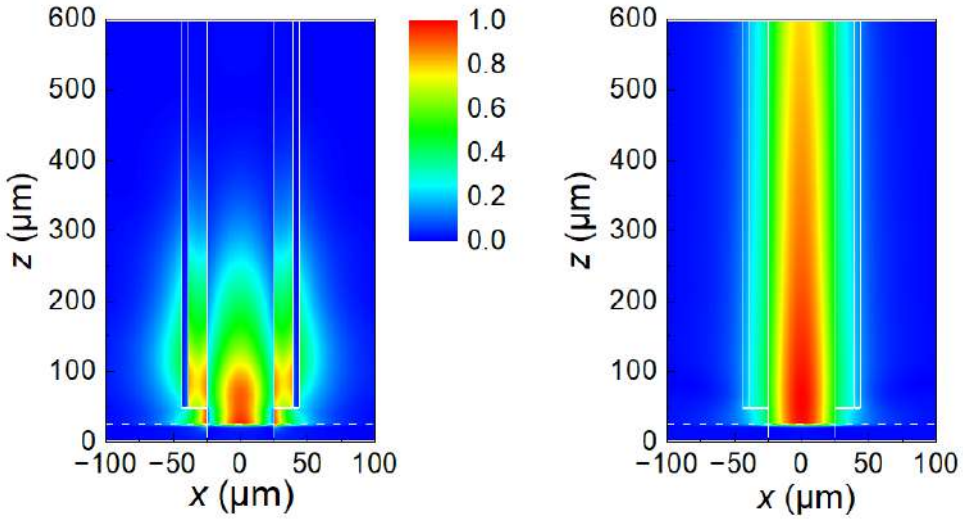


Figure 1: Configuration of a THz waveguide with InAs sidewalls and air buffers.

(b) TM wave

Figure 2: Field distributions.

around $z = 300$ μm. Incidentally, it is confirmed that the waveguide acts as a simple TE/TM pass waveguide for the case without the water in the buffers.

Coupling quantum mechanical molecular excitations with localized surface plasmons using boundary element methods in the time-domain

S. Corni[1,2*]

[1]Dept. Chemical Sciences, Univ. Padua, Italy
[2]CNR Institute of Nanoscience, Modena, Italy
[*]corresponding author: stefano.corni@unipd.it

Abstract: Boundary element methods are powerful numerical tools to solve Maxwell equations, also involving plasmonic nanostructures. We have developed models where such electromagnetic descriptions are coupled with a quantum mechanical description of nearby molecules, specifically in the time domain, so to disclose basic mechanisms of the time-resolved process of molecular nanoplasmonics.

The optical properties of plasmonic nanostructures can be often described very accurately by electromagnetic modeling. This amounts to neglect most of the microscopic details of the nanostructure, treating it as a continuum medium characterized by its bulk dielectric function and its shape and boundaries. Among the different options to solve the resulting Maxwell equations for light-nanostructure interactions, surface integral approaches, numerically solved by boundary element methods (BEMs),[1,2] became popular for their computational efficiency and accuracy. Such methods are also most suitable to set up multiscale modeling approaches of molecular nanoplasmonic systems, i.e., nanostructures interacting with specific molecules. The latter can in fact be described by quantum chemistry methods coupled to BEM for the nanostructures.[3,4] Such modeling was initially limited to frequency domain description of optical phenomena. This however is not the natural framework to describe many of the currently investigated molecular nanoplasmonics phenomena, i.e., those where light pulses and time-resolved detection is used. We have therefore extended such approaches, in the quasi-static regime, to time-dependent versions and exploited their flexibility to interface them with various quantum chemistry descriptions and codes.[5,6] Specific applications ranges from time-resolved Surface Enhanced Raman spectroscopy[7] to hot carrier injections in molecules[8]

The Fourier Modal Method, equipped with Adaptive Spatial Resolution, simplified for shallow gratings

B. Guizal[1*]

[1]Laboratoire Charles Coulomb (L2C), UMR 5221 CNRS- Université de Montpellier, F-34095 Montpellier, France
[*]corresponding author: brahim.guizal@umontpellier.fr

Abstract: We present a simplification of the well-known Fourier Modal Method (FMM) equipped with Adaptive Spatial Resolution (ASR) concept for gratings with subwavelength heights. We show that in this case it is possible to compute the scattering matrix of the structure by solving only one eigenvalue problem (instead of three) which reduces the most expensive computational part of the FMMASR algorithm. This approach is very efficient and thus suitable for periodic metasurfaces.

The Fourier Modal Method[1] is one of the most versatile and efficient methods for modeling diffraction from gratings. This is why it is suitable for modeling metasurfaces based on binary gratings. The problem with this approach is that for metallic structures, it is necessary to truncate the Fourier series representing the fields to a high order implying the use of large matrices (especially in the case of crossed gratings). This situation can be improved by using the ASR concept[2] to accelerate the convergence rate and thus reduce the size of the matrices in play. Still, this remains demanding from the computational point of view, for certain applications, because the heart of the FMM is based on the solution of an eigenvalue problem. This later has a cost scaling with the third power of the dimension of the matrices involved. This can be a severe limitation and hinder the use of the FMM.

On the other hand, an interesting class of metasurfaces is made of gratings with subwavelength thicknesses. In this special case, it is possible (via a Taylor series expansion of the phase propagation matrix) to simplify the FMMASR is such a way that it is no longer needed to solve any eigenvalue problem[3]. This proves to be very efficient in reducing the computational cost.

After recalling the principle of the FMMASR and the details of the corresponding algorithm, I will show how the assumption of subwavelength height leads to a simplified scattering matrix where it is sufficient to solve one eigenvalue problem. Numerical examples will be presented to support this new algorithm.

Photothermal Engineering in Graphene Nanoplasmonics

J. D. Cox[1,2*]

[1]POLIMA—Center for Polariton-driven Light−Matter Interactions, University of Southern Denmark, DK-5230 Odense M, Denmark
[2]Danish Institute for Advanced Study, University of Southern Denmark, DK-5230 Odense M, Denmark

Abstract: We theoretically explore the photothermal response of localized plasmons supported by graphene nanostructures. Our simulations reveal intriguing possibilities to achieve unity-order optical modulation, strong nonlinear light-matter interactions, and chiral-optic effects by resonantly exciting plasmons sustained by absorbed photothermal energy.

Plasmons in electrically doped graphene offer extreme electromagnetic field confinement and active tunability, uniquely addressing the limitations of their counterparts in noble metals. In addition, the linear electronic band structure and atomic thickness of graphene, which are at the origin of its high optoelectronic tunability, together with its low heat capacity, give rise to a substantial photothermal response: optical energy absorbed in graphene is rapidly converted to heat within ~10s of femtoseconds, such that the two-dimensional electron gas reaches temperatures of several thousand Kelvin when illuminated by pulses of moderate (~1 J/m2) optical fluence, and gradually cools by transferring energy to phonons on ~1 picosecond timescales [1].

Here we theoretically explore unique possibilities to leverage the thermal activation and control of localized plasmons in graphene nanostructures for controlling light-matter interactions at the nanoscale. We first discuss the photothermal response of small graphene nanoislands, characterized using atomistic quantum mechanical simulations, and the conditions under which their supported plasmon resonances undergo unity-order changes triggered by the absorption of single photons [2]. We then explore the thermal activation of mid- and near-infrared plasmons in mesoscale graphene nanoribbons (GNRs) of ≤10 nm width, revealing their capability to drive a large coherent nonlinear optical response associated with harmonic generation and the optical Kerr effect [3]. Combined ab initio modelling and self-consistent perturbation theory reveals prominent quantum finite-size effects in these GNRs that impact their supported thermoplasmons, which can be optically induced by fluences commensurate with those used in ultrafast optical experiments. Finally, we investigate thermal magnetoplasmons (TMPs) in graphene nanodisks at finite temperature and in the presence of a static perpendicular magnetic field [4]. Specifically, we show that TMPs in graphene undergo strong hybridization with transitions between thermally populated Landau levels, presenting opportunities to control chiral absorption and chiral thermal emission in a metasurface comprised of a graphene nanodisk array and a gold mirror in a Salisbury screen configuration.

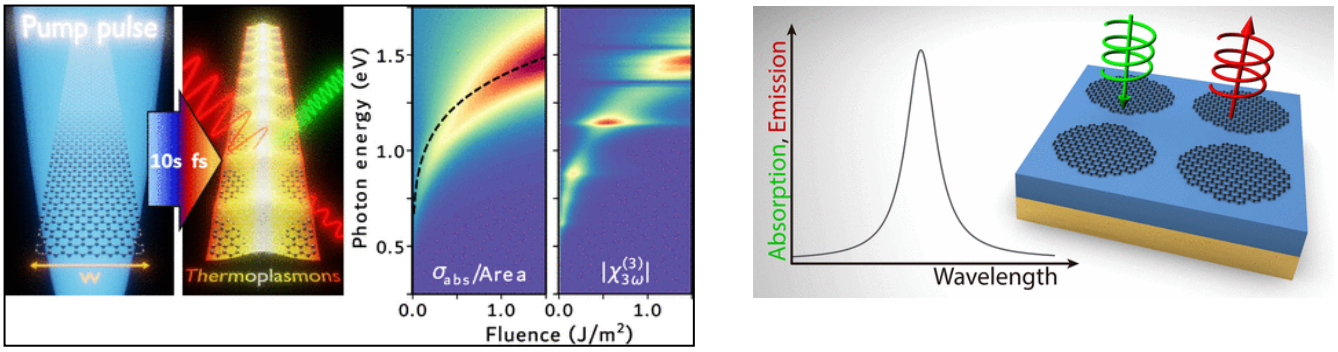

Figure 1 – (left panel) Transient thermoplasmons in narrow graphene nanoribbons that can be probed in ultrafast nonlinear spectroscopy [3]. (right panel) Perfect chiral absorption and chiral emission driven by thermal magnetoplasmons in a graphene nanodisk array [4].

Multiphysics Topology Optimization for Optimal Photon-Electron Interaction in Geometrically Tailored Quantum-Well Environments

Rasmus Ellebæk Christiansen[1,2,*], Ole Sigmund[1,2]

[1] Department of Civil and Mechanical Engineering, Technical University of Denmark,
Nils Koppels Allé Building 404, Kongens Lyngby, 2800, Denmark.

Abstract: We present a multi-physics-based Topology-Optimization framework for maximizing photon-electron interaction by co-location of an electronic and an optical state, solely through tailoring of the environment geometry. Hereby, we seek to achieve electron confinement without the need for embedding quantum dots of different materials, enabling simpler, scalable fabrication.

High-fidelity conversion between optical (photon) and electrical (electron) signals in optical interconnects is critical to the operation of the vast data centers and communication networks underpinning modern society. If such reliable signal-conversion can be achieved at the few-photon/-electron level at the nanoscale, it may be possible to exploit near-lossless information transport offered by photons for realizing on-chip energy-efficient opto-electronic computational devices useful in the green transition and for the next generation of machine learning systems, among others.

Existing devices demonstrating few-particle interaction at nanoscale are often based on quantum dots (QDs); tens of nanometer-sized particles, of different material composition than the background medium, offering near-perfect spatial confinement of electrons due to the electronic energy barrier offered by the QD [1]. Exact positioning of the QDs is required for spatial co-location of the electrons with the photons, which may be geometrically confined to deep sub-wavelength focal spots using extreme dielectric confinement (EDC) [2]. Consistent and stable nano-meter-precise positioning of QDs is an unsolved problem, however.

An alternative to using QDs for electron confinement are the use of quantum wells (QWs); a layer of material confining the electronic states to two dimensions (2D) encapsulated in the lateral (third) dimension by some background medium. Atomic-scale precision in the lateral placement of QWs in a scalable fashion has been achieved, however by the nature of the QWs, electrons are free to roam in the horizontal dimensions, significantly reducing their spatial co-location with the photons in existing EDC devices.

Inspired by recent modelling work [3], we develop a multi-physics topology-optimization [4] based framework for spatial co-location of photons and electrons in the QW solely by geometric means. We tailor EDC structures simultaneously supporting electronic potential barriers, recovering strong spatial confinement of the electrons in all spatial dimensions, hereby co-locating the two particles. We will present our multi-physics framework used to model the photons and electrons assuming time-harmonic field behavior with appropriate boundary conditions truncating the modelling domain. That is, we use a wave-equation derived from Maxwells equations to model the photonic states.

$$\nabla \times \nabla \times \mathbf{E}(\mathbf{r}) - \frac{\omega^2}{c^2}\varepsilon_r(\mathbf{r})\mathbf{E}(\mathbf{r}) = \mathbf{0}, \qquad \mathbf{r} \in \Omega_{EM}$$

Here **E** denotes the electric field, ω the angular frequency, c the speed of light, ε_r the relative permittivity, Ω_{EM} the modelling domain and **r** the spatial coordinate. A wave equation derived from the Schrödinger equation is used to model the electronic states. Which for a single electron takes the form,

$$-\frac{\hbar^2}{2}\nabla \cdot \left(\boldsymbol{m}_{eff,e}(\boldsymbol{r})^{-1} \cdot \nabla\right)\psi_e + (V(\boldsymbol{r}) - E)\psi_e = 0, \qquad \mathbf{r} \in \Omega_{\mathrm{QM}}$$

Here, $\hbar$ denotes planks constant over two pi, m_{eff} the effective mass of the electron, V the background potential, E the electron energy, ψ_e the electronic wave function and Ω_{QM} the modelling domain. We define the normalized overlap of the two wave-functions as our figure of merit to be maximized.

$$\Phi = \int_{\Omega_T} \frac{|\mathbf{E}(\xi, \mathbf{r})|}{\int_{\Omega_{\mathrm{EM}}} |\mathbf{E}(\xi, \boldsymbol{r})|\, d\boldsymbol{r}} \cdot \frac{|\psi_e(\xi, \boldsymbol{r})|}{\int_{\Omega_{\mathrm{QM}}} |\psi_e(\xi, \boldsymbol{r})|\, d\boldsymbol{r}} d\boldsymbol{r}$$

Where ξ denotes the design field controlling the device geometry and Ω_T the target overlap domain. We present the topology optimization model, a set of optimized geometries as well as a study of the effect of imposing various fabrication constraints on the designs.

Metasurfaces with Integrated MEMS structures as Tunable Elements for Spoof Surface Plasmon Polaritons

L. Franke[1], S. Klingel[1], and M. Rahm[1,*]

[1]Department of Electrical and Computer Engineering and Research Center OPTIMAS, Erwin-Schroedinger-Strasse, RPTU Kaiserslautern-Landau, 67663 Kaiserslautern, Germany

Abstract: By proper design, we tailor the dispersion of spoof surface plasmon polaritons on metasurfaces in a wide frequency range to implement on-chip networks with tunable properties, as e.g. tunable filters and beam steering leaky wave antennas. The practical implementation relies on the integration of MEMS into the metasurface unit cells.

Advancing on-chip communication at higher frequencies depends on miniaturizing plasmonic networks. While static metasurfaces reliably guide SSPPs in a broad range of frequencies, real-time reconfigurability at microwave or terahertz ranges remains challenging. Current solutions primarily integrate graphene monolayers with metasurfaces [1,2].

Here, we designed and implemented a tunable low-pass filter for spoof surface plasmon polaritons on a fishbone metasurface. In this structure, the fishbones are formed by MEMS bridges, whose bending can be continuously tuned by application of a bias voltage. Without bias voltage, the surface plasmon polaritons can freely pass the filter and travel from the transmitting horn antenna to the receiving horn antenna (see Fig. 1). By increasing the bias voltage and thus changing the bending curvature of the fishbone bridges, the transmission of the filter can be continuously tuned. In our case, the low-pass filter was operated at a cut-off frequency of 83 GHz. We achieved continuous tuning in the attenuation band with a maximum of 15 dB. The applied approach is readily scalable to higher frequencies, including the terahertz frequency range.

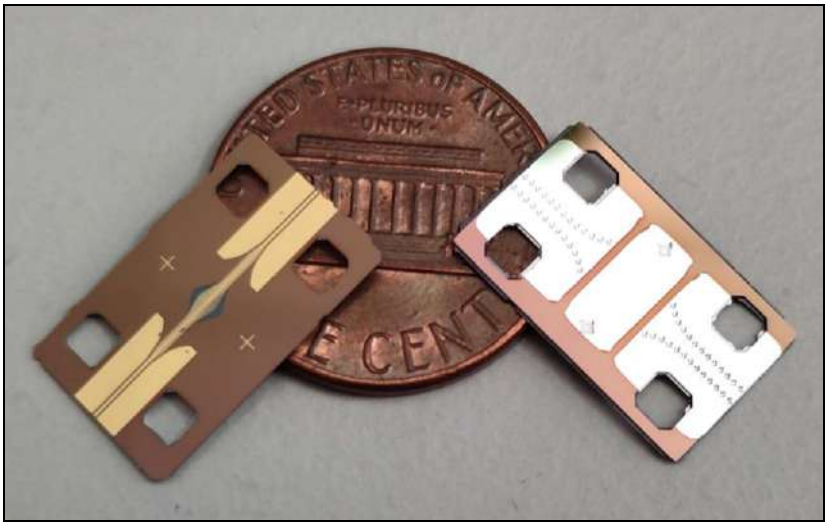

Fig. 2: Photograph of a MEMS-based fishbone metasurface, including the horn antennas.

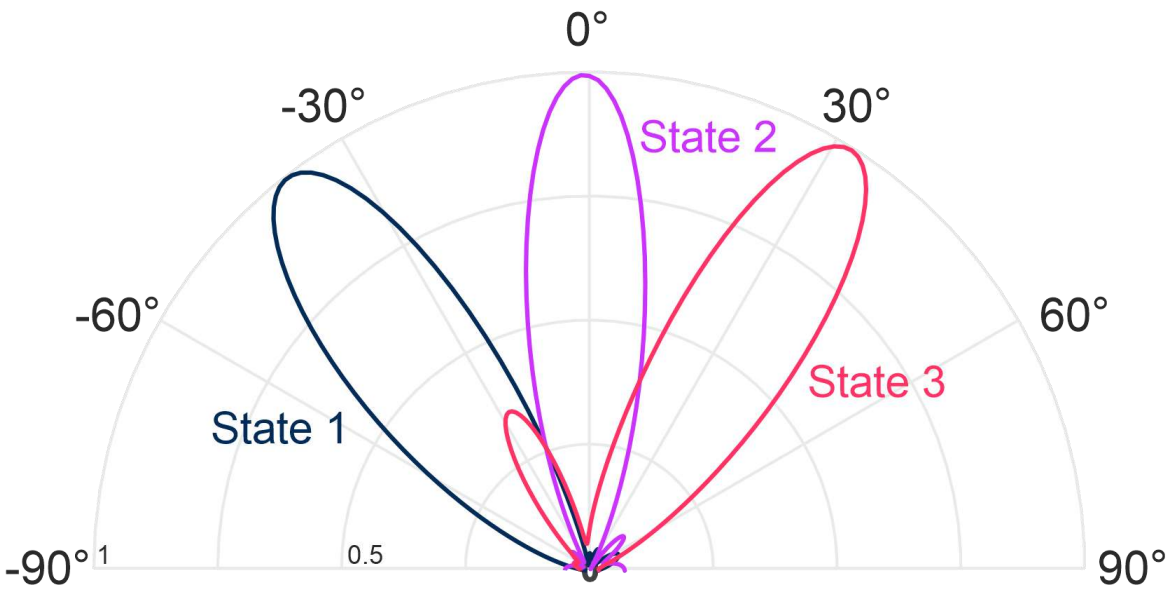

Fig. 2: Simulated beam steering at 57.5 GHz by a MEMS-based metasurface for three different states.

As another example, we designed a beam steering leaky wave antenna that can deflect the beam within a range of more than 60° at an operating frequency of 57.5 GHz. The metasurface again consists of a fishbone structure with tunable MEMS bridges as fishbones. In this case however, the MEMS bridges periodically vary in length, thus forming a diffraction grating that couples the surface plasmon polaritons to a free space propagating mode even without the application of a bias voltage. When a bias voltage is applied, however, the MEMS bridge bending strongly depends on the bridge length, which allows us to deliberately tune the diffraction grating period and modulus. As a result, the diffracted beam can be efficiently steered. Fig. 2 shows the simulated beam steering of microwaves at 57.5 GHz for three different states, where state 1 corresponds to no bias voltage, state 2 to a bias voltage of 105 V and state 3 to a bias voltage of 120 V.

GSTCs: A connection to exact spherical multipoles

Hossein Allahverdizadeh[1], Karim Achouri[1*]
[1]École Polytechnique Fédérale de Lausanne (EPFL), Switzerland
karim.achouri@epfl.ch (corresponding author)

Abstract

Metasurfaces are subwavelength structures that manipulate both local and nonlocal electromagnetic properties, enabling interesting phenomena. Conventional methods like the Generalized Sheet Transition Conditions (GSTC) focus primarily on far-field calculations and often overlook near-field distributions. In this work, we extend the GSTC method by using a multipolar decomposition to connect near-field properties with far-field scattering, offering clearer physical insights. Our method is able to accommodate for oblique incidence by accounting for higher-order multipoles, offering significant advances over traditional approaches that were limited to normal incidence. Additionally, our method properly accounts for the presence of different media on both sides of the metasurface, allowing for effective generalization to various background materials, including layered substrates and embedded elements. By overcoming previous challenges in adapting multipolar decomposition for environments with different media and oblique incidence, our method creates a more systematic approach to interpreting metasurface behaviors in complex scenarios.

"Metasurfaces exhibit fascinating phenomena by manipulating the electromagnetic properties of local elements and introducing nonlocal effects throughout the structure, allowing researchers to flexibly control wave scattering properties. Several modeling techniques have been developed to offer reliable methodologies for describing the effects of these structures, among which the Generalized Sheet Transition Conditions (GSTC) method is a key approach [1]. The GSTC consists in calculating fitted susceptibility tensors based on far-field incident and scattered waves, considering an equivalent imaginary boundary sheet. Although the GSTC show promising results, it predominantly emphasizes far-field calculations, with limited attention to the near-field distribution. Moreover, the technique has been mostly limited to dipolar responses with local interactions.

In this study, we use a multipolar decomposition as a bridge to connect near-field characteristics to the GSTC by calculating equivalent currents for the sheet and the corresponding near-field densities. This approach not only enables a deeper understanding of complex near-field distributions, particularly for intricate unit cell structures and phenomena like Bound States in the Continuum (BICs), but also provides insights into the physical effects within the unit cell. Using this method, susceptibility tensor calculations become less opaque and more systematic. This approach sheds new light on the susceptibility tensors, transforming it from a 'black box' into a tool with tangible physical interpretation.

Additionally, we extend our method to accommodate oblique incidence, addressing limitations in previous studies that focused solely on normal incidence. Our approach introduces new contributions from higher-order multipoles in angular regimes. This generalization is not achieved merely by incorporating additional higher-order multipoles; rather, it involves accounting for the transverse components of the wave vector present in oblique incidence. These transverse components can excite extra resonances within the object, leading to novel contributions in both radiative and non-radiative regimes. In complex scenarios, such as those involving accidental BICs, it becomes essential to investigate these methods thoroughly and map the resulting multipolar distributions to their radiation characteristics, thereby elucidating the interactions among the emergent modes.

Furthermore, adapting multipolar decomposition to different background materials has proven challenging in previous works. Until now, there was no straightforward method for cases involving multi-media environments and oblique incidence. A common approach based on Green's functions has been both challenging and computationally intensive, particularly when layered substrates are considered: breaking the structure inversion symmetry typically leads to the emergence of higher-order multipoles and makes its implementation more challenging [2]. By contrast, our method employs boundary conditions, treating the metasurface as an equivalent current sheet with an effective surface current given by [3, 4]

$$\mathbf{J}_{\mathrm{s}} = j\omega\mathbf{p} + \nabla\times\mathbf{m} - \frac{j\omega}{2}\nabla\cdot\mathbf{Q} - \frac{1}{2}\nabla\times(\nabla\cdot\mathbf{S}) + \ldots + \frac{(-1)^{n-1}j\omega}{n!}\nabla^{n-1}\cdot(\mathbf{P}_n) + \frac{(-1)^{n-1}}{n!}\nabla^{n-1}\cdot(\nabla\times\mathbf{M}_n), \quad (1)$$

where $\mathbf{J}_{\mathrm{s}}$ is expressed in terms of the multipolar components $\{\mathbf{p}, \mathbf{m}, \mathbf{Q}, \mathbf{S}, \mathbf{P}, \mathbf{M}\}$ that respectively correspond to electric dipole, magnetic dipole, electrical quadrupole, magnetic quadrupole, n^{th}-order electric multipole and n^{th}-order magnetic multipole. The figure below compares the fields scattered obliquely by a metasurface, computed using COMSOL and our method. The subscript c denotes the results of COMSOL, while g represents those obtained using the GSTC method.

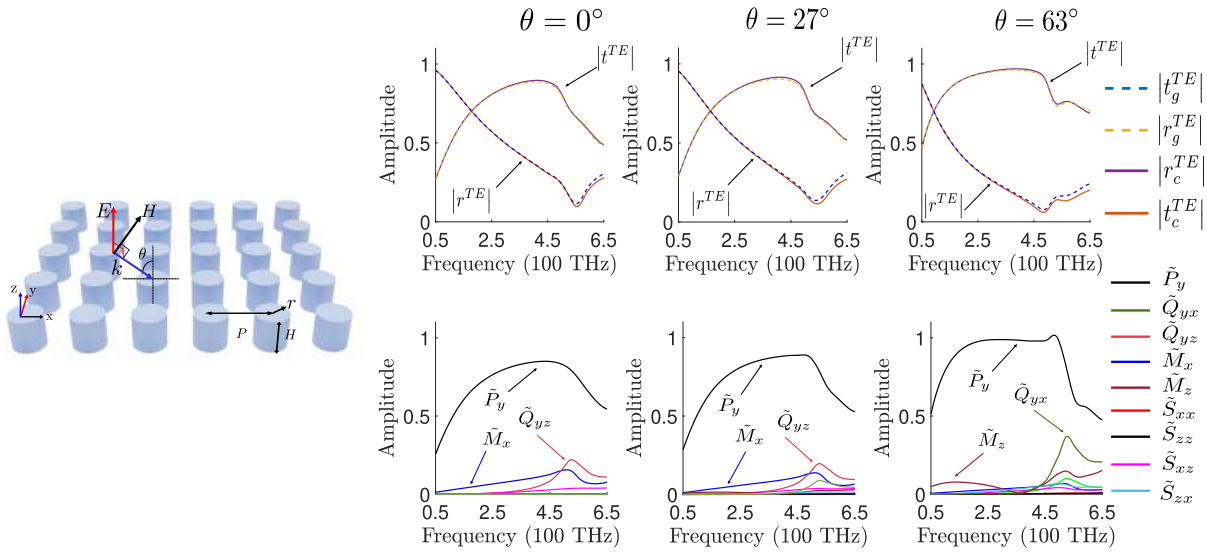

Figure 1: Simulation and theoretical results for nano-gold cylinders for $P = 225$ nm and $H = 95$ nm and $r = 100$ nm under TE illumination for three incidence angles of $\theta = 0°, 27°, 63°$.

Abstract: Efficient solution of inverse problems is ubiquitous across many disciplines in engineering and physics. In this manuscript, we introduce physics-informed multi-channel Bayesian optimization (BO) and apply it to inverse design problems in nanophotonics and nanometrology. By learning the vector-valued physical properties of numerically simulated systems, from which the final cost is constructed, our approach achieves faster convergence compared to other optimization methods.

Bayesian decision theory combined with Gaussian processes (GPs) [1] has emerged as a robust machine learning tool for approximating and optimizing different cost functions associated with the physical process under investigation. Gaussian process posteriors are constructed by applying Bayesian conditioning on all observed cost evaluations, creating a stochastic model that represents the underlying objective function. This technology is particularly useful in the context of inverse device design due to its inherent ability to quantify model uncertainty in the unexplored regions of device's parameters, where the observed cost evaluations are sparse. Such uncertainty quantification is essential for the development of efficient active learning algorithms, where the candidate designs are chosen selectively in order to improve the overall search process and decrease the total number of iterations. In practice, when dealing with nanophotonic devices of arbitrary shapes and materials, solving an inverse problem and finding an optimal device design for a given functionality entails a series of calls to Maxwell's numerical solver which is often time- and resource-intensive [2]. The Bayesian algorithm effectively reduces the number of forward solver evaluations needed to find good device candidates by strategically balancing exploration of the search space with exploitation of the promising parameter regions, leveraging information from all previous cost evaluations resulting in sample-efficient search processes.
The inverse design task in nanophotonics is typically formulated as an optimization problem, where the final scalar objective to be minimized in the space of device's parameters is defined as the L_2 norm between the target vector $\mathbf{y}$, representing the desired device functionality, and the candidate vector $\mathbf{y}'$ obtained by numerical simulation of the structure suggested by the optimizer. Directly modeling the scalar objective $\|\mathbf{y} - \mathbf{y}'\|_2$ with GP inherently leads to a loss of information as this objective is strictly positive in the search space, whereas the individual components of the vector-valued functions $\mathbf{y}$ and $\mathbf{y}'$ can take on both positive and negative values. The consequences of this information loss can result in a slower convergence of the classical BO and suboptimal designs.
To tackle this issue, we propose multi-output Gaussian processes to learn the components of physically meaningful vector-valued observation $\mathbf{y}'$ directly, from which the final objective surrogate is constructed. This approach allows us to extract more information from the underlying physical processes leading to the more accurate surrogate model of the final objective. As a result, we dramatically accelerate inverse problem solving and reach better final structure designs

compared to classical single-channel BO and several well known heuristic methods. Additionally, we extend this concept to the optimization of scalar objective functions derived from an *arbitrary* non-linear function of components of $\mathbf{y}'$, significantly broadening the applicability of our approach to a wide range of inverse problems.
As a representative example, here we demonstrate an inverse design of a nanostructured beam splitter, aiming to distribute light equally across all diffraction orders [3]. Therefore, the final design objective subject to minimization can be defined as the variance function of the simulated diffracted power fluxes with the constraint on the specified total transmission efficiency. In each iteration of the algorithm, we simulate the beam-splitter structure with finite-element method implemented in the solver *JCMsuite* [4] and extract the diffracted power flux vector $\mathbf{y}'$ which we learn with multi-output GP. The final variance objective is assembled from these *learned* quantities and minimized with the help of acquisition function of choice. From Figure 1 it is clear that multi-channel BO outperforms single-channel BO and heuristic methods in the number of iterations needed to find a good beam-splitter candidate.

Abstract: Heavily doped semiconductors have emerged as an enabling platform for mid-infrared photonics, leveraging free electrons to achieve strong and tunable nonlocal-nonlinear light-matter interactions. In this talk, we will discuss recent theoretical and experimental studies on third harmonic generation and Kerr nonlinearity in heavily doped semiconductors, in which hydrodynamic contributions dominate.

Heavily doped semiconductors have emerged as a promising platform mid-infrared photonics, providing tunable optical properties with low optical losses. These materials achieve their unique optical behavior through free-electron densities on the order of 10^{18}-10^{19} cm^{-3}, which allows precisely tuning the plasma wavelengths simply by adjusting doping levels. Importantly, free-electrons in heavily doped semiconductors exhibit quantum hydrodynamic behavior, which together with their low effective electron mass can leads to strong nonlocal and nonlinear light-matter interactions. Moreover, heavily doped semiconductors are compatible with already mature fabrication processes, making them a compelling alternative to traditional noble metal-based plasmonics.

The behavior of these materials can be understood and predicted using a hydrodynamic theory (HT) that captures free-electron dynamics, accounting for quantum pressure, nonlocal electron density variations, and convective dynamics, leading to a more accurate description of both linear and nonlinear optical responses, including nonlinear optical effects up to the third order [1]. While these effects are typically negligible in metals, they dominate in heavily doped semiconductors due to their lower carrier density. We will discuss how recent experiments on third-harmonic generation (THG) in InGaAs nanoantennas have revealed that hydrodynamic nonlinearities dominate over traditional lattice contributions [2]. These hydrodynamic contributions boost THG efficiency to control and enhance optical nonlinearities in plasmonic semiconductor nanostructures.

Unlike noble metals, where nonlinear interactions are largely confined to surfaces, these semiconductors support charge density waves known as longitudinal bulk plasmons (LBPs), which extend deep into the material. LBPs are intrinsically nonlocal excitations that fulfill $\varepsilon(\omega, \mathbf{k}) = 0$, where ε is the permittivivty and ω and $\mathbf{k}$ are the frequency and wavevector respectively. LBPs can trigger exceptionally large nonlinearities. Building on this, we have developed a theoretical framework to describe Kerr-type nonlinearities by combining metallic gap plasmons strongly coupled to LBPs in hybrid nanopatch antennas [3]. In this design, LBPs provide a large nonlinear interaction volume, while gap plasmons confine light to subwavelength dimensions, amplifying the nonlinear response. Using a time-domain method to solve hydrodynamic-Maxwell equations, we have demonstrated optical bistability at a ultralow threshold of 1 mW/μm. This effect arises from a feedback loop in which the Kerr nonlinearity shifts the LBP resonance, increasing reflectance hysteresis by 60%, a feature that

could be crucial for applications in optical memory and logic gates. Additionally, we study the electrostatic tuning of these nonlinear properties using metal-oxide-semiconductor (MOS) structures with gold electrodes and ultra-thin hafnium dioxide layers [4]. Our theory incorporates electrostatic and hydrodynamic frameworks to describe the electronic dynamics, demonstrating electrically tunable linear and nonlinear modulation. Specifically, applying a voltage bias dynamically modulates the free-electron density from depletion to accumulation, effectively tuning the plasma wavelength with a sensitivity of 0.89 μm/V. This control reduces bistability thresholds to just 10 μW, critical for next-generation reconfigurable photonic devices.

Finally, we translate these effects into practical photonic circuits. We have designed hybrid waveguides incorporating a 3.5 μm InGaAs core, evanescently coupled to a 30 nm heavily doped InGaAs layer, supporting free-electron Kerr-type nonlinearities [5]. This configuration supports long-propagating modes with very high nonlinear coefficients, surpassing traditional waveguides. Based on this, we design a Mach-Zehnder interferometer capable of achieving 60% transmission modulation as a function of the input power.

These advances position heavily doped semiconductors as promising platform for mid-IR photonics by combining highly nonlinear and nonlocal responses with electrostatic gating for tunability, with potential for ultra-fast (<1 ps switching), low-power photonic devices. Moreover, the compatibility of heavily doped semiconductors with existing foundry-compatible fabrication techniques makes large-scale adoption feasible.

Tunable plasmonic metasurfaces with epsilon-near-zero semiconductors: The case for a quantum carrier model

Abstract: We model MOS capacitors using the drift-diffusion, density-gradient and Schrödinger-Poisson theories, connecting carrier distributions to permittivity distributions via the Drude model, then to electrodynamic computations to determine the optical performance of devices. This comprehensive approach enables accurate predictions of the voltage-gated performance of tunable plasmonic metasurfaces and high-speed electroabsorption modulators.

Resonant nanometallic structures, such as plasmonic nanoantennas, are essential to the conversion of light to surface plasmon-polaritons (SPPs) localized to ultra-small volumes. Such structures can provide highly enhanced fields, strong confinement, high surface sensitivity, and can double as a device electrode for applying voltages or passing currents to active regions in optoelectronic devices. In optoelectronics, metallic nanostructures supporting SPPs can be exploited for high-performance beam-steering devices and electro-optic modulators [1-6].

Metal oxide semiconductor (MOS) capacitors are useful electronic structures for enabling tunable metasurfaces [1-5] or high-speed electroabsorption modulators [6-8] where the metal contact also operates as a plasmonic nanostructure. Indium tin oxide (ITO) is of interest as the semiconductor in such MOS structures, as the real part of its optical permittivity can be driven through zero to become negative under accumulation, enabling epsilon-near-zero (ENZ) effects which further enhance fields in tandem with plasmonic enhancement. The carrier density profile produced under accumulation in such MOS capacitors is required to determine the associated permittivity profile following the carrier dispersion effect. The permittivity profiles are then used in optical computations to determine the gated optical response of surface plasmons supported by nanostructures incorporating MOS structures.

The carrier density profile in MOS capacitors can be computed under gating using two classical theories - conventional drift-diffusion (CDD) and density-gradient (DG) - and a self-consistent Schrödinger-Poisson (SP) quantum theory [7]. Under accumulation the predictions made by the CDD and SP models differ considerably, such that the former results in one ENZ point but the latter leads to two, as can be appreciated from Fig. 1. Consequently, the CDD model significantly underestimates perturbations of SPPs and yields incorrect details in SPP fields near ENZ points. The discrepancy is large enough to invalidate the CDD model in MOS structures on ENZ materials under accumulation, strongly motivating a quantum carrier model in this regime. Once calibrated the DG model approximates well the SP model while being computationally more efficient.

We discuss application of these models to tunable metasurfaces [5] and high-speed electroabsorption modulators [8]. Our approach consists in modelling the electrostatic performance of the MOS capacitor using the CDD, DG and SP theories, then connecting the resulting carrier distributions to permittivity distributions via the Drude model, and then carrying out electrodynamic computations to determine the optical performance of

devices. This comprehensive approach enables accurate predictions of the voltage-gated performance of tunable metasurfaces and high-speed electro-optic modulators.

An FFT-accelerated PML-BIE method for 3D acoustic scattering problems in layered media

Hangya Wang[1] and Wangtao Lu[1*]
[1]Zhejiang University, China
wangtaolu@zju.edu.cn (corresponding author)

Abstract

For a 3D acoustic scattering problem in a two-layer medium with an axisymmetric interface, we use PML to truncate the unbounded domain, PML transformed Green's functions to derive boundary integral equations, and design FFT-accelerated high-accuracy quadrature rules. Numerical examples demonstrate the effectiveness of the PML-based BIE solver.

1 Introduction

This paper is concerned with three-dimensional acoustic wave scattering in two-layer media, where the two homogeneous layers are separated by a locally perturbed plane featuring an axially symmetric perturbation. A fast novel boundary integral equation (BIE) method is proposed to solve the scattering problem within a cylindrical perfectly matched layer (PML) truncation. We use PML-transformed Green's functions to derive BIEs in terms of single- and double-layer potentials for the wave field and its normal derivative on the boundary of each truncated homogeneous region. These BIEs, combined with interface and PML boundary conditions, form a complete system that accurately approximates the scattering problem. An FFT-based approach is introduced to efficiently and accurately discretize the surface integral operators in the BIEs, where a new kernel splitting technique is developed to resolve instabilities arising from the complex arguments in Green's functions. Numerical experiments demonstrate the efficiency and accuracy of the proposed method, as well as the exponential decay of truncation errors introduced by the PML. Readers are referred to [1] for details.

2 Equations

As shown in Fig 1(a), the scattered field u^{s} due to a given incident wave u^{inc} is governed by:

$$\Delta u^{\mathrm{s}}(\boldsymbol{r}) + \omega_j^2 u^{\mathrm{s}}(\boldsymbol{r}) = 0, \quad \text{for} \quad \boldsymbol{r} = (x, y, z) \in \Omega_j, \tag{1}$$

$$u^{s,1}\big|_\Gamma - u^{s,2}\big|_\Gamma = u_{\mathrm{ref}}^{\mathrm{inc},2}\Big|_\Gamma - u_{\mathrm{ref}}^{\mathrm{inc},1}\Big|_\Gamma, \tag{2}$$

$$\frac{\partial u^{s,1}}{\partial \boldsymbol{\nu}}\bigg|_\Gamma - \frac{\partial u^{s,2}}{\partial \boldsymbol{\nu}}\bigg|_\Gamma = \frac{\partial u_{\mathrm{ref}}^{\mathrm{inc},2}}{\partial \boldsymbol{\nu}}\bigg|_\Gamma - \frac{\partial u_{\mathrm{ref}}^{\mathrm{inc},1}}{\partial \boldsymbol{\nu}}\bigg|_\Gamma, \tag{3}$$

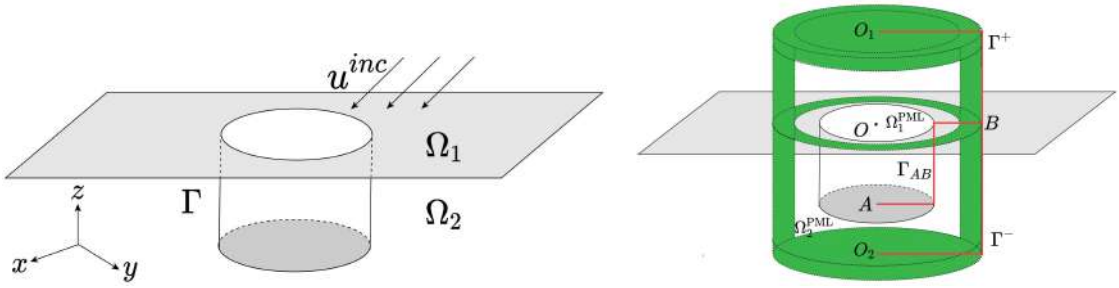
$$\lim_{|\boldsymbol{r}|\to\infty} |\boldsymbol{r}| \left(\partial_{|\boldsymbol{r}|} - \mathbf{i}\omega_j\right) u^s = 0, \quad \text{in} \quad \Omega_j, \quad j = 1, 2, \tag{4}$$

where Γ and the two domains Ω_j are all axisymmetric. For $\boldsymbol{r} = (\rho\cos\theta, \rho\sin\theta, z) \in \mathbb{R}^3$, the cylindrical PML is defined by the complex stretching $\tilde{\boldsymbol{r}}(\boldsymbol{r}) = (\tilde{\rho}\cos\theta, \tilde{\rho}\cos\theta, \tilde{z})$ where

$$\tilde{\rho}(\rho) = \rho + \mathbf{i}\int_0^\rho \sigma_\rho(t)dt, \quad \tilde{z}(z) = z + \mathbf{i}\int_0^z \sigma_z(t)dt.$$

The complexified scattered field $\tilde{u}^s(\boldsymbol{r}) = u^s(\tilde{\boldsymbol{r}}(\boldsymbol{r}))$ satisfies

$$\nabla \cdot \left(\mathbf{A}\nabla \tilde{u}^{s,j}\right) + \omega_j^2 J \tilde{u}^{s,j} = 0, \quad \text{in} \quad \Omega_j, \quad j = 1, 2. \tag{5}$$



By using the complexified Green's functions $\tilde{G}^j(\boldsymbol{r}; \boldsymbol{r}') = \frac{e^{i\omega_j \text{dist}(\boldsymbol{r};\boldsymbol{r}')}}{4\pi \text{dist}(\boldsymbol{r};\boldsymbol{r}')}$, we derive two governing BIEs on the truncated interface Γ_{AB} due to the PML:

$$(\tilde{\mathcal{K}}^j_{AB} - \tilde{\mathcal{K}}^0 1)\tilde{u}^{s,1} \approx \tilde{\mathcal{S}}^j_{AB} \partial_{\boldsymbol{\nu}_c} \tilde{u}^{s,1}, \quad \text{on} \quad \Gamma_{AB}, \tag{6}$$

where $\tilde{\mathcal{S}}^j_{AB}$ and $\tilde{\mathcal{K}}^j_{AB}$ are single- and double-layer integral operators defined only on Γ_{AB} and $\tilde{\mathcal{K}}^0$ is the double-layer operator for the complexified Laplacian. By complexifying the interface conditions (2) and (3) with the cylindrical PML, and by numerically discretizing the BIEs (6), we are able to compute $\tilde{u}^s$ with high accuracy.

Abstract

The fully automated inverse design tools developed at Synopsys can be used for large and complex metaoptics systems, such as hybrid metalens systems, to reduce physical size and specify complex metasurfaces to achieve high performance. Minimal design experience is required of designers because of pre-built knowledge in the design tools.

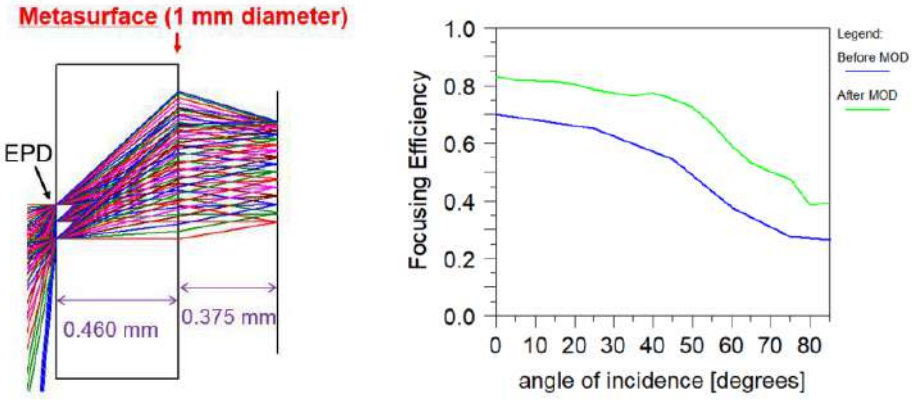
Summary

MetaOptic Designer (MOD) [1], has been widely used to design various metaoptics devices because it is easy to use and requires minimal design knowledge. Its effectiveness and accuracy have been validated both numerically and experimentally for simple applications, such as holographic displays [2] and LiDAR systems [3]. In this paper, we apply MOD to more complex systems.

The first example is a hybrid system co-designed in CODE V and MOD with a singlet to replace a double Gauss refractive lens system with six pieces. The meta-atom used for the metasurface is an Si_3N_4 pillar on a glass substrate with a period of 0.4μm. Its transfer function, both phase and amplitude, is shown Fig. 1(a). As shown in Fig. 1(d), the hybrid system can focus RGB light similarly to the refractive lens system [Fig. 1(c)], but it is 5 times smaller in physical size.

(a) (b) (c) (d)

Fig. 1 Transfer function: (a)phase and (b)amplitude; Focus of RGB (c)refractive lenses and (d)hybrid system.



The performance of the hybrid system in terms of both absolute focusing efficiency (AFE) and Strehl ratio for different wavelengths and different FOVs has been calculated using CODE V [4] and summarized in Table 1. The simple hybrid system can image surprisingly well, although the blue light experiences relatively low efficiency due to low transmission, as shown in Fig. 1(b).

Table 1. Absolute focusing efficiency & Strehl ratio

Wavelength \ FOV	0°	10°	20°	28°
0.6563μm (R)	68.14% & 0.744	66.07% & 0.781	64.15% & 0.730	67.74% & 0.739
0.5876μm (G)	74.31% & 0.862	69.72% & 0.882	68.94% & 0.835	69.90% & 0.831

0.4861μm (B)	69.70% &0.807	56.14% & 0.791	43.52% & 0.685	39.85% & 0.694

The second example is an ultra-wide FOV metalens, which is very challenging to design with a single tool. Here we combine ray-based and wave-based design tools [5], using CODE V to do the initial design shown in Fig. 2(a), then further optimize it in MOD. Comparing the AFE before and after further optimization in MOD demonstrates the AFE has been improved significantly as shown in Fig. 2(b).

(a) (b)

Fig. 2 (a) Initial design in CODE V, (b) Further optimization in MOD with better results

As demonstrated in Ref. [6], multi-metasurface systems perform better than a single metasurface. With the same Si meta-atom library as used in Ref. [6], we quickly and easily created a similar design as shown in Fig. 3. Details will be reported at the META 2025 conference.

Abstract: This presentation discusses recent advances in the design and simulation of large-scale metalenses. We will present a complete simulation workflow from the design of individual meta-atoms to the simulation of complete optical systems. Future directions for research and potential industrial applications are highlighted.

Metalenses are composed of meticulously arranged meta-atoms with sub-wavelength structures. By fine-tuning the geometry and location of these individual elements, we can control the phase, amplitude, and polarization of transmitted or reflected light. Recent advancements in the simulation and fabrication of metalenses [1] have garnered significant interest from both academia and industry. However, the design and optimization of large-scale metalenses remains challenging, necessitating the development of improved simulation methods and the utilization of modern high-performance computing (HPC) systems.

The first step in metalens design often is the construction of a meta-atom database. Here, we will discuss and compare different numerical methods to simulate individual meta-atoms. Specifically, we present the respective strengths and weaknesses of the finite-difference time-domain (FDTD) method and the rigorous coupled-wave analysis (RCWA) approach for this purpose. With a suitable database in hand, the next step typically is the optimization of the arrangement of meta-atoms to achieve the desired overall metalens response. We will again compare different approaches with a focus on adjoint methods which have been particularly effective in the optimization of large-scale lenses.

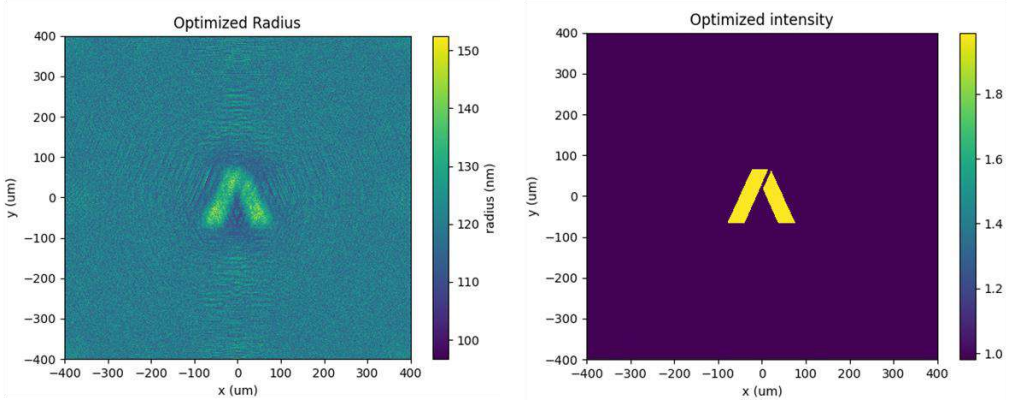

Figure 1. Optimization results for pillar shaped meta-atoms: The optimized radius distribution (left) and intensity in the image plane (right) is shown for a stylized letter “A”.

Optimization is typically performed using approximations such as the local periodic approximation (LPA), making it crucial to verify the final design before manufacturing. To this end, we demonstrate the utilization of multi-GPU systems to conduct full-scale FDTD simulations of optical metalenses with diameters exceeding 1

mm. Once the individual metalens design is finalized and verified, engineers often need to simulate the entire optical system, which may include a combination of traditional optical elements and metalenses. Raytracing is generally the preferred method for such simulations; however, accurately incorporating metalenses in raytracing simulations without compromising efficiency or accuracy remains a challenge. We show that the recently developed Windowed Fourier Transform (WFT) method [2]maintains the expected performance of raytracing while handling metalenses more accurately than previous methods.

Abstract: We study the radiating properties of dimer grating supporting quasi-bound states in the continuum (QBICs) with a novel approach based on the quasi-normal mode method. This approach allows an accurate calculation of the Purcell factor, light extraction and radiative enhancement coefficients for a unique quantum emitter.

Increasing the light matter interaction in photonic nanostructures is fundamental for lighting, communication, imaging, and medicine applications. Metasurfaces, photonic crystals and gratings are today essential nanophotonics platforms used to both enhance the spontaneous emission and extract the emitted light [1]. Optical bound states in the continuum (BICs) constitute an elegant solution to boost the photoluminescence quantum yield. BICs are eigen electromagnetic modes with forbidden radiation or equivalently infinite Q-factors. These BICs must be converted into quasi-BICs (QBICs) of high but finite Q-factors so that they can radiate toward the external medium [2]. The calculation of the radiative properties of nanophotonic structures supporting QBICs is thus crucial for realizing efficient emissive devices. Many such numerical studies use a dipole source placed within the periodic cell [1,3]. However, this approach assumes that periodic emitters produce coherent radiation, in contrast to the inherently incoherent nature of the spontaneous emission process. The periodic set of coherent emitters also introduces spurious interferences that prevent the accurate calculation of radiative properties at off – Γ points. To avoid this issue, the reciprocity principle can be used to calculate the radiated power in the far field emitted by a single quantum emitter in a periodic structure [4]. However, this method fails when dealing with photonic systems supporting dark modes such as BICs since external coupling with a plane wave is forbidden. In this context, the quasi-normal mode (QNM) method appears as an interesting approach as the radiated field of a single non-periodic dipole is reconstructed from the eigenmodes of the structure [5]. In this work, we develop a QNM theory to calculate the radiative properties of a dimer grating which supports QBICs. With this approach we can calculate the normalized decay rate (Fp) as well as the Light Extraction Efficiency (LEE) for a unique quantum emitter (QE). These two factors can be combined to calculate the Radiative Enhancement (RE), product of the LEE and the normalized decay rate.

The dimmer grating consists of a supercell period 2D, made of TiO_2 ribbons of width $w \pm \Delta w$ with $w = D/2$ and height h =150 nm above a quartz substrate. We denote the gap distance $L \pm \Delta L$. The ribbons are embedded within a TEOS layer of 200 nm height. To determine the geometry of the dimmer grating, we introduce the coefficients $\alpha = \Delta w/2w$ and $\beta = \Delta L/2L$. For the regular grating with $\alpha = 0$ and $\beta = 0$ presents a BIC at the Γ-point, for the wavelength of 681.67 nm.

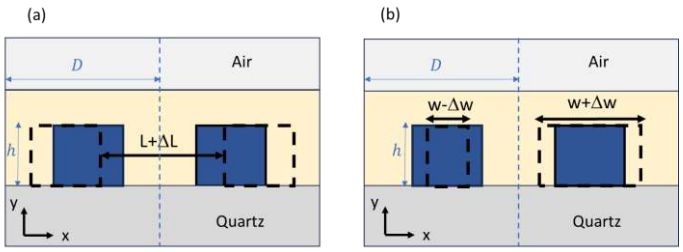

Figure 1: schematic of a dimer grating.

When the in-plane symmetry of the grating is broken by varying the position or the size of the ribbons, the BIC transforms into a QBIC, enabling radiation in the normal direction. To analyze this dynamic, we determine the evolution of the resonant wavelength and Q-factor in the (α, β) parameter space as shown Fig. 2a-b.

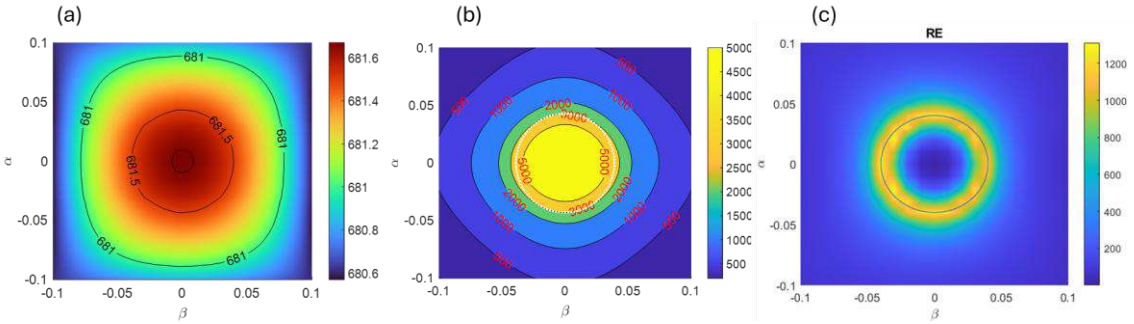

Figure 2:(a), (b), (c) represents respectively the resonant wavelength of the QBIC, the Q-factor and the RE in the parameter space (α, β). The white circle in (b) corresponds to the iso-wavelength λ_0 = 681.5nm.

To get a high Q-factor (larger than 3000) and a feasible dimer grating, we focus on the resonant iso-wavelength of $\lambda_0 = 681.5$ nm. Next, we use the QMN expansion to calculate the RE in the normal direction and for the target wavelength for the QBIC. We observe that the RE reaches very large values up to 1600 when a weak modification of 4\% is either introduced for the size or the gap distance of the dimer. This approach allows us to design the optimal dimer grating able to enhance the spontaneous emission at a given emission direction.

Effect of top metallic contacts on energy conversion performances for near-field thermophotovoltaics

M. Antezza
University of Montpellier, Laboratoire Charles Coulomb, Montpellier, France
and
Institute Universitaire de France, Paris, France
mauro.antezza@umontpellier.fr

Abstract: We study Effect of top metallic contacts on energy conversion performances for near-field thermophotovoltaics. We find behaviors differing substantially from those predicted by previous simplistic approaches, with significant impact on the net radiative power absorbed by the cell and, consequently, on the generated electrical power.

The design of metallic contact grids on the front side of thermophotovoltaic cells is critical since it can cause significant optical and electrical resistive losses, particularly in the near field. However, from the theoretical point of view, this effect has been either discarded or studied by means of extremely simplified models like the shadowing methods, that consist in simply ignoring the fraction of the semiconductor surface covered by metal. Our study [1], based on a rigorous three-body theoretical framework and implemented using the scattering matrix approach with the Fourier modal method augmented with adaptive spatial resolution, provides deeper insight into the influence of the front metal contact grid. This approach allows direct access to the radiative power absorbed by the semiconductor, enabling the proposal of an alternative definition for the thermophotovoltaic cell efficiency. By modeling this grid as a metallic grating, we demonstrate its significant impact on the net radiative power absorbed by the cell and, consequently, on the generated electrical power. Our analysis reveals behaviors differing substantially from those predicted by previous simplistic approaches.

In the rapidly evolving fields of photonics and radio frequency (RF) engineering, accurate and efficient electromagnetic (EM) simulations are essential for driving innovation. However, traditional EM solvers often struggle to keep pace with the growing complexity of modern designs and fail to fully leverage emerging algorithms and computational technologies.

This talk will explore the future of electromagnetic solvers in the era of cloud computing, GPUs, and AI. We will discuss how these advancements enable unprecedented speed and efficiency in tackling complex engineering challenges, including the design and fabrication of photonic integrated circuits (PICs), mission-critical electromagnetic compatibility (EMC) analysis, and AI-driven optimization for next-generation antenna design. By embracing these cutting-edge technologies, EM solvers can unlock new possibilities for faster, more accurate, and more scalable simulations, accelerating progress in photonics and RF engineering.

Inverse design and knowledge discovery in nanophotonics through integration of shape optimization and machine learning algorithms

Reza Marzban and Ali Adibi

School of Electrical and Computer Engineering, Georgia Institute of Technology

Short Abstract: This talk is focused on a new approach for inverse design and knowledge discovery in large-scale nanostructures by combining topological optimization and machine-learning algorithms to enable the optimization of all structural and physical parameters while providing better visualization of the input-output relationship for knowledge discovery through dimensionality reduction.

Summary: With great progress in fabrication technologies, new classes of nanophotonic and metaphotonic devices with a very large number of design parameters have been realized. The large number of design parameters along with the nonuniqueness of the optimal solution has necessitated new approaches for both the design of these structures and providing insight into their operation (i.e., knowledge discovery). Two major classes of these approaches are based on machine learning and shape optimization (e.g., topological optimization) techniques, each with positive aspects and shortcomings.

This talk is focused on a new hybrid approach for the inverse design and knowledge discovery in large-scale nanostructures by combining the unique features of topological optimization and machine-learning algorithms. This approach allows for optimization of all design parameters including geometrical features and physical (e.g., material) parameters of passive and active nanophotonic structures. In addition, by using properly trained dimensionality reduction techniques, visualization of the input-output relationship and knowledge discovery are facilitated, and computational complexity is reduced.

In addition to describing the fundamental aspects of this hybrid technique, its applications to forming functional metaphotonic devices for wavefront engineering will be discussed, and the potentials of this approach as a new paradigm in the design of large-scale nanophotonic structures will be covered.

Adiabatic time modulations vs. Photonic time interfaces

M. Antyufeyeva[1,2], and V. Pacheco-Peña[1*]

Abstract: We develop an in-depth theoretical study on the potential properties of temporal adiabatic modulations of the refractive index of the medium where a wave travels. The results are compared with the field distribution produced by photonic time interfaces demonstrating the potential to mimic time refracted signals.

As it is known, wave propagation can be tailored by *shaping the space* where a wave propagates. i.e., one can place objects of different dimensions and materials (spatial inhomogeneities) along the path where a wave propagates. While such wave control is carried out in the frequency domain where inhomogeneities are only spatially dependent (three spatial dimensions), the recent introduction of time as an additional degree of freedom has opened many opportunities to further manipulate wave-matter interactions [1–3]. One of such examples are photonic time interfaces where the optical properties of the medium where a wave propagates rapidly changes in time from one value to a different value at a certain time [4]. Ideally, time interfaces are modelled using Heaviside functions (or step functions) where the optical properties (permittivity, permeability, refractive index) abruptly change in time). Recent experimental works have demonstrated the existence of time interfaces from water waves up to the optical regime [5–7]. These works are clear evidence that, as long as the time modulation is faster than the period of the wave traveling inside the medium, the main features of time interfaces will still exist (backward and forward waves, frequency conversion, etc.) despite non-zero rising/falling times[8–17].

The main challenge in this context is the fast modulation of the optical properties of the material where a wave propagates which may require complex experimental setups to achieve. Recently, it has been shown that adiabatic modulations can indeed be used to, for instance, reduce the backward wave produced by time interfaces while still enabling frequency conversion [18]. Such scenario is indeed the temporal equivalent of a spatial tapering of waveguides, for instance. However, an interesting question is: is it indeed possible to fully mimic time interfaces using adiabatic modulations of the optical properties of the material where a wave propagates?

Inspired by the opportunities that time varying and spacetime metamaterials can open for a four-dimensional wave control and the importance of time interfaces as the equivalent of spatial interfaces in the time domain, in this work we study the potential of smooth modulation of the optical properties of materials [19]. Specifically, we consider a cavity filled with a material having a time dependent refractive index. For the sake of simplicity, we focus our attention on the case where the impedance remains constant for all times while the permittivity (and then the corresponding permeability) is changed from ε_1 to ε_2 in time following the general expression $\varepsilon(t) = (A\varepsilon_1 + \varepsilon_2 - \varepsilon_1)A^{-1}$ with $A = 1 + e^{-\gamma(t-t_0)}$, and with γ as a parameter used to change the rise/fall time (Δt). As it will be shown in detail during the conference, our theoretical analysis (carried out using the Evolutionary Approach to Electromagnetics in time domain, EAE [20]) allows us to calculate full analytical expressions for the rising/fall times that produce the same total mode amplitudes inside the cavity as that produced by a temporal interface. In order words, we will show how, indeed, there are some rise/fall times for smooth modulation of the optical properties of the medium where it is possible to mimic the same response as the time refracted signal produced by time interfaces. These results may open further potential experimental demonstrations of time

interfaces by relaxing the need of fast time modulated media.

Spin-mediated radiative caloritronics

P. Ben-Abdallah[1,*]

[1] *Laboratoire Charles Fabry, UMR 8501, Institut d'Optique, CNRS, Université Paris-Saclay, 2 Avenue Augustin Fresnel, 91127 Palaiseau Cedex, France*

The Spin Hall effect [1–3] and its inverse counterpart [4–8] are fundamental phenomena in condensed matter physics that have greatly contributed to the progress of modern spintronics. These effects harness the interaction between charge currents and spin dynamics in materials. The Spin Hall effect involves the generation of a transverse spin current when an electric current flows through a material, whereas the inverse Spin Hall effect describes the conversion of a spin current into a charge current, oriented perpendicularly to both the spin current and an externally applied electric field.

In this presentation, I will explore the thermal analogs of these effects, which arise from photon exchanges in networks of magneto-optical materials subjected to an external magnetic field. I will examine how the spin angular momentum of thermal photons interacts with radiative heat flux, which serves as a medium for heat transfer.

First, I will discuss how a temperature gradient within these systems can generate a transverse heat flux and a spatial variation in spin angular momentum [9–11], demonstrating the thermal equivalent of the Spin Hall effect. Then, I will introduce the concept of an inverse thermal Hall effect [12], where a gradient in spin angular momentum within non-reciprocal systems drives a heat flux. This effect opens up new possibilities for thermal management strategies that leverage the localized control of light's spin angular momentum.

The interaction between the spin momentum of light and heat transport introduces an additional degree of freedom, paving the way for innovative energy conversion devices and advanced thermal management technologies.

Predictive Modeling for Ultrafast Photothermal Effects in Nanophotonic Systems

Alessandro Alabastri[1,2]

[1]Department of Electrical and Computer Engineering, Rice University, USA
[2]Smalley-Curl Institute, Rice University, USA
*corresponding author: alabastri@rice.edu

Abstract: This work summarizes recent advances in computational methods to describe ultrafast photothermal phenomena in nanophotonic systems. We introduce predictive modeling frameworks integrating electronic dynamics and thermal diffusion, enabling optimized design and enhanced performance in applications such as photocatalysis, photothermal cancer therapy, and solar steam generation.

Recent developments in nanophotonics have opened unprecedented opportunities for controlling and utilizing electromagnetic energy at the nanoscale, particularly in systems where plasmonic nanostructures convert light into hot electrons and, eventually, localized heating. Accurate modeling of these ultrafast phenomena is critical for applications ranging from photocatalysis to cancer therapy.

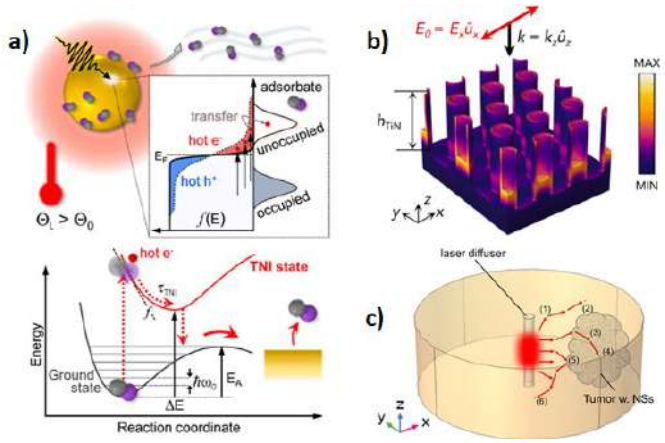

Fig. 1. **a)** Modeling approach for the ultrafast dynamics of plasmonic HCs in the presence of an adsorbate [1]. *Adapted with permission from ACS Nano 2024, 18, 29, 18933–18947. Copyright 2024 American Chemical Society* **b)** TiN metasurfaces as quasi-2D broadband solar absorbers [2]. **c)** Scheme for Nanoparticle Assisted Photothermal Therapy (NAPTT) [3]. *Adapted from Nano Energy, 83, 105828, 2021, Elsevier*

We have developed an original theoretical approach—the Generalized Extended Two-Temperature Model (GE2TM)—to simulate ultrafast energy transfer from plasmonic hot carriers to molecular adsorbates on metallic nanoparticle surfaces [1], Fig. 1a. This approach, accounting for spatial, temporal, and energy resolutions, clarifies how hot electron dynamics and photothermal effects compete during femtosecond-pulsed illumination, leading to nontrivial dependencies on pulse duration, photon energy, and nanostructure geometry. Our framework demonstrates how pulsed illumination conditions can optimize energy transfer efficiency and reaction rates significantly beyond steady-state scenarios.

Upon hot carrier relaxation and electron-phonon scattering, electromagnetic energy is transferred to lattice vibrations as heat. Such heat dissipation in confined dissipative structures can lead to nanoscale heat sources with various applications. For example, we explored the use of ultrathin plasmonic metasurfaces for efficient solar

steam generation [2], Fig. 1b. Our scalable titanium nitride nanocavity arrays achieved over 90% broadband absorption within 250 nm thickness, enabling rapid localized heating and high-performance steam generation. Numerical simulations elucidated the role of quasi-two-dimensional heat dissipation regimes in significantly accelerating evaporation processes, marking a substantial improvement over traditional solar absorbers.

Besides leading to phase changes as in water evaporation, localized heat can also induce other structural changes, such as thermal ablation in live tissues. In this context, we proposed a comprehensive model for nanoparticle-assisted photothermal cancer therapy [3], Fig. 1c. This model combines Monte Carlo-like simulations of photon trajectories, detailed light-to-heat conversion calculations, and bioheat transfer equations that incorporate temperature-dependent tissue properties. By spatially and temporally modulating the laser intensity, we showed that thermal ablation volumes could be increased by 44% while reducing illumination time by 33%, significantly enhancing therapeutic efficiency.

Overall, these computational advances collectively provide robust predictive tools crucial for optimizing nanophotonic designs across diverse photothermal applications, pushing forward our ability to manipulate nanoscale energy transfer processes with precision and efficacy.

Abstract: Terahertz parametric detection offers high sensitivity and, when combined with an injection-seeded terahertz parametric generator, enables measurements with a high dynamic range of 125 dB. We recently found that this technique has a relatively large incident angle tolerance. Here, we evaluate this tolerance and report on its THz scanner application.

Terahertz (THz) parametric detection upconverts THz waves to a near-infrared (NIR) Stokes beam using the inverse process of injection-seeded THz wave parametric generator (is-TPG) [1-4]. This method achieves exceptional detection sensitivity (130 zJ [5]) and dynamic range (125 dB) by combining with is-TPG. It enables various applications, including reagent detection through shields and real-time spectroscopic imaging [1, 6]. This detection process uses THz waves as a seed beam to generate the NIR Stokes beam via upconversion, satisfying a non-collinear phase-matching condition. Typically, THz waves are injected through a Si prism coupler due to the refractive index (nTHz = 5.2) of MgO-doped $LiNbO_3$. However, experiments revealed that detection is possible without an Si prism or strict phase-matching angles, demonstrating large incident angle tolerance. Here we evaluate this tolerance and report on its application in THz scanner measurements.

Firstly, we examined the angular tolerance of THz parametric detection by measuring detection sensitivity at various angles (Fig. 1 (b-e)) and comparing it with 64°(Fig.1 (a)), the non-collinear phase-matching angle. As shown in Fig. 1(f), the input THz wave was generated by is-TPG with a frequency of 1.28 THz. A microchip Nd:YAG laser (wavelength: 1064 nm; pulse width: ~500 ps; output power: 20 mJ after amplification) was used as the pump source, and was split into two beams for is-TPG and THz parametric detection. The THz wave from is-TPG was injected into the $LiNbO_3$ crystal, and the detection Stokes beam was observed with an NIR pyroelectric detector. The input THz wave was attenuated by a calibrated neutral density (ND) filter, and the minimum detectable energy was measured.

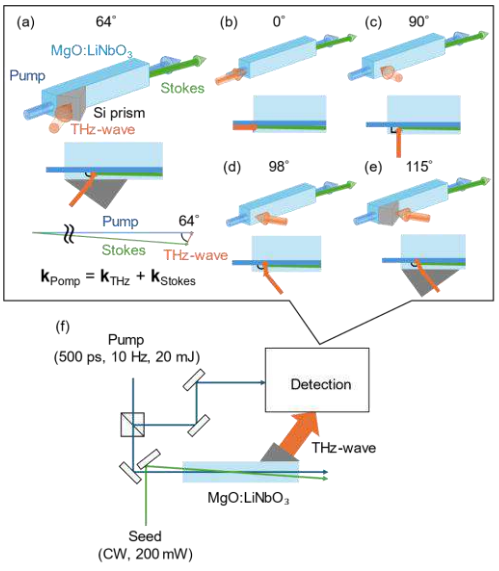

Fig. 1 (a) General THz parametric detection, (b)–(e) the various THz-wave angles of incidence tested: (b) 0°, (c) 90°, (d) 98°, and (e) 115°. (f) Experimental setup overview.

Figure 2 shows the measured minimum detectable energy at each of the angles shown in Fig. 1. THz waves were detected over a very large angular range, from 0° coaxial with the pump beam to 115° in the direction opposite to the pump beam. In the case of conventional is-TPG, the tolerance of the incident angle of the seed beam to the Stokes beam during THz wave generation is as tight as ± 0.03° (FWHM), whereas this condition was significantly relaxed to ±55° (FWHM) in our detection

experiment.

Next, utilizing this large tolerance, we demonstrated a terahertz scanner as shown in Fig. 3. The terahertz wave output from the is-TPG was shaped into a vertically elongated beam using a cylindrical lens and irradiated onto the measurement sample. The transmitted terahertz wave was focused onto a $LiNbO_3$ crystal for parametric detection, transferring the terahertz image onto the detection Stokes beam. By utilizing the large incident angle tolerance, both the terahertz wave and the pump beam were directed onto the same crystal surface. This approach, compared to conventional side-face incidence, enhances the spatial overlap between the pump beam and the terahertz wave, potentially improving image resolution. The detection Stokes beam was then observed using a near-infrared camera to acquire a one-dimensional image of the terahertz wave. The sample was scanned laterally in discrete steps using a translation stage, and the obtained one-dimensional Stokes images were arranged in sequence to reconstruct a two-dimensional image.

The sample, printed with the letters 'T' and 'H' using silver nanoparticle ink, as shown in Fig. 3, was measured at 1.5 THz, and the results are shown in Fig. 4. In both cases, the sample shape was successfully reconstructed, demonstrating the functionality of the scanner.

Understanding collective excitations in finite-sized arrays using discrete-dipole approximation

J. Kelavuori[1], A. Panahpour[1], and M. J. Huttunen[1*]

[1]Tampere University, Finland
[*]corresponding author: mikko.huttunen@tuni.fi

Abstract: Full-wave simulations of diffractive resonances can be accurate but slow. Semi-analytical methods based on lattice-sum calculations provide faster alternatives, with recent adaptations revealing that high-Q metasurfaces can be achieved with small arrays in slow-light environments. Furthermore, lattice-wide simulations not resorting to periodic boundary conditions offer valuable insights into lattice's inter-particle dynamics.

Plasmonic–diffractive metasurfaces have emerged as flat-optics alternatives for lasing [1] and nonlinear optics [2]. Strong light–matter interaction emerging from decreased plasmonic losses naturally improve the capabilities of traditional plasmonic devices based on nanoparticles (NPs). The properties of such structures are often computed using full-wave simulations, such as finite-element or finite-difference schemes. However, such simulations can be moderately slow even when monopartite arrays are investigated while using periodic boundary conditions. This makes designing metasurfaces iteratively with such tools cumbersome, also restricting possibilities to study properties of multipartite arrays.

Semi-analytical computational schemes, such as T-matrix method [3], discrete-dipole approximation (DDA) and lattice-sum approach (LSA) [4], offer faster alternatives for calculating optical properties of metasurfaces. As the name suggests, DDA approximates each NP as point-like dipole, coupled through the electric-dipole radiation pattern, while in T-matrix method electric and magnetic multipoles can be readily included. DDA however offers the fastest scheme due to decreased complexity and is adequate for most metasurface designs. The LSA reduces the computational complexity even further by assuming that each particle experiences identical scattered fields over a finite number of unit cells.

Use of periodic boundary conditions in LSA or full-wave simulations makes it impossible to study collective mode formation in metasurfaces at larger-than-unit cell distances. However, such effects could play a strong role in more realistic arrays consisting of finite number of NPs. As an example, we show in Figure **1** how lattice-wide phase dynamics are important even in periodic arrays of identical scatterers. In Figure **1a),** the plasmonic–diffractive resonance shifts by 10 nm when excited with a Hermite-Gaussian TEM_{20} mode as opposed to fundamental Gaussian mode, due to changed inter-particle phase dynamics across the entire 80×80 plasmonic NP array. This dynamics persists even under plane-wave excitation (Figure **1b)**. Interestingly the dynamics may also explain the observed larger-than-unity transmissions [5], at wavelengths close to the resonance. Given light is not collected over the whole array, the optical power from the outer parts can drive the middle parts due to imperfect phase accumulation, resulting in apparent negative extinction. The dipole-moment distributions in the insets illustrate interesting pattern formation.

In most implementations of the semi-analytical methods, homogeneous surroundings of the NPs are assumed, corresponding to NPs coupling through free-space Green's functions. Recently, we constructed the dipole approximation of LSA inside a mirror waveguide [6]. Surprisingly, this modification revealed interesting dynamics in diffractive resonances; namely their Q-factor is proportional to the group index of refraction of the

surroundings in finite systems, as depicted in Figure **1d)**. This discovery suggests that high-Q metasurfaces could be achieved already with small particle counts, given slow-light can be achieved in the surroundings.

We acknowledge the support of the Flagship of Photonics Research and Innovation (PREIN) funded by the Research Council of Finland (grant no. 320165).

Super-bound States in the Continuum in One-dimensional Gratings on a Substrate

Nan Zhang and Ya Yan Lu*
Department of Mathematics, City University of Hong Kong, Kowloon, Hong Kong
Corresponding author: mayylu@cityu.edu.hk

Abstract: Super-bound states in the continuum (super-BIC) are useful, since they are associated with ultrahigh Q resonances for a wide range of wavevectors. Existing super-BICs are mostly found in periodic structures with up-down mirror symmetry. We show super-BICs in simple gratings on a substrate.

We consider a 1D grating on a substrate with refractive index $n_s = 1.45$, assuming the cladding is air. Each period of the grating consists of two rectangular segments with refractive index $n_1 = 1.45$ and $n_2 = 2.55$, height h_1 and h_2, width w and $L \in w$, respectively, where L is the period. A BIC in such a structure is a guided Bloch mode with frequency ω_* and Bloch wavevector β_* satisfying $\omega_*/c > |\beta_*|$, where c is the speed of light in vacuum. The resonant modes with β near β_* have quality factor $Q \sim 1/|\beta \in \beta_*|^m$, where m typically equals 2. Super-BICs are those with $m \geq 4$ [1,2]. In applications such as lasing, super-BICs are preferred [3].

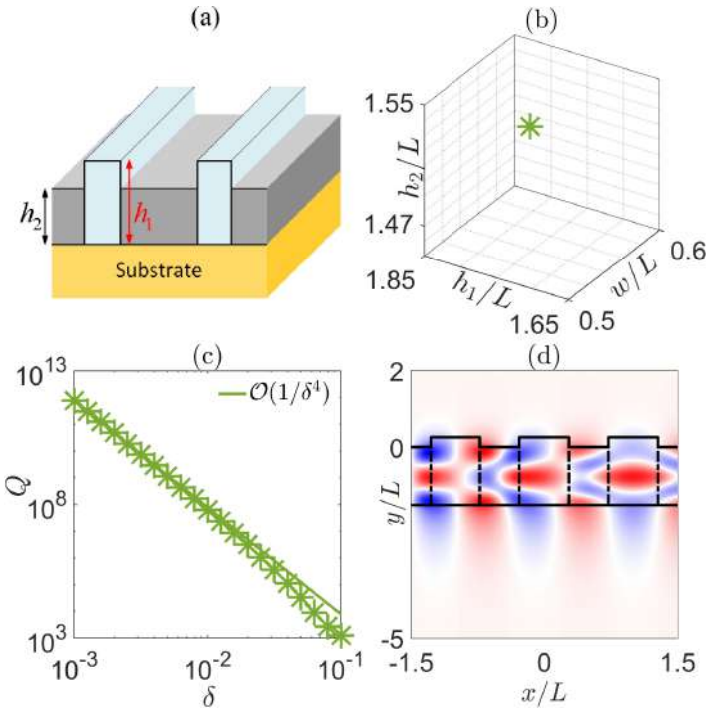

Figure 1: (a) A 1D grating on a substrate; (b) parameter values for an off-Γ super-BIC; (c) Q factor of resonant modes near the super-BIC; (d) electric field distribution of the super-BIC.

As shown in Fig. 1(a), the grating structure with a substrate does not have up-down mir-

ror symmetry. It is easy to find at-Γ BICs (with $\beta_* = 0$) that are protected by the reflection symmetry in the periodic direction. Since the radiation channels above and below the grating are different, it is not easy to find off-Γ BICs (with $\beta_* \neq 0$). It is challenging to find super-BICs (either at-Γ or off-Γ) in structures without the up-down mirror symmetry. We can show that to find an at-Γ super-BIC (actually, there two types with $m = 4$ and 6, respectively), it is necessary to tune two parameters, and to find an off-Γ super-BIC with $m = 4$, it is necessary to tune three parameters. We have developed an efficient numerical method to calculate the super-BIC and the structural parameters together. In Fig. 1(b), we show the values of h_1, h_2 and w to realize an off-Γ super-BIC. Figure 1(c) give a validation that $m = 4$. The electric field distribution of this super-BIC is shown in Fig. 1(d).

Abstract: We show that the fields calculated during the computation of limits via Lagrange duality can be used to improve the performance of inverse design.

The recognition that the constraints implied by any set of linear differential equations can be reformulated to restate the optimization problems encountered in photonic inverse design as a quadratically constrained quadratic program (QCQP) and then convexified via Lagrange duality has proven to be a powerful means of determining fundamental performance limits[1]. As soon as the constraints of total real and reactive power conservation are imposed, the subtle interplay between chosen material properties, device size, wave physics, and attainable objective values for basic scattering quantities is captured to a remarkable extent, including the onset of well-known asymptotics such as quasi-statics and geometric optics, and the possibility of creating resonances[2]. More importantly, through the generalization of considering any number of local power conservation constraints, these convexification methods have been found to be remarkably predictive of what is possible for range of technologically relevant electromagnetic processes; limits coming within a factor of ten of topology optimized structures have been found for variety of basic absorption, scattering and field transformation functions as well as more complex objectives like surface-enhanced Raman scattering.

In this presentation, we demonstrate that the fields computed when calculating performance limits via duality can also directly inform structural discovery through inverse design. Focusing on the exemplary problem of local density of states enhancement, we find that topology optimization initialized with structures derived from duality analysis consistently produces performance gains of roughly an order of magnitude, for sufficiently large design domains, relative to current methods. These results strongly suggest presently untapped potential in photonic inverse design, and highlight a number of open question concerning the mathematical structure of electromagnetic inverse design problems and related convexifications.

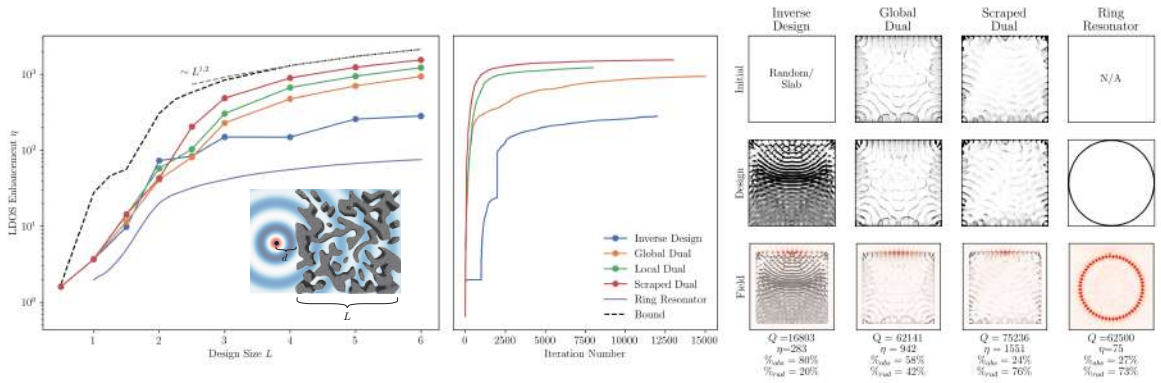

Fig.1: The figure illustrates a comparison between the design method that will be described during this presentation and topology optimization, starting from standard initializations, for the exemplary test problem of enhancing the local density of states (LDOS) outside of a structurable design region, separated by a tenth of a wavelength. Left: LDOS enhancement of for various optimization strategies as a function of the design size L. The solid line indicates the performance of a finetuned ring resonators for reference. Middle: Performance progression as a function of the number of optimization iterations completed for the various initializations. Right: Structures and profiles of the dominant mode field at $L = 6$ for the various design schemes.

Stokes Solitons and PT-Symmetric Coupled Cavities: Two Paths to Mode-Locking Without Saturable Absorbers

Takasumi Tanabe*, Ryo Otake, Riku Imamura, and Heng Wang

Department of Electronics and Electrical Engineering, Keio University, Japan
*corresponding author: takasumi@elec.keio.ac.jp

Abstract: Through numerical analyses, we demonstrate that robust mode-locking can be achieved without the use of saturable absorbers by either exploiting stimulated Raman scattering in dispersion-engineered microresonators or by operating near exceptional points in PT-symmetric coupled cavities.

Mode-locked lasers play a pivotal role in applications such as ultrafast spectroscopy, precision metrology, and high-speed optical communications. Traditionally, achieving mode-locking relies on incorporating saturable absorbers (SAs) into laser cavities, which provide intensity-dependent losses to generate short pulses. However, integrating SAs into high-Q microresonators [1] can degrade their Qs, motivating alternative approaches that circumvent the need for natural SA materials. Our numerical study explored two promising paths in this direction, both of which leverage the unique optical properties of microresonators to generate pulses without the use of conventional SAs.

One approach exploits stimulated Raman scattering in a dispersion-engineered silica microresonator (inset Fig. 1(a)) [2]. By carefully tailoring the group-velocity dispersion profile, it becomes possible to favor Raman comb generation over four-wave mixing (Fig. 1(a) and 1(b)), thereby producing Stokes solitons in a single device (Fig. 1(c)). In this design, the dispersion near the pump wavelength is set to be normal, while both the Stokes and anti-Stokes wavelength regions are engineered to exhibit anomalous dispersion. This arrangement suppresses conventional parametric effects near the pump while supporting intense Raman gain. Numerical simulations based on the Lugiato-Lefever equation with Raman gain indicate that when the pump is a continuous wave, stimulated Raman scattering dominates, resulting in a broad comb that then transitions to a soliton regime in the Stokes region. The resulting pulse is well-localized in time and exhibits a characteristic envelope in frequency space, confirming stable mode-locking without the need for an additional SA.

In these simulations, the anti-Stokes dispersion proves to be significant: mode-locking is achieved only when the anti-Stokes region also falls within the anomalous dispersion regime, as this ensures phase matching and free spectral range alignment across the different spectral components. Indeed, the free spectral range in the anti-Stokes band must closely match that of the Stokes region for strong pulse formation to occur. This condition is achieved by tailoring wedge angles and layer thicknesses in the disk resonator. By stacking three layers with different wedge angles (inset Fig. 1(b)), the device achieves normal dispersion around the pump wavelength and anomalous dispersion, where solitons are desired.

A second approach demonstrates that a coupled-cavity system with gain and loss (Fig. 1(d)) can induce mode-locking by mimicking an artificial SA effect near a parity-time symmetry breaking point, known as an exceptional point (EP) [3]. This design employs two microcavities: one with high Q and another with lower Q. Light initially couples from the high-Q, gain-bearing cavity into the lossy cavity, where it dissipates to a large extent. Yet, when the circulating light intensity rises due to the Kerr effect in the gain cavity, the refractive index shift modifies the resonance frequencies, causing an instantaneous decoupling of the two cavities and, thus, temporarily reducing the net loss. The net effect is analogous to SA: at high intensities, the system's loss

effectively drops, allowing stronger pulses to form and reinforcing mode locking.

Central to this mechanism is the system's proximity to an EP, where small changes in refractive index cause drastic shifts in the complex eigenfrequencies of the coupled resonators (Fig. 1(e)). Simulations based on coupled nonlinear Schrödinger equations reveal that, when tuned near the EP, even modest changes in refractive index yield significant modulation of the system's Q. This capability translates directly to more effective pulse shaping. Numerical results indicate that a stable single-pulse mode-locked state is achieved, resulting in a nearly transform-limited pulse (inset Fig. 1(e)). Importantly, parameter scans indicate that mode-locking is most likely to occur when the initial coupling Q places the system just below the EP.

Comparing the two methods underscores the growing trend of replacing natural SAs with inherent physical effects in high-Q microresonators. Stimulated Raman scattering in engineered dispersion regimes and PT-symmetric coupling near EP both offer effective, power-efficient ways to generate ultrashort pulses. These concepts not only simplify the design and fabrication of integrated mode-locked lasers but also open up new degrees of freedom, such as external control of coupling strength, precise dispersion engineering, or platform materials, all of which can significantly enhance performance. While further exploration of device physics and more sophisticated experimental validations will be needed to confirm the scalability of these designs, the early results are promising. They reveal pathways to achieve mode-locked pulses with minimal physical overhead, high repetition rates, and potentially wide optical bandwidth. Ultimately, these breakthroughs may spur new advances in integrated photonics, ultrafast science, and next-generation optical communication systems.

Quantum Effects in Nanophotonic Light–Matter Interactions

P. André D. Gonçalves [1]

[1] POLIMA – Center for Polariton-driven Light–Matter Interactions, University of Southern Denmark, Campusvej 55, DK-5230 Odense M, Denmark
padgo@mci.sdu.dk

Abstract **– Advances in fabrication and spectromicroscopy techniques have enabled unprecedented access to quantum mechanical effects underlying various nanophotonic phenomena, challenging their description solely within classical electrodynamics. Here, I will present a suite of quantum-informed theoretical frameworks for accurately describing light–matter interactions in nanophotonics and discuss how these approaches provide new insights and unlock new capabilities. Topics will include quantum corrections to plasmon spectra and plasmon-enhanced light–matter interactions, as well as the exploration of quantum effects governing electron–light–matter interactions in various electron-beam-based spectroscopies of current interest.**

Advances in topology optimization for nanophotonics

Antonio Calà Lesina[1,2,3]

Abstract: Inverse design methods based on topology optimization can uncover nanophotonic structures in 3D with free-form shapes beyond human intuition, and optical functionalities not obtainable with conventional design methods. This talk highlights the recent achievements of my team in topology optimization for nanophotonics and integrated optics.

Advances in computing capabilities and inverse design methods have recently enabled the discovery and engineering of novel and unconventional nanophotonic devices. By exploring large design spaces one can find new conceptual free-form designs that provide a solution to complex optimization problems, thus unlocking advanced optical functionalities. Gradient-based topology optimization is a robust inverse design technique that allows us to explore large design spaces in a computationally efficient manner. This is due to efficient techniques for the calculation of the gradient, such as the adjoint method. This talk focuses on the recent achievements of my research group in computational nanophotonics and inverse design via topology optimization, which include:

- the inverse design of nanostructures made of arbitrary dispersive optical materials thanks to a formulation of the adjoint method in the time domain [1],
- the optimization of metallic and dielectric nanostructures and metasurfaces to achieve broadband absorption [2, 3],
- anapole effects in plasmonic meta-atoms that can be exploited as building blocks for transparent metasurfaces and metamaterials [4],
- integrated beam splitters designed via topology optimization to achieve arbitrary phases at the output ports [5], and
- the topology optimization of nanostructures where the aim is to achieve a desired multipolar response in order to engineer the nanoantenna's scattering properties [6].

Abstract: We present a self-consistent multiphysics simulation framework for modeling the optoelectronic response of graphene-based devices in THz. The model accounts its thermodynamic response, offering valuable insights into the ultrafast processes that define graphene's behavior under strong THz fields. Two examples of ultrafast and nonlinear modulators are discussed.

Graphene’s unique optical and electronic properties—such as its remarkably high carrier mobility, broad-spectrum optical absorption, and strong nonlinear optical response—make it an exceptional material for ultrafast and tunable photonics [1-3]. Its ability to integrate seamlessly into plasmonic and dielectric structures allows for highly efficient light-matter interactions and significant enhancements in field confinement. Nonlinear effects, particularly in the THz regime, are significantly amplified through electrostatic gating and interactions with intense THz pulses, which induce substantial changes in graphene’s conductivity via carrier heating. This carrier heating leads to changes in the material’s electronic properties, which in turn modify its optical response. Furthermore, embedding graphene in metamaterials, especially topological photonic crystals, results in an even greater enhancement of harmonic generation. This is achieved by exploiting the engineered interface states within these structures, which facilitate even stronger localized field enhancement. The unique combination of these features creates a powerful synergy that promises not only to drive forward the development of advanced, efficient nonlinear optical devices for next-generation photonic systems, ranging from communication technologies to quantum information processing.

We present a self-consistent multiphysics simulation framework that models graphene’s nonlinear response under strong THz illumination, providing a comprehensive approach that aligns well with experimental observations. This framework offers critical insights into graphene’s carrier dynamics and enables predictive device engineering, making it a versatile tool for designing advanced graphene-based optoelectronic components. The study investigates self-action and third-harmonic generation, utilizing a well-established simulation framework [4,5] to model graphene’s response under THz illumination. Coupled opto-thermal calculations enable us to extract photo-induced carrier heating, track the redistribution of carriers, and assess the impact of these processes on both linear and nonlinear conductivity of graphene. By integrating these computational methods, we aim to provide deeper insights into the fundamental mechanisms driving THz-induced nonlinear effects in graphene-based topological photonic structures.

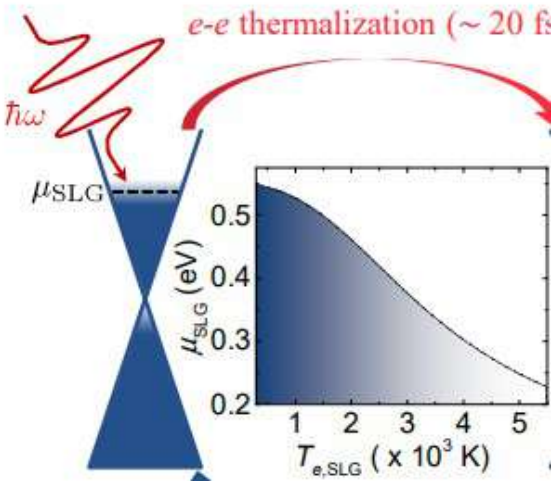

Figure 1: Charge carrier distribution evolution in graphene under THz excitation. Energy absorption raises carrier temperature, redistributing charge carriers. Middle graph: decrease in chemical potential as temperature increases.

To validate our framework, we apply it to a practical graphene-based optoelectronic device: a Salisbury screen configuration with a ionic liquid layer between monolayer graphene and a grounded gold backplate. Our results, compared with experimental data, confirm the accuracy of our approach [1]. At low field strengths, the device exhibits near-perfect absorption at 2.3 THz due to destructive interference effects. As the THz field strength increases, graphene's conductivity is significantly modulated by carrier heating, leading to a rapid shift in the absorption spectrum. Additionally, we investigate graphene ribbons placed within a photonic crystal topological cavity. By leveraging the coupling between topological surface states and plasmonic resonances in graphene ribbons, we design novel configurations to efficiently extract third-harmonic waves. This approach combines advanced modeling tools with material assumptions, enabling the development of a robust framework that supports both forward (transmission) and backward (reflection) propagation of the generated waves. The synergy between these factors enhances the system's efficiency and versatility, opening up applications in nonlinear optics and photonics. Notably, since no back reflector is required, the device operates effectively in both transmission and reflection modes.

Focusing of heat flux radiated by magneto-optical nanoemitters in the presence of a magnetic-field

Abstract: We describe the near-field heat flux radiated by magneto-optical nanoemitters close to a substrate in the presence of a magnetic field. We demonstrate that this can induce an amplification of the flux and a focusing of the Poynting field at the substrate interface, opening promising perspectives for heat-assisted magnetic-recording technology.

The development of fluctuational electrodynamics and the discovery that radiative heat flux can be strongly amplified in the near field have paved the way to several applications including heat-assisted magnetic recording (HAMR) [1, 2]. In HAMR, a small surface area of a magnetic material is heated to raise its temperature close to the Curie temperature, where its magnetic coercivity is weak. Then by applying a magnetic field a new magnetic state can be recorded inside the material. While the hot spot area should be minimized to approach the superparamagnetic limit, radiative heat focusing by a conventional scanning probe microscope is constrained by the emission pattern of its tip in the near-field regime. In a recent work [3] a theory describing heat flux radiated in the near-field regime by several interacting nanoemitters has been introduced, demonstrating that the thermal energy can be focused and amplified into smaller spots than single emitters.

We extend this study to magneto-optical many-body systems [4] whose optical properties can be manipulated by applying a magnetic field. Our system consists of N spherical having equal radius r, placed in vacuum and in proximity of a substrate. Following the approach of [5], we derive the Poynting vector at any position. This formalism is then applied to the scenario of a single emitter made of InSb (a magneto-optical material recently studied in the context of near-field radiative heat transfer [6]) close to a substrate made of SiC.

We study the maximum of the Poynting vector below the nanoemitter and its Full Width Half Maximum (FWHM) as a function of the applied magnetic field B for different radii r of the nanoparticle. The results, shown in Fig. 1(a,b), highlight a non-monotonic behavior, according to which the maximum Poynting vector (FWHM) first increases (decreases) as a function of B, then decreases (increases), by reaching values even below (above) the reference one for $B = 0$ [7]. This highlights an ideal scenario as a function of B, since it shows the existence of an optimal magnetic field for which not only is the local heat flux quantitatively increased, but it is also more focused on the surface of the substrate.

We performed a detailed spectral investigation of the effect. We first analyze the spectrum of the Poynting vector below the nanoparticle, shown in Fig. 1(c,d). For $B = 0$ we remark two resonances, one at higher frequencies corresponding to SiC, one at lower frequency stemming from the InSb nanoparticle. It is known that the presence of a magnetic field induces the appearance of two further InSb resonances. The effect is manifest in Fig. 1(c), where we remark the existence of an optimal field for which one of this resonances matches the one of SiC, thus leading to a strong amplification.

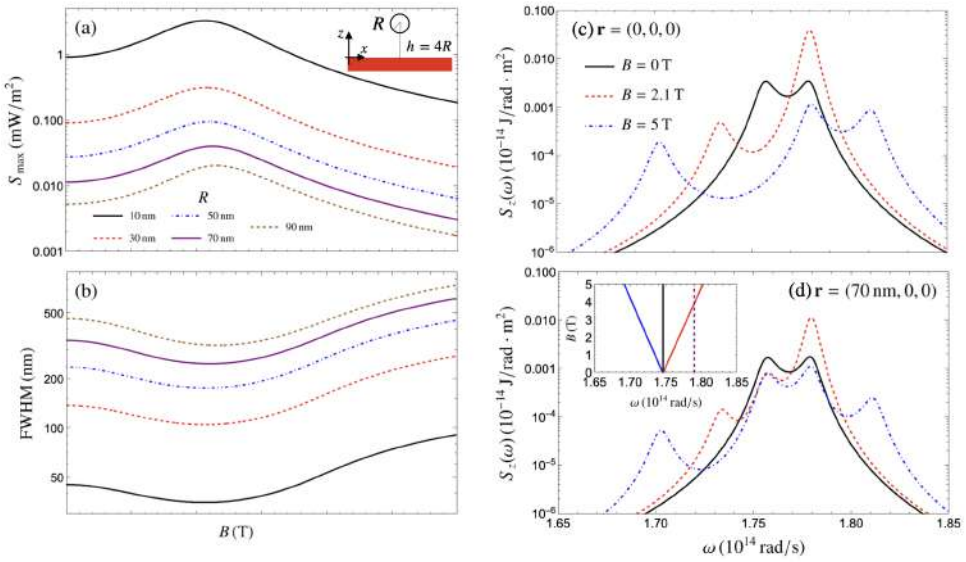

Figure 1: (a) Poynting vector $S_{\max}$ below the nanoparticle, placed at $(0, 0, 4r)$, and (b) FWHM as a function of the applied magnetic field B for different radii (see legend). (c-d) Spectral decomposition of the z component of the Poynting vector at (c) the origin and (d) at $(70\,\text{nm}, 0, 0)$, for different values of the applied magnetic field (see legend). The inset of (d) shows the three resonances of InSb, the vertical dashed purple line the resonance frequency of SiC.

To explain the reduction of FWHM, we present [Fig. 1(d)] the spectral analysis at a different coordinate, corresponding to half the FWHM at $B = 0$. We observe that the enhancement at the peak frequency (the resonance of SiC) is less pronounced. This can be attributed to the fact that the almost monochromatic nature of the heat flux is a purely near-field effect: it strongly depends on the distance and is more pronounced right below the nanoparticle. Although the heat flux is amplified on the entire surface, the distance-dependent amplification is stronger right below the nanoparticle and is at the origin of the desired reduction of FWHM.

Abstract: In pursuit of optimal photonic designs, substantial progress has been made on two complementary fronts: bottom-up structural optimizations (inverse design) discover complex high-performing structures but offer no guarantees of optimality, while top-down field optimizations (convex relaxations) reveal fundamental performance limits but offer no guarantees that structures meeting these limits exist. We bridge the gap between these two parallel paradigms by presenting a ``verlan" method that exploits local and global wave information encoded in performance bounds to guide inverse design towards better-performing structures. Structures informed by limits outperform standard (random) inverse-design initializations by close to an order of magnitude and approach fundamental performance limits within a factor of two, highlighting the possibility of accessing significant untapped performance improvements.

The design of optical components has relied for many decades on a small number of well-understood physical mechanisms for light control, e.g. index guiding, photonic bandgaps, and material resonances. However, with growing freedom for structuring materials down to the nanoscale and increasing demands on device functionality and complexity, this paradigm is currently being partially supplanted by computational inverse design: structural optimization over an enormous number of parameterizing degrees of freedom [1-2]. The high-dimensional and nonconvex nature of the inverse design problem often leads to uncertainty (Fig. 1, center): adjoint gradient-based algorithms are generally necessary for navigating the high-dimensional design space, and if an optimization fails to achieve a desired level of performance, it may be that either the algorithm is "stuck" in a sub-par local optimum, or that the desired performance is physically impossible to achieve. To address this uncertainty, recent progress has been made on elucidating fundamental limits to photonic performance which no structure may exceed (e.g. duality limits shown in Fig. 1, top right) [3]. The key to such performance bounds rests on a reformulation of the structural design problem to an optimization over fields (instead of geometry) subject to power conservation constraints that are quadratic functions of the fields (Fig. 1, top left).

When there is a significant performance gap between bounds and existing designs, the situation is intriguing: are the limits loose, signifying a large duality gap, or are there as-yet undiscovered superior designs? The wave nature of light allows for complicated interference patterns that create many local structural optima (Fig. 1, center). Moreover, photonic devices often rely on physical effects that are highly sensitive to small structural perturbations (e.g., high-quality resonances, multipole cancellation, localized fields), making structural optimization numerically ill-conditioned. Photonic inverse design with adjoint gradients is thus strongly contingent on the starting point, and given the high dimensional design space, it is impossible to exhaustively sample different initializations. We report a novel method that exploits Lagrangian dual limits to extract structure templates for guiding and accelerating inverse design [4]. To differentiate from existing initialization methods based primarily on random sampling and to emphasize the role of duality, we refer to our new approach as "verlan" design. We apply verlan extraction in conjunction with topology optimization to discover 2D structures

that maximize the Purcell enhancement of nearby out-of-plane point sources, an ill-conditioned and challenging structural optimization problem. Verlan inverse designs achieve over one thousand-fold Purcell enhancement despite the choice of a low-index and lossy medium, outperforming random initializations by nearly an order of magnitude and approaching performance limits to within a factor of two. Our results represent a significant step towards a practical general-purpose framework for integrating performance limits and inverse design.

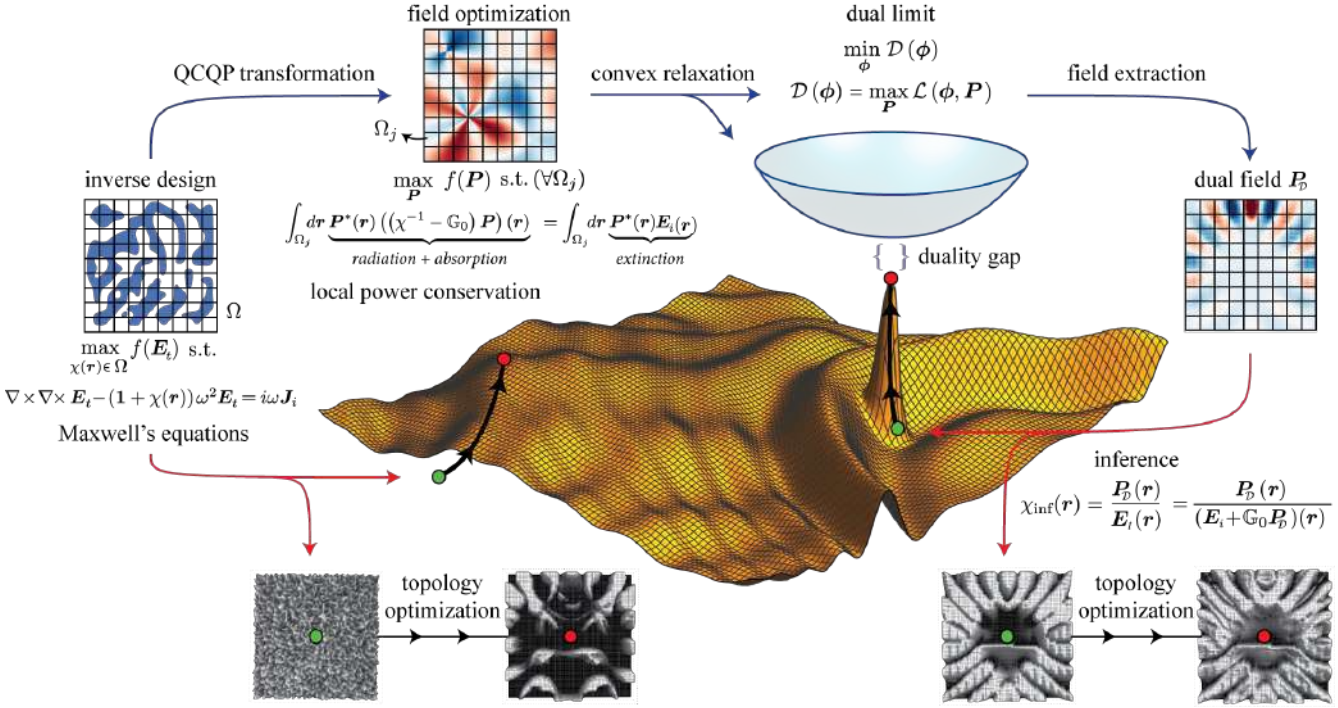

Figure 1: Schematic of verlan design methodology. The optimization landscape of photonic design—illustrated as a surface—is often very complicated, exhibiting ill-conditioning and many local optima which can trap gradient-based (adjoint) algorithms. Limits to device performance can be evaluated by transforming the inverse design problem into a quadratically constrained quadratic field optimization program (QCQP) that is then relaxed (e.g. Lagrange duality) to obtain limits on achievable performance. In contrast to structural optimization, the dual program (minimization over Lagrange multipliers) is convex, with a unique global optimum corresponding to the tightest bound. The "polarization" associated with the dual optimum encodes global characteristics of optimal fields. Retracing these set of transformations illustrates the major steps involved in our verlan method: the original inverse design problem is converted into a QCQP over the polarization field, which is then convexified via Lagrange duality to produce a dual polarization field. A material profile is then inferred from the dual fields and used to initialize local optimization (e.g. topology optimization).

Abstract: Digital signal processing has revolutionized many fields of science and engineering, but it still shows critical limits; a long-sought solution is optical analog computing. We demonstrate here that nonlinear phenomena combined with engineered nonlocality in flat optics can be leveraged to synthesize Volterra kernels able to outperform linear devices.

In this work, I will present our recent findings on the use of nonlocality and nonlinearity for image processing in space and time. Flat-optics devices exhibiting a linear local (LL) response are defined by a position-dependent linear transfer function $T_{LL}(\mathbf{r})$, which can be locally tailored by engineering metaatoms arranged within metasurfaces. An input signal, defined in real space as $I_\omega(\mathbf{r})$, is filtered linearly and locally, and transformed into an output $O_\omega(\mathbf{r})=T_{LL}(\mathbf{r})I_\omega(\mathbf{r})$. Wavefront engineering is arguably the most prominent application for LL systems [1]. Spatial dispersion, i.e., nonlocality, is usually regarded as a nonideality in LL flat-optics devices. However, the nonlocal response of metasurfaces has been recently indicated as an effective means to achieve advanced functionalities based on the independent control of spectral and angular selectivity [2].

To date, investigations into nonlocality have primarily focused on the linear-optics regime. The action of linear nonlocal (LN) systems is well described by a k-dependent transfer function $T_{NL}(\mathbf{k})$, which describes how the metasurface filters the angular spectrum of an input function, according to $O_\omega(\mathbf{k})=T_{NL}(\mathbf{k})I_\omega(\mathbf{k})$. Nonlocal metasurfaces are well suited for analog computing and image processing. For example, n-th order differentiation is easily achieved with transfer functions of type (jk)n, while integration is obtained by synthesizing transfer functions of the type (jk)1/n [3].

Despite the advantages, linear approaches — both local and nonlocal — face limitations related to the restricted numerical aperture and frequency bandwidth, and the inherent linearity of the mathematical operations that one can engineer. Here I show that the combination of nonlinear and nonlocal effects in the same flat-optics device is a powerful strategy to achieve advanced image processing and analog computing functionalities with reduced structural complexity and increased efficiencies in terms of angular and frequency bandwidth [4, 5].

The concept of image processing with nonlinear flat optics is illustrated in figure 1. The input image is a pump field (ω_0 in figure 1) with its polarization and space-time structure which impinges on a nonlinear nonlocal thin film. The space-time dependent structure of the generated second harmonic ($2\omega_0$ in figure 1) is used to extract key features of the input image. By exploring the simple scenario of a uniform thin film, we demonstrate edge detection in space and in time. In our proposed nonlinear flat-optics solution, the non-resonant nature of the nonlinear interaction allows edge detection over a broadband spectrum with ultra–high contrast.

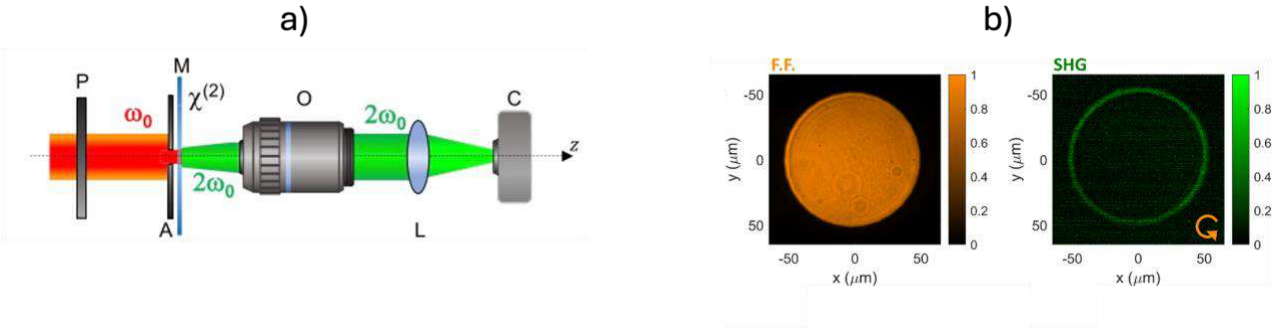

Figure 1. a): Setup for image processing with a nonlinear flat-optics element. P (polarizer); A (aperture); M (flat-optics element/metasurface); O (objective); L (lens); C (camera). b): example of edge detection on a circular aperture.

Our results indicate that Volterra kernels of nonlinear nonlocal flat optics can open new opportunities in applications such as image processing, item recognition for computer vision, high-contrast and high-resolution microscopy, implementation of nonlinear functions for analog deep learning.

Abstract: We present a one-shot deep learning approach to the inverse design of microstructures whose absorption spectra are tuned to allow the selective detection of a specific chemical species. We test the approach in a periodic array of silicon carbide surface phonon polariton microresonators.

In the last decade, Deep Learning (DL) approaches have become increasingly popular for solving a numerous technological and scientific problems. More specifically, DL has recently started competing with global optimization algorithms and adjoint methods as the tool of choice for inverse design in the field of nanophotonics, showing noteworthy achievements when working on systems such as photonic crystals, nano-scatterers, gratings, Bragg mirrors, etc. While data generation and training of the DL model might require significant computational effort, high evaluation speed, differentiability, and the possibility of obtaining latent representations of complex data can give DL an edge over more conventional inverse design methodologies[1,2].

The usage of Surface Phonon Polaritons (SPhPs) in nanophotonics has demonstrated great promise for sub-wavelength light confinement in polar dielectrics[3]. The significant reduction of optical losses and wide availability of polar crystals makes SPhPs a viable alternative to plasmonic systems. These modes can be excited between the longitudinal optical and transverse optical phonon frequencies, in the so-called Reststrahlen band of the dielectric which, for most materials of interest, spans the Terahertz and mid-infrared ranges of the spectrum[3].

In the present work, we showcase a DL model aimed at inverse-designing a nanostructure whose absorption spectrum is matched to the spectral signature of a specific chemical substance in its gaseous or liquid state; to this end, we built a simple model of a SiC (Reststrahlen band from 25 to 29 THz) nanoarray and applied the DL algorithm to it.

Data generation is carried out by producing absorption spectra of SiC nanostructures, like the ones showed in Figure 1(a) and 1(b), varying the pillars' dimensions and the parameters of the unit cell of the periodic array. The simulated spectra are computed using the Electromagnetic Waves, Frequency Domain module of the COMSOL Multiphysics package. For the training process, a direct, one-shot network is adopted, in the form of a conditional variational autoencoder. The loss function depends on the overlap between the absorption spectra of the SiC microstructure and of the chemical species of interest, in proximity of its dominant spectral signature. The DL approach is here initially applied to a simple and well-studied system, with a limited parameter space, in order to allow for a straightforward evaluation of the obtained results. Its success paves the way toward applications to more complex structures, with possible applications to radiative cooling[5] and gas sensors[6].

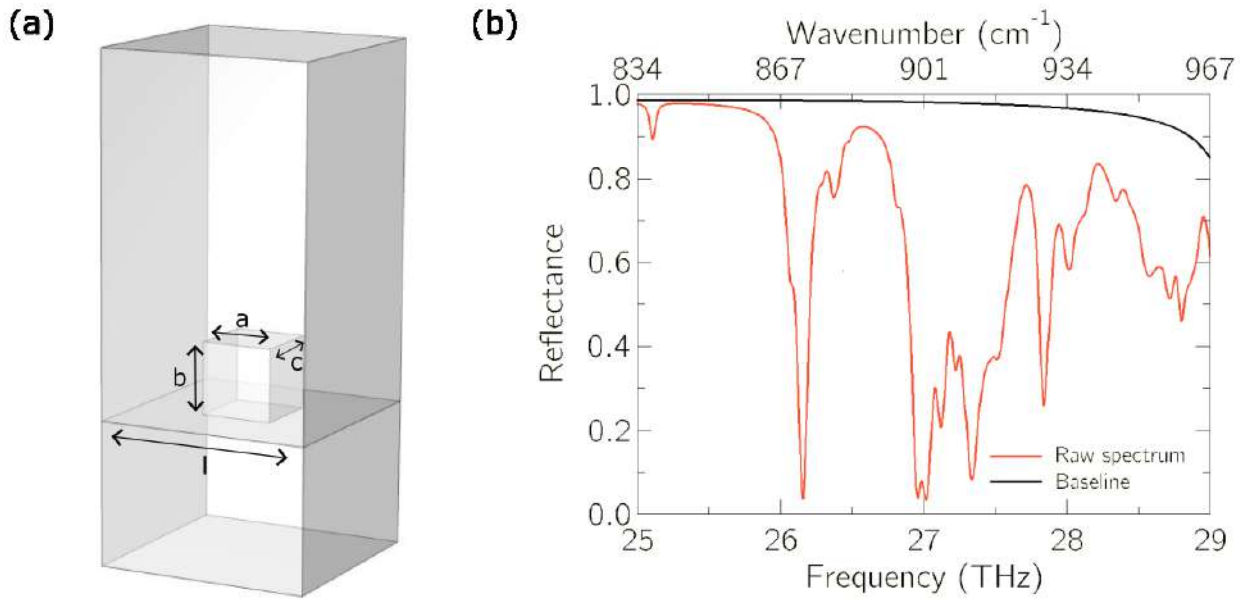

Figure 1: (a) Schematics of the unit cell simulated in COMSOL Multiphysics: a SiC parallelepiped-shaped microresonator of edges *a*, *b* and *c* on top of a substrate of the same material, with air above it. The square-based cell is repeated in two dimensions with periodicity *l*. (b) An example of a reflectance spectrum for a cell with $a = b = c = 1$ μm and $l = 3$ μm, compared with the SiC baseline. This is the raw spectrum computed by COMSOL, to be converted in an absorption one.

Nanophotonic Design for Augmented Reality Displays: Opportunities and Challenges

Christina Spaegele[1]

[1]Meta, United States
cspaegele@meta.com

Abstract: This talk explores the opportunities and challenges of computational design for nanophotonic components in Augmented Reality (AR) devices. It discusses the stringent requirements for AR displays, the potential of nanophotonics, and the complexities introduced by factors like unwanted artifacts and fabrication constraints in achieving high-performance AR displays.

Augmented Reality (AR) has the potential to fundamentally change how we interact with digital information by integrating it into our physical environment in a seamless and intuitive way. To achieve this vision, it is essential to develop displays that can blend in with reality without causing visual obstructions or disrupting the user's perception of their surroundings. This necessitates a large field of view display with variable focus that can fit within the form factor of a typical sunglass and is efficient enough for an all-day use.

While significant progress has been made in this area, further breakthroughs in Materials, OptoElectronics and Photonics are necessary to meet the stringent requirements for size, quality, efficiency, and cost. Nanophotonic components hold great promise for enabling the development of high-performance AR displays due to their lightweight nature, potential for smaller footprint, and increased control of light-matter interactions. However, the combination of increased design freedom with the need to consider factors such as unwanted artifacts and fabrication constraints introduces substantial design complexity. This talk gives an overview of the opportunities and important parameters for the computational design of nanophotonic components in Augmented Reality devices.

Hybrid Silicon Metamaterial combining Microstructured Silicon surface with Silicon / Silicon Dioxide multilayer as a Selective Emitter for Thermophotovoltaic Applications

Abstract

We propose a broadband selective emitter for thermophotovoltaic applications, combining a microstructured doped silicon surface with a Si/SiO_2 multilayer. This structure enhances emissivity in the above bandgap spectral region (i.e., for wavelengths shorter than λ_{gap}) while suppressing emissivity in the below bandgap region (i.e., for wavelengths longer than λ_{gap}) over a broad spectral range. The structure composition and properties are optimized using a Particle Swarm Optimization algorithm.

Thermophotovoltaic (TPV) systems convert thermal radiation into electricity and are generally made of two main components: an infrared radiation emitter, and a photovoltaic (PV) cell. Selective emitters are often used to tune the spectral range of emitted radiation for a better match with the used PV cell bandgap in order to increase the overall system efficiency. The design and optimization of selective emitters has become a key research focus in the TPV community during the past two decades. Various structural designs of selective emitters have been developed for TPV systems, including metal-dielectric multilayer [1], as well as 1D and 2D photonic crystals (PC) [2,3].

In this work, we propose a silicon based selective emitter (SE) to take benefit of the widespread and affordability of silicon micro and nano-fabrication techniques. The proposed SE combines a PC made of Silicon and Silicon Dioxide deposited on a periodic array of triangular grooves etched in a heavily doped silicon substrate (Figure 1). The emitter radiative properties are calculated using the transfer matrix method (TMM) combined with the effective medium theory (EMT). In this approach, the grooves are considered as a stack of layers composed of a mixture of silicon and air, with different volume fractions depending on the depth. The silicon volume fraction goes from zero above the grooves tip to 1 in the silicon bulk. The effective permittivity of each layer is calculated using the Bruggeman homogenization equation. Using the TMM, we compute the spectral reflectance and absorptance of the whole structure.

The simulation results of the triangular Si grooves grating show that the gradual change in the refractive index of the Si/air mixture with altitude enhances the optical impedance matching between the air and the material's surface, thereby improving light absorption, which exceeds 99% between 1 and 5 μm for a groove height of 10 μm. In order to evaluate the spectral performance of the triangular grooves, we calculate the spectral efficiency η_{sp}, which represents the fraction of power emitted by the thermal emitter at its expected operation temperature (we consider $T = 1500$ K in our case) in the above bandgap spectral range of the considered TPV cell (up to 1.7 μm, corresponding a GaSb cell, $E_g = 0.72$ eV).

$$\eta_{\text{sp}} = \frac{\int_{\lambda_{\min}}^{\lambda_{\text{gap}}} \epsilon_\lambda(T,\lambda) \cdot E_{b\lambda}(T,\lambda)\, d\lambda}{\int_{\lambda_{\min}}^{\lambda_{\max}} \epsilon_\lambda(T,\lambda) \cdot E_{b\lambda}(T,\lambda)\, d\lambda}, \text{ with } E_{b\lambda}(T,\lambda) = \frac{2hc^2}{\lambda^5}\left(\frac{1}{e^{\frac{hc}{\lambda KT}} \in 1}\right)$$

Where ϵ_λ is the emissivity of the structure, $E_{b\lambda}$ is the spectral blackbody emissive power, $\lambda_{\text{gap}} = 1.7\mu m$ is the wavelength corresponding to the bandgap energy of the cell. In our calculations,

we have considered $\lambda_{\min} = 1\mu m$ and $\lambda_{\max} = 5\mu m$. Different doping levels (from 10^{18} to $5 \times 10^{19}\,\mathrm{cm}^{-3}$) and groove heights (from 500 nm to 10 μm) have been considered and the spectral efficiency does not exceed 25%. Optimizing the emissivity is therefore essential to maximize the power that will be converted by the TPV cell. For this purpose, we use a 1D PC alternating Si and SiO_2 layers on the top of the doped Si grooves to filter radiation at wavelengths above the bandgap (ABG) wavelength, hence improving spectral efficiency.

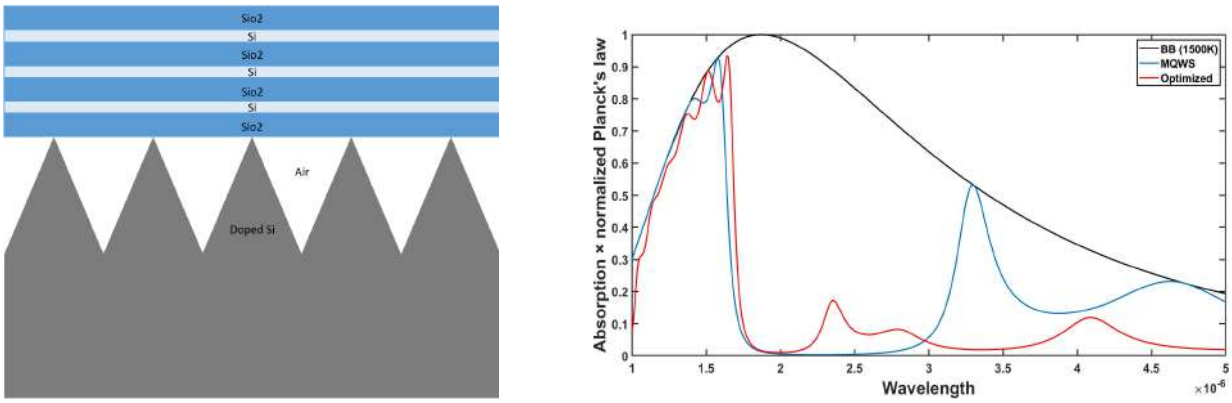

Figure 1: (a) The proposed selective emitter: a photonic crystal on triangularly grooved Si periodic grating with a doping concentration of $5 \times 10^{19}\,\mathrm{cm}^{-3}$. (b) Comparison of the absorption weighted by Planck's law at 1500 K between a quarter-wave structure (MQWS) and the optimized structure.

Some works have already proposed this strategy using PC filter with quarter-wave stack (MQWS) thicknesses [4]. This strategy leads in our case to a spectral efficiency up to ($\eta_{sp\%}$=49.47 %). Further optimization of the PC layers thicknesses would enable broadening of the photonic bandgap and increasing the spectral efficiency. We used the Particle Swarm Optimization (PSO) method for this optimization task. A random population of p structures (particles) is initially generated. Each particle has an initial position and velocity within the search space. The position coordinate in each dimension defines the value of a parameter of the multilayer structure, the thickness in our case. The particles are allowed to move within the search space, i.e. to vary the layers thickness, looking for an optimum. At each step of their movement and of the optimization algorithm, the emissivity of each particle is calculated using the TMM and compared to the target emissivity. After this comparison, the position x_i and velocity v_i of each particle i are updated taking into account the particle inertia (its velocity), memory (its knowledge of previous positions performances) and information provided by other particles (the position of the best performing particle) [5]. This method leads in our case to an optimized design exhibiting a spectral efficiency $\eta_{sp} = 71.45$ %.

Abstract: We enhance the phase mask design process of proximity-field nanopatterning by integrating a GPU-accelerated convergent Born series solver with gradient-based optimization. This method outperforms FDTD in 2D and 3D simulations, enabling efficient, high-contrast nanostructure design. Our approach advances PnP, expanding its potential for complex 3D nanofabrication.

1. Introduction

Enhancing productivity in 3D nanoprinting is crucial for advancing applications in energy storage, sensors, photonic devices, and microrobotics. Among various techniques, proximity-field nanopatterning (PnP) stands out for its ability to balance high productivity with satisfactory spatial resolution. This method relies on coherent light passing through a phase mask to generate intricate 3D hologram patterns within a photoresist. However, traditional approaches for designing phase masks often result in low-contrast patterns, limiting the complexity of achievable nanostructures.

Recent developments integrating numerical simulations with optimization algorithms have addressed these challenges by enabling high-contrast patterns. Gradient-based optimization has proven effective for refining phase mask designs iteratively. However, designing large-scale phase masks remains computationally demanding, particularly for multi-layered structures requiring 3D simulations. Traditional methods like the finite-difference time-domain (FDTD) approach struggle with computational feasibility, making large-scale designs impractical.

Frequency-domain solvers provide simulation results using less computational resources by eliminating time-stepping and improving accuracy for steady-state scattering analysis. Even though those approaches have been validated in previous studies, they suffer from scalability issues, especially for simulating three-dimensional (3D) space.

This work proposes a convergent Born series frequency-domain solver that enhances computational efficiency and stability. This solver stably works for 3D simulation by ensuring mathematical stability. Coupled with GPU acceleration, this solver significantly reduces simulation time and extends the applicability of PnP for complex nanostructure fabrication.

2. Result

We compared the design results with an FDTD-based design tool in a 1D periodic phase mask to validate our approach. This setup mimics a PnP process where a normal plane wave illuminates the phase mask, creating a desired diffraction pattern. Our solver achieves a 2.6-fold speedup in CPU-based computation compared to a commercial FDTD solver and a 30-fold speedup when using GPU.

Further, we extended our approach to 2D phase masks, designing structures that generate specific interference patterns such as a focal point, a single helix, and a double helix. These designs were optimized using 3D electromagnetic simulations and GPU acceleration, reducing computation time per iteration to 45 seconds—several hours faster than a CPU-based reference solver. The optimized phase masks effectively directed light into the desired patterns, demonstrating the feasibility of generating complex chiral nanostructures using normal plane wave illumination alone.

3. Conclusion

This study demonstrates the practical inverse design of 2D phase masks capable of generating intricate 3D holograms while significantly reducing computational costs. We enable rapid and reliable optimization of large-scale phase masks by integrating GPU-accelerated frequency-domain solvers into the PnP process. This approach opens new possibilities for scalable, high-contrast nanopatterning with applications across photonics, sensors, and other advanced nanomanufacturing fields.

Tailoring the design space of structurally colored stretchable materials

B. Abdennadher[1], M. Saba[1], U. Steiner[1], and M. Kolle[2]

bilel.abdennadher@unifr.ch

Abstract

Large scale-structural colored streachable material was recently developed. We aim to parametrize its design space using two surface roughness parameters: the autocorrelation length and the Root Mean Square. By tuning roughness, we control diffuse and specular scattering, enhancing light diffusion and minimizing iridescence for improved sensing applications.

Large-scale, structural colored stretchable material was recently developed. We aim to parametrize its design space using two surface roughness parameters: the autocorrelation length and the Root Mean Square. By tuning roughness, we control diffuse and specular scattering, enhancing light diffusion and minimizing iridescence for improved sensing applications.

Structurally colored stretchable material was recently fabricated using Lippmann photography and photosensitive elastomers [1]. This process generates refractive index variations in the material, making it act as a distributed Bragg reflector. We aim to expand these materials' design space and improve their scattering properties by mainly controlling their surface roughness. Specifically, we want to modify the light scattering behavior—from specular to more diffuse—and minimize iridescence by tuning the roughness of the photonic material itself and adding a rough, transparent, thick top layer. Thus, this approach will provide new possible applications of these materials in optical sensors.

The idea behind using a rough top coat is to introduce initial diffusion before the light interacts with the Bragg reflector; this broadens the scattered light cone and enhances total diffusion. Selecting a thick top coat of the photonic material simplifies our analytical model. Since the thickness exceeds the coherence length of light, we can treat the system from a far-field perspective, allowing intensities to add up more straightforwardly. Additionally, assuming that the top coat is homogeneous and transparent, no scattering occurs within it, ensuring that light propagates through it without more diffusion.

To model the scattering behavior, we consider a system composed of three sequential scattering events: (1) transmission from air into the rough top coat, (2) reflection at the interface between the top coat and the photonic material, and (3) transmission back into the air from the top surface. By tuning the roughness of both the photonic material and the top coat, we can control the balance between specular and diffuse scattering.

For a fixed incident angle $(\theta_{\text{in}}, \varphi_{\text{in}})$ and a fixed observation angle $(\theta_{\text{out}}, \varphi_{\text{out}})$, the total intensity results from contributions spanning all possible intermediate angles (θ_1, φ_1) and (θ_2, φ_2), accounting for the cumulative scattering effects. Here, θ represents the polar angle, and φ is the azimuthal angle. The resulting sequence of interactions is described as:

$$I(\theta_{\text{in}}, \varphi_{\text{in}}, \theta_{\text{out}}, \varphi_{\text{out}}) = \int_{\theta_1} \int_{\varphi_1} \int_{\theta_2} \int_{\varphi_2} T_1(\theta_{\text{in}}, \varphi_{\text{in}}, \theta_1, \varphi_1) \cdot R(\theta_1, \varphi_1, \theta_2, \varphi_2) \cdot T_2(\theta_2, \varphi_2, \theta_{\text{out}}, \varphi_{\text{out}}) \tag{1}$$

$$\cdot \sin(\theta_1) \cdot \sin(\theta_2)\, d\theta_1\, d\varphi_1\, d\theta_2\, d\varphi_2 \tag{2}$$

To quantify intensities in both transmission cases T_1, T_2, and in reflection R, we adapt the Generalized Harvey-Shack (GHS) Method, a semi-analytical model used to describe the scattering signature of light on moderately rough surfaces. In the literature, only a numerical model using GHS was provided for the reflection scenario [2, 3]. Therefore, we aim to extend it to include the transmission case. This extension will enable us to provide a precise prediction of angular light behavior and will allow us to link the total angular spread intensity of the system to two main roughness parameters: the autocorrelation length (lateral distance) and the root mean square (height distribution).

To better understand the core concept of the Generalized Harvey-Shack Method [2, 3], this theory aims to provide a linear system that characterizes the scattering signature of a material depending on its surface parameters. As empirical experiments show a shift-invariance behavior of the scattered light when looked at from different incident angles, this suggests the existence of a Surface Transfer Function that universally describes the scattering behavior. This function is an analogy to the linear system formulation in image formation, particularly the Optical Transfer Function OTF, which characterizes the system's ability to transfer contrast and detail from an image object to its image. The Surface Transfer Function is given by the normalized autocorrelation function of the Pupil function of the scattering process (describing amplitude and phase variation due to roughness). The Fourier transform of the Surface Transfer Function represents the angular intensity variation of the propagation vectors in the far field, which is our primary interest to measure.

Efficient lookup table computation for the design of metalenses leveraging propagation phase

A. Locatelli[1*], M. Gandolfi[1], D. Rocco[1], O. Sergaeva[1], and C. De Angelis[1]

[1]Department of Information Engineering, University of Brescia, Italy

Abstract: We introduce an efficient technique to accelerate the computation of lookup tables for the design of metalenses leveraging propagation phase. Our approach determines the phase imposed by each meta-atom through an analysis of the modal properties of a uniform waveguide array cross-section.

Research in the field of optical metasurfaces has been experiencing a rapid growth in the last decade, with potential applications in a plethora of different scenarios [1]. In particular, metalenses have attracted the interest of the scientific community thanks to the possibility of replacing conventional bulky optical components for wavefront shaping with flat-optics devices [2]. In this framework, impressive experimental results have already been reported in the literature, see e.g., fabrication of a 100-mm diameter metalens composed of billions of nanostructures [3]. As a matter of fact, design rules which are commonly used for metalenses are based on a combination of pre-calculated lookup tables for the meta-atoms, cumbersome 3D full-wave simulations of the real device, and optimization techniques needed to refine the efficiency. In a nutshell, the development of efficient numerical models plays a pivotal role in metalens design and research (see e.g. [4, 5]).

Two different physical mechanisms have been proposed so far to get meta-atoms imposing the required phase change, which is in the $0-2\pi$ range. The first approach exploits modulation of the propagation delay in a truncated waveguide structure [6], whereas the main alternative technique relies on scattering by nanoresonators characterized by properly engineered Mie resonances [7]. Hereinafter we focus on the first paradigm, i.e., metalenses based on guiding effect in high-index pillars. The goal of this work is indeed to demonstrate a fast and accurate technique accelerating the computation of the phase imposed by each meta-atom as a function of one or more geometrical parameters. We propose to model the metasurface under exam as a waveguide array, by considering both the dielectric and the air band of the periodic structure. In particular, the plane wave impinging onto the metalens is projected onto the mode profiles of the two bands, and the overall imposed phase is then estimated by weighing the propagation constants of the modes through an overlap integral. This technique considers both coupling between the (identical) meta-atoms and excitation of multiple bands. At the same time, computational efficiency is extremely high since fast modal analysis of 2D structures is sufficient for the generation of the complete lookup table for a 3D metalens.

As an example, we consider a 2D metalens composed of a periodic 1D arrangement (along x-axis) of silicon bricks ($n = 3.3$) in air. Each high-index brick has height $h = 1050$ nm, and the width W can be varied between 100 and 500 nm to get the required $0-2\pi$ phase variation (see Fig. 1a). It should be noted that the structure is invariant along the z-axis. Furthermore, incident light is a plane-wave polarized along x-axis at the wavelength of 1550 nm. The lookup table can be generated by using 2D full-wave simulations wherein a plane-wave is launched from a 1D port, and phase is evaluated by collecting the transmitted field with another port on the opposite side of the metalens (see blue lines in Figs. 1b and 1c). These results can be compared with the outcomes of approximate techniques. On one hand, we applied the simplest model that describes the metalens as a collection

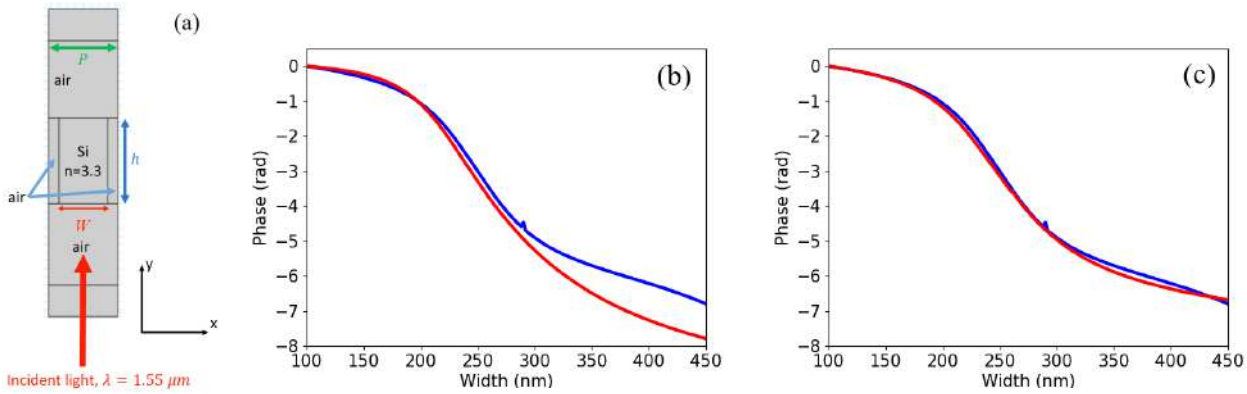

Figure 1. (a) Schematic view of the unit cell of the 2D metalens. Phase lookup table of the metasurface as a function of the width W evaluated from full-wave simulations (blue lines) and approximate models (red lines). (b) Single-waveguide model. (c) Waveguide-array model with multiple-band excitation.

of isolated waveguides. In this scenario, the phase can be estimated as $\Phi = \beta h$, where β is the propagation constant of the TM guided mode of a 1D slab waveguide. Fig. 1b demonstrates that agreement with full-wave simulations is decent, but far from being satisfactory for design of a real device. On the other hand, in Fig. 1c we report the lookup table obtained by modeling the metalens as a 1D waveguide array characterized by a dielectric band, which is generated by the coupled guided modes of the neighboring slabs, and by an air band. In stark contrast with the previous case, agreement with full-wave simulations is quite good over the entire width range.

We envisage that the reported results open the way to a fast and accurate generation of libraries of meta-atoms for design of metalenses leveraging propagation phase with realistic 3D geometries. Furthermore, investigation of the behavior of the described modeling procedure with tilted incidence is underway. Last, but not least, the possibility of exploiting this technique to refine the lookup table approach by also including the effects due to the modulation of the geometrical parameters along the surface of the metalens can be explored.

Abstract

In this study, we use the Boundary Element Method (BEM) to analyze the propagation modes and characterize the electromagnetic field distribution in the hexapolar microstructured optical fibers (MOFs). More specifically, we are interested in the proportion of the field located in an outer corona surrounding the air holes, a key region for loss engineering and the sensitivity of fiber optic sensors. Our results show that BEM provides better accuracy in calculating propagation modes than traditional methods such as finite element method.

1 Introduction

Microstructured optical fibers (MOFs) have attracted growing interest due to their light guiding properties, enabling advanced applications in telecommunications, optical sensors and biophotonics [1]. In this context, it is essential to understand and optimize the electromagnetic field distribution in these fibers, particularly in the corona outside the air holes, a key region influencing sensor losses and sensitivity [2]. To carry out this analysis, we use BEM, which offers an effective alternative to traditional methods such as the finite element method (FEM), notably by reducing computational complexity and improving the accuracy of propagation mode calculations. In this study, we analyze the distribution of the electromagnetic field, denoted RSI, in the 1 and 2 regions of the hexapole microstructured fiber.We evaluate this proportion for each propagation mode to identify evanescent modes that generate a very large RSI in the 1 region. This analysis enables us to identify and propose optimal configurations of the hexapole MOF for optical sensing.

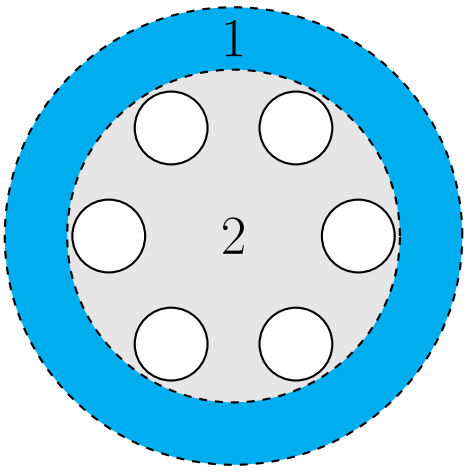

Figure 1: Hexapolar microstructured fiber.

The fraction of the total power located in the region 1 and 2 is evaluated as:

$$RSI = \frac{\int_{(1,2)} \Re(E_x H_y - E_y H_x) dxdy}{\int_{total} \Re(E_x H_y - E_y H_x) dxdy} \quad (1)$$

where Ex, Ey, Hx et Hy are the transverse electric and magnetic fields

2 Boundary element method

The integral approach we have adopted is based on the formulation developed in [3]. It corresponds to an eigenvalue problem where the eigenvectors represent the transverse or longitudinal components of the field at the interfaces, in other words, at the boundary of the Ω_l air holes. Every components u of the electromagnetic field of the mode satisfies the following Green's representation formula:

$$u(\mathbf{r}) = \pm \left(\int_{\partial\Omega_j} G(\mathbf{r}, \tilde{\mathbf{r}}) \frac{\partial u(\tilde{\mathbf{r}})}{\partial(\tilde{\mathbf{r}})} \mathrm{d}s(\tilde{\mathbf{r}}) \; - \int_{\partial\Omega_j} \frac{\partial G(\mathbf{r}, \tilde{\mathbf{r}})}{\partial(\tilde{\mathbf{r}})} \, u(\tilde{\mathbf{r}}) \mathrm{d}s(\tilde{\mathbf{r}}) \right), \; \mathbf{r} \notin \partial\Omega_j \,, \tag{2}$$

The table highlights the RSI and complex effective indices for two modes, revealing a strong asymmetry in energy distribution between regions, with a first mode mainly confined to a specific region (RSI=99.01%) and a second mode showing a more balanced distribution (RSI=62.63%).

MOF.	**neff**	**RSI**	
		RSI_1	RSI_2
MODE.[1]	$1.4453952 + j3.1952e-08$	0.96%	99.01%
MODE.[2]	$1.2973449 - j5.8943e-11$	62.63%	37.35%

Table 1: Relative sensitivity values in each region

3 Conclusion

In this study, we analyzed hexapolar microstructured optical fibers using the boundary element method, focusing on the proportion of the electromagnetic field in a corona external to the air holes. Our results show that this approach offers a better possibility of calculating higher-order propagation modes than conventional methods, notably the finite element method. In addition, we have highlighted the influence of the fiber's geometric parameters on field distribution, and proposed optimized configurations to improve sensitivity and minimize losses. These results pave the way for new fiber designs suitable for applications in telecommunications, optical sensors and biophotonics, where precise control of field distribution is essential.

Cosine beams for near-field space division multiple access in 6G communications and beyond

S. Droulias*, G. Stratidakis, and A. Alexiou

Department of Digital Systems, University of Piraeus, Piraeus 18534, Greece

*corresponding author: sdroulias@unipi.gr

Abstract: In this work, we propose the family of cosine beams that satisfy the orthogonality condition, offering a multitude of communication modes for multiple access in the near-field. We introduce the concept of near-field space division multiple access (NF-SDMA) to enable spatial multiplexing and capacity improvements for 6G near-field wireless connectivity.

Wireless communications are nowadays shifting to higher frequencies and the utilization of large radiating apertures for manipulating the wavefront of the radiated wave, to acquire curvature beyond the typical far-field planar form. For example, focused beams are ideal for concentrating the power at controllable distances and small areas, a key element for energy efficient communications and localization applications [1,2]. Such beams could be used in a multiple access scheme, to boost connectivity to unprecedented performance levels. Multiple access offers the advantage of having several users simultaneously served with minimum interference and maximum resource allocation. It relies on the orthogonality of beams, a key element for successfully retrieving the information assigned to different beams, even though all such beams may coexist. For example, in classical far-field space division multiple access (SDMA) it is possible to distinguish multiple users at different angles, due to the angular beam orthogonality. Despite the various attempts, to date, the design of near-field multiple access schemes relies primarily on the utilization of focused beams, which are either entirely non-orthogonal or achieve orthogonality only asymptotically [3]. Hence, a multiple access scheme based on beams that have strictly zero correlation, is still missing.

Consider a transmitter (Tx), such as a uniform planar array (UPA), centered at the origin of the coordinate system, with its plane extending on the *xy*-plane, as shown in Fig.1(a). A receiver (Rx) is located at distance L, with its surface also residing on the *xy*-plane. The Tx generates beams that propagate along the *z*-axis, the *E*-field of which at the observation point $\mathbf{r} = (x,y,z)$ is $\mathbf{E}(\mathbf{r}) = \mathbf{E}(x,y,z)$. The correlation of two such beams $\mathbf{E}_1(x,y,z)$, $\mathbf{E}_2(x,y,z)$ at distance $z = L$, as defined in terms of their inner product on the transverse *xy*-plane, is written as

$$C = \frac{\iint_{-\infty}^{+\infty} E_1(x,y;L)E_2^*(x,y;L)dxdy}{\sqrt{\iint_{-\infty}^{+\infty} |E_1(x,y;L)|^2 dxdy}\sqrt{\iint_{-\infty}^{+\infty} |E_1(x,y;L)|^2 dxdy}} \quad (1)$$

where E_1, E_2 are the magnitudes of the *E*-field vectors.

In this work we propose cosine beams as a family of beams that satisfy the near-field orthogonality property, i.e. $C = 0$. A cosine beam is a beam formed by the superposition of two waves traveling at opposite oblique angles [4]. The distance z_{max} marks the cosine beam range, i.e. the propagation distance for which the standing wave is formed in the transverse (*xy*) plane, as shown in Fig.1(a). Such beams offer the necessary condition $C = 0$ (see Fig.1(b),(c)), offering a multitude of communication modes, as shown in Fig.1(d),(e). By applying a global phase of the form $kx \sin\theta$ at the Tx, the beam can be steered towards any desirable angle θ.

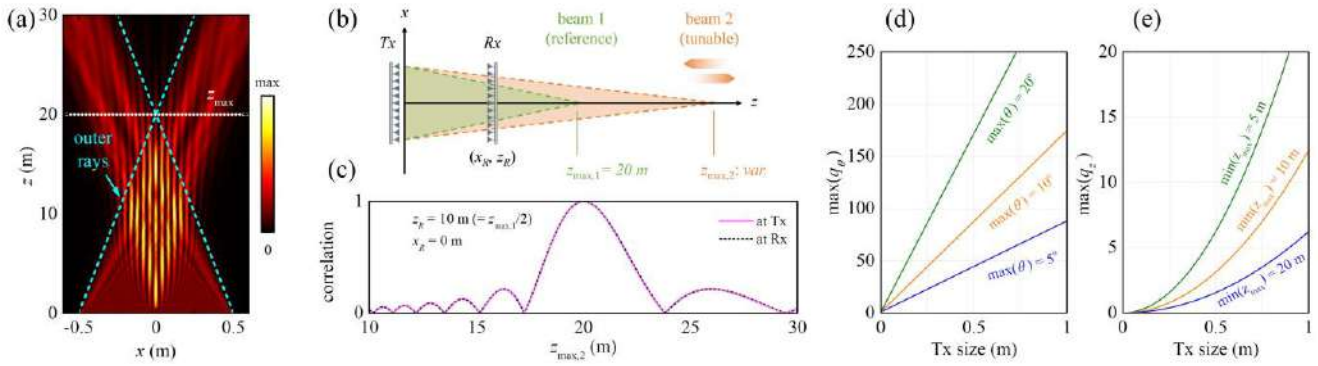

Figure 1. Cosine beams for NF-SDMA. (a) Intensity of numerically propagated beam, using an array of size 1 m. The operation frequency is 150 GHz. (b) Schematic illustration of two cosine beams generated by a transmitter (Tx) and directed towards the receiver (Rx), located at (x_R, z_R). Beam 1 has fixed $z_{max,1}$ = 20 m, and is used as reference. Beam 2 has tunable z_{max}, accounting for a multitude of cosine beams. (c) Beam correlation at the Tx and the Rx, as a function of $z_{max,2}$, for Rx of size 1 m, located at (x_R = 0 m, z_R = 10 m). (d) Maximum number of communication modes per maximum steering angle, max(q_θ), as a function of the array size; examples for max(θ) = 5°, 10°, 20°, the maximum angle at which the cosine beams are steered. (e) Maximum number of communication modes per minimum convergence distance, max(q_z), as a function of the array size; examples for $z_{max} \geq$ 5 m, 10 m, 20 m.

We provide analytical expressions for the cosine beam orthogonality and we prove theoretically that there is a countable set of mutually orthogonal beams, all propagating along the same direction. We also prove that the same conclusion holds for beams propagating along different directions, providing an ideal means for multiple access in both the angular and the distance domain. For different Tx sizes, we numerically verify that the orthogonality of the proposed beams is successfully retrieved at a receiver that resides in the near-field of the transmitter, and is also robust to displacements of the receiver. With the aid of cosine beams, we introduce the concept of near-field SDMA (NF-SDMA) to bring into the near-field the classical far-field SDMA and its benefits, which are essential for novel near-field applications in future wireless communications.

Abstract: A dimer grating is engineered to increase the light emission of a dipole source in the normal direction through the transformation of a bound state in the continuum (BIC) into a quasi-BIC (QBIC). We study the effect of controlled and structural disorder on the structure.

The design of photonic structures capable of enhancing the emission of quantum emitters is an active area of research [1] with applications in lighting, imaging... The performance of those structures is measured by the radiative enhancement (RE), product of the emitters normalized decay rate and the light extraction efficiency. Periodic gratings supporting symmetry-protected BICs have been proposed as an efficient solution to increase light emission in off-normal directions [2,3]. In this work, we study a dimer grating where asymmetry is introduced to transform the BIC into a QBIC radiating at the Γ point.

The dimer grating of period $2 \times D = 2 \times 420$ nm is built from TiO_2 ribbons of height $h = 150$ nm and width $w = \frac{D}{2}$ separated by a distance L. A 200 nm TEOS cover layer protects the grating and contains a dipole which is centered between the dimer elements and emits light at a wavelength $\lambda = 618.5$ nm. Figure 1 presents the two kinds of perturbations we consider: width variations $w \pm \Delta w$ and gap variations $L \pm \Delta L$, respectively characterized by parameters $\alpha = \frac{\Delta w}{w}$ and $\beta = \frac{\Delta L}{L}$. All simulations are performed using the quasi-normal mode method [4].

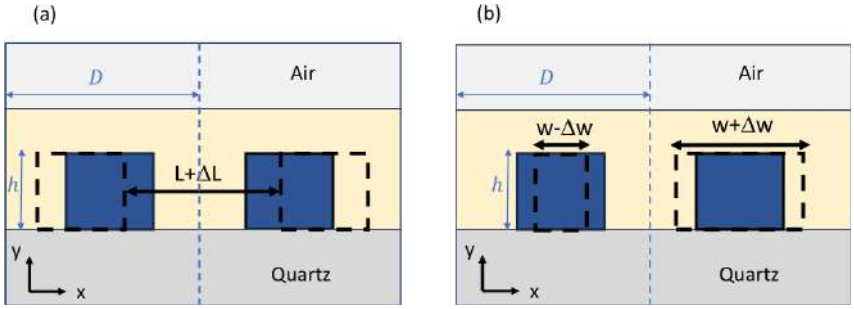

Figure 1: Schematic of a dimer grating made of two TiO_2 ribbons embedded in a TEOS layer. (a) and (b) are respectively modified gap $L \pm \Delta L$ and widths w±Δw dimer gratings.

The symmetry of the dimer structure ($\alpha = \beta = 0$) leads to a BIC existing at the Γ point. The infinite Q-factor of the mode increases the dipole emission through the Purcell effect but prevents the light extraction from the structure, resulting in a null radiative enhancement. Through a breaking of the dimer symmetry induced by α and β perturbations, we observe a radiative enhancement at the Γ point which can be explained as the transformation of the BIC into a QBIC with a lower Purcell factor but a non-zero light extraction efficiency. RE values up to 1600 are obtained in the normal direction with the dimer grating. RE values for both structures are presented in figure 2.

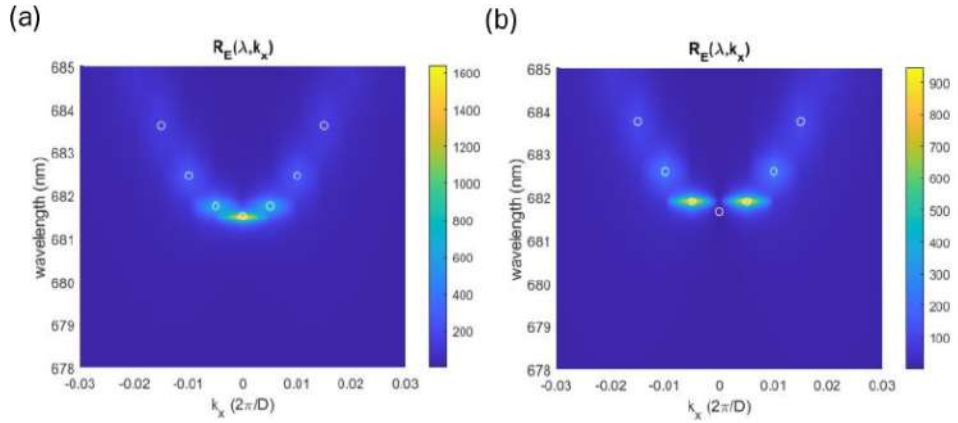

Figure 2: Directive radiative enhancement coefficient $R_E(\lambda, k_x)$ calculated: (a) for the dimer structure with $\alpha = 0$ and $\beta = 0.08$, (b) for the regular grating with $\alpha = 0$ and $\beta = 0$.

Structural disorder induced by fabrication imperfection is another source of asymmetry. It is known that BICs and QBICs are sensitive to this kind of disorder [5]. We study its effect on the dimer structure by independently randomly perturbing the position and width of the elements in a supercell. Results presented in figure 3 show that structural disorder on the ribbon's width greatly reduces the RE by splitting the QBIC energy on multiple wavelength. Conversely, the dimer structure is robust to structural disorder on the position of the elements.

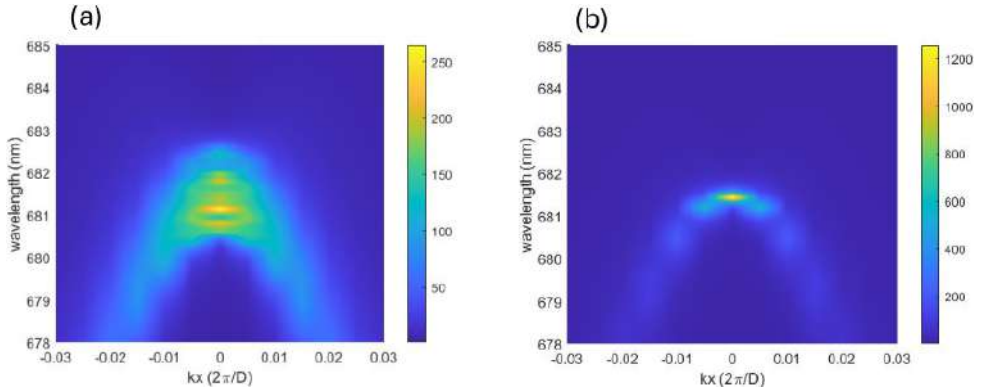

Figure 3: Average $R_E(\lambda, k_x)$ for the dimer grating with ($\alpha = 0$, $\beta = 0.08$) calculated for a perturbation strength $\delta = 1.2\%$: (a) when disorder only affects the width of the ribbons, (b) when disorder only impacts the position of the ribbons.

Abstract: Lead halide perovskites, with their unique structural and optical properties like bright photoluminescence and highly tunable band gap have gathered significant attention due to their enormous number of optoelectronic applications. In this work, we demonstrate in-situ photoluminescence lifetime imaging and describe the kinetics of halide anion exchange inside $CsPbBr_3$ nanocrystals.

Nanocrystalline lead halide perovskites (LHPs) have recently emerged as prominent low-dimensional semiconductors due to their combination of bright direct optical transitions, unique structural and optical properties, room-temperature stable excitonic states [1], and single-photon emission capabilities [2]. Their straightforward and cost-effective synthesis from abundant elements makes LHPs an appealing, high-performance alternative to conventional optoelectronic materials [3]. Initially developed for photovoltaic applications, achieving light-conversion efficiencies surpassing 26%, LHPs are now gaining recognition as versatile materials for a variety of optoelectronic uses, including gamma radiation detectors and scintillators [4].

Among the LHPs, the all-inorganic $CsPbBr_3$ perovskite stands out for its unique optical and structural properties such as low non-radiative losses, high tolerance to structural defects, and bright, narrow photoluminescence (PL) emission in the green region of the visible spectrum (~2.4 eV/520 nm) with quantum yields exceeding 90% and a linewidth of approximately 56 meV (12 nm) in its nanocrystalline form [5, 6]. Due to its inherent ionic nature, the electronic structure and optical properties of $CsPbBr_3$ can be tuned across the entire visible spectrum [(1.4–3.6) eV] by incorporating different halides [7]. This band gap engineering offers not only an enormous amount of potential optoelectronic applications but also a significant insight into molecular dynamic processes in such nanosized systems.

In this work, we demonstrate *in-situ* observation of halide anion exchange kinetics in $CsPbBr_3$ nanocrystals dispersed in a toluene solution by photoluminescence lifetime imaging with state-of-art Leica Stellaris Falcon 8 Fluorescence Lifetime Imaging Microscope (FLIM). The $CsPbBr_3$ nanocrystals dispersed in toluene are placed into a micro-cuvette system and halides (I, Cl) are introduced to the solution through injection of their precursors (CsI, ZrI, DDACl) dispersed either in isopropyl alcohol or toluene. The wideband sensing of FLIM allows for real-time observation of the halide exchange in $CsPbBr_3$ (Figure 1), which is revealed by recording the photoluminescence lifetime of the perovskite chemical phases. This allows for determination of the reaction's kinetics, reveals intermittent perovskite phases and helps to elucidate the underlying physical and chemical processes.

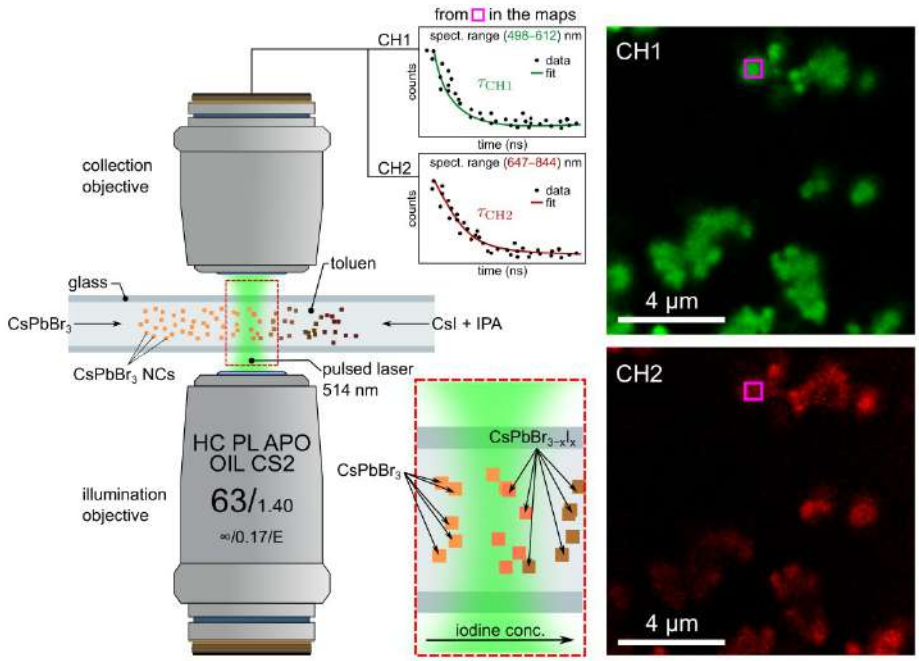

Figure 1 Schematics of the *in-situ* photoluminescence lifetime imaging of halide anion exchange in $CsPbBr_3$ nanocrystals.

Abstract

Anisotropic 2D metal nanoparticles (2D-MNP) of radius *r*, which form arrays on corrugated sapphire, show in-phase longitudinal plasmon hybridization from strong inter-particle coupling. This hybridization includes anisotropic plasmonic responses dependent on the inter-particle distance *S*, excitation polarization angle *σ*, and pumping (laser) wavelength, making the substrates suitable for applications requiring tunable plasmonic properties.

Structural and Optical Characterization:

In the fabricated 2D-MNP arrays, sapphire templates subjected to thermal annealing have been utilized, resulting in periodic corrugations. Au films of various thicknesses (2–10 nm) were deposited to form the grains with the average diameters of ~30 nm. Atomic force microscopy (AFM) confirmed the anisotropic in-plane ordering of Au grains on the corrugated substrates. Reflection and transmission spectra were obtained for different polarization angles (σ = 0°, 45°, and 90°) by using ellipsometry. The shifts in plasmon resonance wavelengths (λ_p) with increasing Au thickness have been shown.

Results and Discussion

Plasmon Hybridization and Anisotropic Response

Far-field measurements revealed longitudinal bonding and transverse anti-bonding plasmon modes in the arrays. The wavelength λ_p is red-shifted while increasing the Au thickness, that is attributed to strong inter-particle coupling. These effects were stronger pronounced for the samples with smaller corrugation periods *P*, indicating the importance of precise inter-particle distances in anisotropic plasmonic behavior.

Electromagnetic (EM) simulations reveal near-field distributions consistent with the experimental results. These distributions show the enhanced coupling in the arrays with $S < r$, producing the localized plasmonic hotspots. The anisotropic plasmonic response has further been confirmed by measuring reflectance spectra for different polarizations, by highlighting the role of inter-particle distance in tuning the plasmonic modes.

SERS Enhancement Mechanism

The polarized SERS measurements showed the strong anisotropic enhancements for phenyl-thiolate analytes. Excitation at λ_{exc}=633 nm produced significant SERS dichroism, with lower-frequency Stokes peaks ($\lambda_{Stokes1}$) exhibiting $cos^2(\sigma)$ dependency, while higher-frequency peaks ($\lambda_{Stokes2}$) follow $sin^2(\sigma)$ dependency. The observed differences were linked to the near-field enhancement factors, *g* and g^s, which are associated, respectively, with the plasmonic coupling and the ordering of 2D-MNP arrays:

$$I_{SERS}(\lambda_{exc}) \propto |\alpha_R|^2 |gg^s|^2 I_{exc}(\lambda_{exc}) \quad (1)$$

where I_{SERS} is intensity of the emitted SERS peaks and I_{exc} is intensity of laser light.

At λ_{exc} = 785 nm, the anisotropy in SERS enhancement is more pronounced, as it relies on the dipole scattering intensity influenced by the array's ordering. The comparison of flat and corrugated templates indicates that smaller corrugation periods *P* can produce higher enhancements, demonstrating the interplay between nanoparticle arrangement and plasmon resonance tuning.

Implications for SERS Applications

The combination of the distributed hotspots and broader plasmonic resonances makes the proposed substrates ideal for reliable and reproducible SERS sensing. The observed anisotropic SERS effects provide new insights into the possible role of plasmon hybridization in optimizing SERS performance. The dichroic behavior observed at Stokes peaks highlights the potential of the substrates of the used type in advanced sensing applications, particularly in polarized SERS techniques.

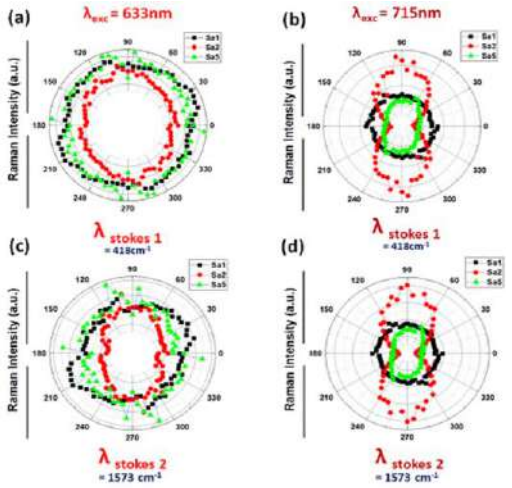

Figure 1. (a) and (c): example of SERS dichroism for $\lambda_{Stokes1}$ and $\lambda_{Stokes2}$ peaks on flat sapphire (sample Sa1) and corrugated sapphire, Sa2 (P=30nm) and Sa5 (P=150nm) samples measured for $\Delta\sigma = 5^o$ at λ_{exc} = 633nm. (b) and (d): example of SERS dichroism for $\lambda_{Stokes1}$ and $\lambda_{Stokes2}$ peaks on Sa1, Sa2 and Sa5 samples measured for $\Delta\sigma = 5^o$ at λ_{exc} = 785nm.

Conclusions

The ordered 2D-MNP arrays with the inter-particle spacing S smaller than the radius r were fabricated by depositing non-percolated ultrathin Au films onto the corrugated sapphire templates. The golden grains with diameter d nucleated anisotropically onto the templates with period $P \approx d$. In contrast, the templates with $P \gg d$ produced disordered grain nucleation. *First, the novelty of the results presented here is an anisotropic response of the collective plasmon modes arising in the 2D-MNP arrays, depending on the polarization azimuthal angle σ*. The simulated spectra and EM near-field distributions confirm this anisotropy and reveal plasmon hybridization. *The second interesting conclusion from SERS experiments states that the transverse collective plasmon modes excited at λ_{exc}=633nm< λ_p depend primarily on S rather than the extent of order in the MNP arrays.* It is supported by similar absolute SERS intensities at σ=90^o for flat substrate $P \approx d$, and substrate with $P \gg d$. Conversely, at λ_{exc}=785 nm > λ_{LP1}, the absolute SERS intensities at σ=90^o and σ=0^o are varied among the investigated samples, indicating that the ordering of MNP arrays affects the dipole mode scattering intensity and contributed to anisotropic SERS enhancement. *The third important outcome of our investigation is the SERS dichroism dependence on λ_{exc}, λ_p, and σ.* The lower-frequency Stokes-shifted peaks ($\lambda_{Stokes1}$), being closer to λ_p and λ_{exc}, exhibit a $cos^2(\sigma)$ dependency, that is consistent with the $|E|^4$ mechanism. In contrast, higher Stokes-shifted peaks ($\lambda_{Stokes2}$) follow a $sin^2(\sigma)$ dependency, being driven by variations of the enhancement factors (g at λ_{exc} and g^s at λ_{Stokes}) that validates the EM near-field mechanism of SERS. Finally, the essential criteria for reliable, reproducible, and feasible SERS measurements, such as distributed hotspots, broad resonance peaks (enabling wider Stokes-shifted ranges), and near-field enhancements up to 10^{10}, were successfully met.

Abstract: Etching is a complex and costly method for making nano-structuration in photonics. In this work, we present an innovative approach to fabricate meta-surfaces without etching, using Pulsed Laser Deposition combined with liftoff processing to enhance rare earth emission.

Rare earth based micro- and nano-photonics are promising for applications in quantum optics or telecommunication [1], [2]. Materials such as Y_2O_3 and Al_2O_3 are suitable hosts for lanthanide ions, including Erbium (for telecom wavelength) and Europium (for visible light applications). However, their microfabrication requires etching processes, which currently increases the cost and limits the design flexibility of devices [2], [3], [8]. In 2021, we have demonstrated for the first time that micro-strips of Y_2O_3:Eu^{3+} could be fabricated ~~are possible to make~~ without etching by combining Pulsed Laser Deposition (PLD) with liftoff processing [4]. Later on, we have extended our technic~~s~~ to other materials, including Al_2O_3 with Er doping [5] and we have improved the resolution fabrication down to few micrometers [6]. More recently, we have also shown that beam filtered PLD can provide high quality films suitable for waveguide applications [7]. Finaly, we are now exploring etching-free photonic crystals, showing very promising results for nano-metric structurations.

Figure 1-a illustrates the PLD principle. A high-fluence laser is focused on a target, ejecting a high kinetic energy plume that deposits matter onto a substrate. This directive method enables thus the production of high-quality layers at room temperatures, surpassing other methods in certain aspects. Following this, a lithography step is performed (Figure 1-b), after which lift-off processing can be performed directly after deposition (Figure 1-c) to create micro or nanostructures (Figure 1-d) [4]. Nevertheless, several optimizations are required, such as the control of the photoresist sidewall slopes (Figure 1-b), the layer quality (Figure 1-c) and the clean liftoff process to obtain smooth sidewalls (Figure 1-d).

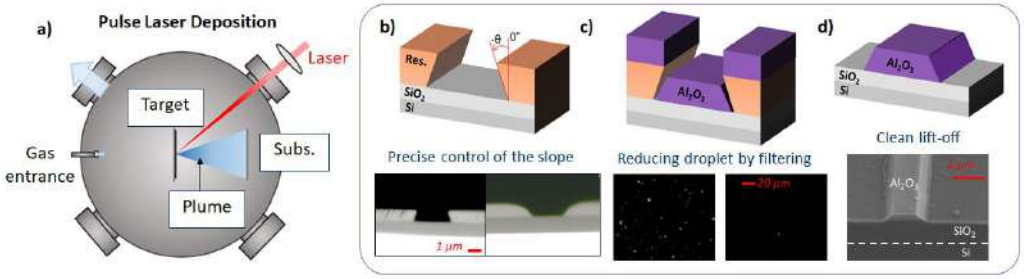

Figure 1 : a) Pulsed laser deposition technics; Processing and optimization for b) slope control of the lithography, c) layer quality improvement and d) clean liftoff

Figure 2 shows examples of rare-earth-doped microstructures with various shapes, such as micro-bowls arrays (Figure 2-a), gratings (Figure 2-b), ring resonators (Figure 2-c), nanopillars (Figure 2-d) and photonic crystals (Figure 2-e). In addition to the cost advantage, this approach provides access to new shapes, such as micro-bowls or localized doped rings, that are challenging to achieve using conventional methods (ANR project IDEAL 2025-28 in progress). The deposited thicknesses are intrinsically linked to the photosensitive resin thickness, with a typical thickness ratio of approximately 1:3. This allows the fabrication of structures around 500 nm thick with micrometric resolution (e.g., waveguides, infrared gratings) or thinner layers, approximately 100 nm layers, with sub-micrometric resolution (e.g., micro pillars or photonic crystals).

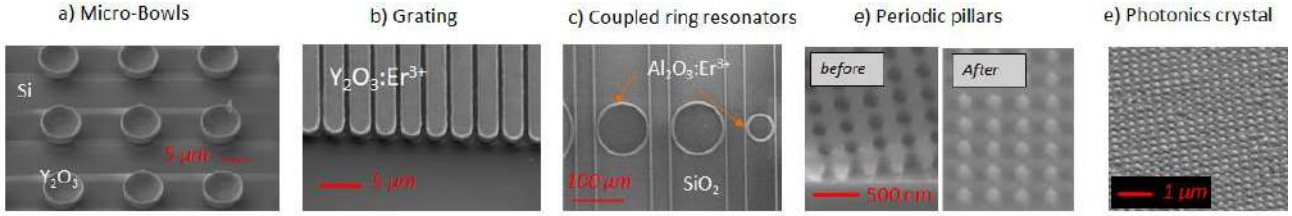

Figure 2: SEM imaging for a) arrays of micro bowls, b) grating, c) ring resonator, periodic pillar and e) photonics crystal.

Figure 3 presents optical characterizations of the fabricated devices, including the photoluminescence of microstrip for various materials and doping configurations [4], [5] (Figure 3-a) and the modified reflectivity showing the Erbium photoluminescence enhancement (Figure 3-b and c) [6]. Furthermore, we recently demonstrated low-losse waveguides made of Al_2O_3, achieving losses as low as 2 dB/cm [7].

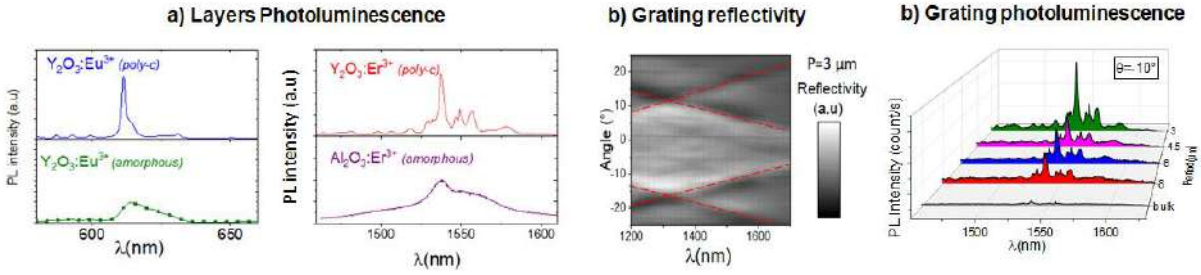

Figure 3 : Photoluminescence measurements in microstrip with different materials and doping [4], [5] *; b) reflectivity measurement in 3µm period grating and c)associated photoluminescence as a function of the grating period* [6]

This work highlights the significant potential of our approach combining PLD and liftoff-for fabricating innovative devices with rare earth doping. It could also be extended to other materials and applications currently constrained by etching limitations.

Abstract: Bipartite, two-dimensional periodic arrays stand as promising platforms for photonic applications. By controlling the nanoparticle positioning within the unit cell, we demonstrate that these systems can be exploited to achieve perfect absorption and to excite out-of-plane lattice resonances at normal incidence, which exhibit outstanding quality factors.

Lattice resonances are collective modes supported by periodic arrays of nanoparticles, arising from their coherent interactions [1]. While monopartite configurations (arrays with only one particle per unit cell) provide the simplest setting for observing these modes, bipartite arrays offer a compelling avenue for exploration. In particular, controlling the relative positioning of the two nanoparticles within the unit cell serves as a powerful tool for tailoring and accessing remarkable optical phenomena not achievable in monopartite systems. Here, we demonstrate that bipartite systems can be leveraged to achieve perfect absorption in planar arrays and to excite out-of-plane lattice resonances at normal incidence. Furthermore, the resonances exhibit higher quality factors and greater tunability than traditional methods seeking similar goals, which makes these bipartite arrays as promising platforms for advanced optical applications.

Figure 1 summarizes the main results discussed in this communication, with Figure 1(a) presenting a schematic of the bipartite arrays under consideration in their most general form.

Placing the first particle at the origin and the second at the center of the unit cell cancels all electric-magnetic interactions between the nanostructures. In this configuration, purely electric and magnetic lattice resonances will not interact, allowing for their independent tuning. Such an effect can be leveraged to achieve perfect absorption by overlapping electric and magnetic lattice resonances (LRs) [2]. This principle can be demonstrated in a bipartite system composed of gold and silicon nanoparticles, which act as sources of electric- (ED) and magnetic dipolar (MD) resonances, respectively. Figure 1(b) demonstrates how, by carefully controlling the lattice period, the wavelengths at which these resonances overlap is precisely tuned, enabling for the perfect absorption effect.

Alternatively, a position like $(x, y) = (a_x/4, a_y/4)$ enables interactions that couple in-plane (x or y) and out-of-plane coordinates (z). In particular, the interaction between in-plane dipoles can induce an out-of-plane dipole moment, allowing for the excitation of out-of-plane lattice resonances at normal incidence [3]. This approach offers a significant advantage over conventional methods that rely on oblique incidence excitation, which often degrade the quality of the resonance and limit their applicability in integrated devices. As illustrated in Figure 1(c), by working with a bipartite array of silver nanospheres in vacuum we are able to generate out-of-plane lattice resonances with outstanding quality factors, advantageous for applications in lasing and biosensing.

Thus, our work paves the way for the design of bipartite arrays of nanostructures as platforms for advanced optical effects, enabling their exploitation in a wide range of photonic applications.

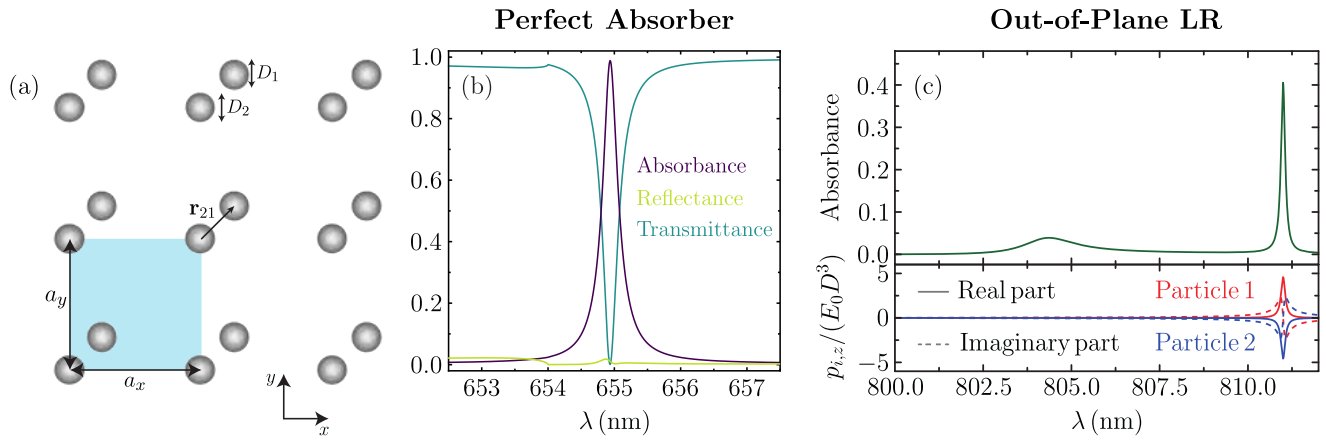

Figure 1. (a) Schematics of the bipartite systems under consideration. (b) Perfect absorber, achieved with a bipartite array that contains a gold and a silicon nanoparticle. The geometrical parameters of the system are: $a_x = 654$nm, $a_y = 649$nm, $D_{Au} = 98$nm, $D_{Si} = 140$nm, and $\boldsymbol{r_{21}} = (a_x/2, a_y/2, 0.0)$. (c) Excitation of an out-of-plane lattice resonance under normal incidence (λ~811nm) in a bipartite, square array composed of equal silver nanospheres. The parameters in this case are: $a_x = a_y = 800$nm, $D_{Ag} = 160$nm, and a relative position of $\boldsymbol{r_{21}} = (a_x/4, a_y/4, 0.0)$.

Abstract:
We demonstrate and discuss two approaches to designing complex liquid crystal (LC) photonic devices – shape and topology optimization. The methods are applied to LC filters, holograms and waveguides. The latter two were manufactured using photopatterning. With these design and manufacturing techniques we design high performance liquid crystal photonic devices.

Optical elements based on liquid crystals (LCs) are widely used for different applications due to their mechanical and electro-optical properties. The optical birefringence is actively exploited in LC-based optical devices [1], [2], [3]. With photoalignment, it is possible to create alignment patterns with very fine features, but the characteristic length scale of the LC is a necessary consideration during the design of LC optical devices. The design can be adjusted for the relaxation of the LC, by computing the full director configuration simulation or approximated with various mapping functions. Computer-generated holograms (CGHs) are promising for many applications [4], [5], [6]. The CGHs are 2D phase or amplitude patterns which when illuminated by a coherent light source are reconstructed into a 2D or 3D image in space. Optical waveguides are essential for tele- and data communication technology. In existing waveguide platforms, the propagation of light is realized efficiently, but for modulation and routing, hybrid integration with other material systems is often necessary [7], [8], [9]. Topology optimization is a powerful computational inverse design method that has been applied in engineering and scientific research to design and optimize structures with optimal physical or mechanical properties. Topology optimization for photonics is enabling the design of improved optical/photonic components and devices [10], [11], [12].
We design LC optical filters with specific transmission spectra using topology optimization. We design short-pass filters in various wavelength ranges which can work as standalone devices or be integrated into soft matter waveguides. We explore other transmission spectra such as Gaussian or linear. We developed a shape optimization design framework based on Signed Distance Functions (SDFs), where we can construct complex geometry and vector fields completely parametrically. A Python implementation of this framework is available in SPOMSO [13]. Using this approach and the photopatterning manufacturing method, we realize 3D waveguides in the bulk of the LC, by only defining the anchoring patterns on the surface. We show straight and curved waveguides with various radii of curvature and discuss the associated losses [14]. Another approach to design of complex geometry is by using topology optimization. We developed a topology optimization-based algorithm which generates phase-only 2D computer-generated holograms - TO-CGH [15]. With our algorithm, we can enforce design, manufacturing,

and material constraints. The liquid crystal-based computer-generated phase-only holograms are also manufactured using photoalignment. We further develop the algorithm to use different far-field solvers and to support full RGB holograms.

Abstract: Mechanical metamaterials enable novel behaviors like tunable crack openings in thin metal films. These "meta-crack" sensors, combining high sensitivity and conformal contact, outperform conventional sensors. Leveraging Poisson-induced contraction and metamaterials, they offer adjustable sensitivity and strain range, with applications in bio-diagnostics like real-time stroke detection, revolutionizing healthcare innovations.

Mechanical metamaterials offer insights into novel mechanical behaviors by inducing unexpected deformations in conventional materials. In this study, we explore the unique phenomenon of crack opening in thin metal films, which exhibits distinctive behavior when coupled with a metamaterial structure. Thin-film crack sensors are advantageous due to their simple fabrication process, thin profile, and ability to achieve conformal contact with various surfaces, enabling broad applicability. The induced cracks in the thin film result in significant changes in electrical conductivity even under minor deformations, making them highly sensitive sensors. Unlike conventional sensors, the key feature lies not in binary on/off resistance changes but in the Poisson-induced contraction, which prevents immediate separation of crack surfaces. This creates transient contact areas, maintaining sensor functionality. However, this mechanism can also reduce sensitivity. By incorporating metamaterial structures, we successfully controlled the crack opening behavior, allowing tunable sensor sensitivity and an extended measurable strain range.[1] Furthermore, we demonstrate the application potential of these "meta-crack" sensors in bio-diagnostics, including real-time stroke detection.[1] This presentation will cover the deformation mechanisms, sensor applications, and practical implementations of these advancements, highlighting their potential in healthcare and beyond.

Figure 1a demonstrates through SEM imaging that cracks with meta-structured substrates exhibit faster interface opening under tensile strain compared to those without meta structures.[1] The meta-crack sensor is composed of a crack-induced conductive Mo layer (50 nm thick), a MoO_3 adhesive layer (15 nm thick), and a substrate featuring an auxetic structure. The substrate combines a PBAT base matrix (30 μm thick) and a PLA auxetic structure (10 μm thick). With a Poisson's ratio of -0.9, the sensor achieves a gauge factor at least four times higher than conventional crack sensors at a strain of 3×10^{-3}, delivering an exceptional strain resolution in the 10^{-5} range.

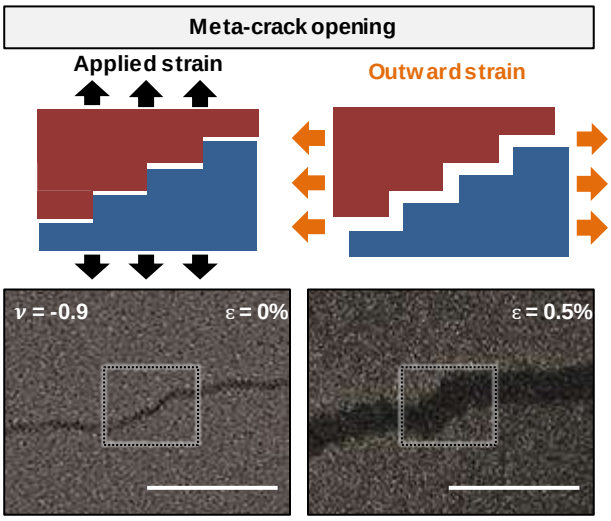

Figure 1. Illustration and SEM images highlight the step-shaped crack boundaries and their response to vertical tensile strain (5×10^{-3}) in meta-cracks characterized by a Poisson's ratio of -0.9. Abstract: We present a new class of all-optically tunable, light-generating metasurfaces. By coupling virtual excitons in two-dimensional semiconductors with off-resonant photons from a strong field, we attain ultrafast spectral and amplitude control of harmonic generation in nonlinear metasurfaces. Our work represents a significant advancement in the development of compact light sources.

Nonlinear metasurfaces are a special class of compact light-generating photonic platform, where light's parameters such as amplitude, phase and polarization can be controlled with nanoscale precision[1]. This powerful control has allowed multiple demonstrations such as nonlinear holography, imaging and generation of entangled photons[1-3]. Active tuning in ultrafast temporal scales will greatly expand the capabilities of nonlinear metasurfaces, in particular for all-optical information processing. However, most all-optical control schemes rely on resonant excitation, limiting their tuning rate to the lifetime of electronic excitations, which range from hundreds of femtoseconds (hot-electrons) to picoseconds (electron-hole recombination).

Here, we introduce a novel approach to attain ultrafast control of coherent light generation from metasurfaces by coupling an off-resonant strong laser field to virtual excitons in two-dimensional semiconductors. The scheme for all-optical tuning is illustrated in Figure 1(a), and is based on the AC Stark effect. A broadband femtosecond fundamental pulse (red pulse) excites a monolayer WS_2, with its third-harmonic emission (blue pulse) slightly above the excitonic resonance (613 nm). A second strong, off-resonant beam (green pulse, 800 nm), with electric field amplitude exceeding 10^8 V/m, couples to the virtual excitons, as depicted in the energy level diagram in Figure 1(b). This strong light-matter coupling induces a blue shift of the exciton peak and, consequently, the third-harmonic spectrum, which can be tuned by the gate pulse energy (Figure 1(c)). Since this interaction involves only virtual excitons, the tuning mechanism is in principle instantaneous with the gate pulse. However, nonlinear absorption of the gate beam can slow the tuning rate to the picosecond regime (Figure 1(d)).

Figure 1(e) shows self-tunable third-harmonic generation in a plasmon-exciton metasurface that utilizes only the intensity of the fundamental beam as the tunable parameter. The metasurface consists of an arrays of gold nanorods on monolayer WS_2 fabricated using near-field inverse design[4] (Figure 1(f)). The spectrum of the third-harmonic is tunable by up to 40 meV. This large tunability enables new applications such as a dynamic beam steering, as shown in figure 1(f). Under illumination by a circularly-polarized strong field, a periodic array of rotating rods on WS_2 generates third harmonic at an angle defined by the periodicity of the array, the helicity of the input pulse, and the central wavelength of the third harmonic beam. As we control the intensity of the fundamental pulse, the angle of the emitted third harmonic beam is tuned due to the change of the peak third-harmonic spectrum.

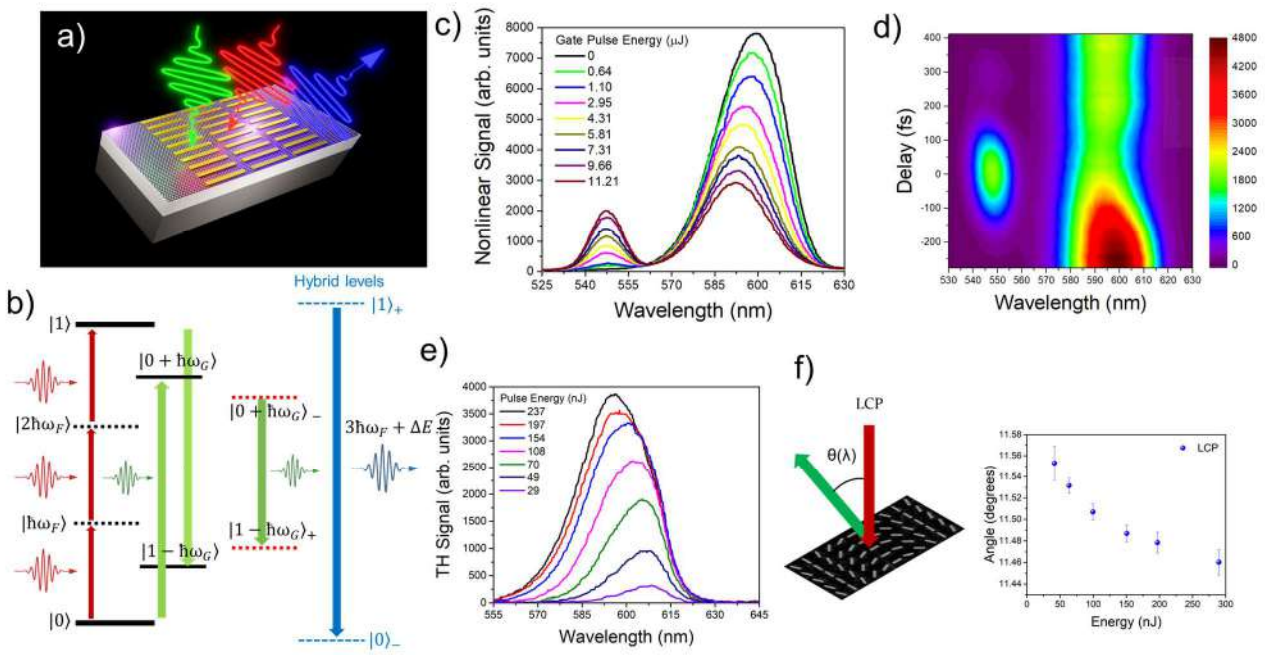

Figure 1. Tuning nonlinear metasurfaces with strong fields. a) Illustration of the tuning process. Fundamental pulse (red), control (green), third-harmonic (blue). b) Energy levels for the gated third harmonic generation. c) Third harmonic spectrum of monolayer WS_s as a function of the gate pulse energy. d) Ultrafast time-delayed measurements. e) Self-tunable metasurface, showing the TH spectra for various pulse energies of the fundamental beam. f) Self-beam steering in a phase-controlled nonlinear metasurface.

Abstract: An all Al metasurface, through numerical evaluation and THz-TDS spectroscopy, shows enhanced light-matter interaction via the presence of multimode ultra strong coupling (USC) with FW-BIC's occurring near the anti-crossings.

The phenomena of ultra strong coupling (USC), has applications in low loss on-chip communication, nonlinear harmonic generation, and will be critical for quantum computing architectures including the growing sector of quantum information technology [1,2]. USC can be achieved by placing a resonator inside a cavity with distinct resonances for both the resonator and cavity. The resulting interaction between the two resonances is exhibited through a spectral line splitting which is the creation of an upper and lower polariton. The polaritons are quasi-particles that have properties of both light and matter. The cavity creates a photon field, and the resonator creates a matter excitation. The coupled light-matter interaction creates these quasi-particles known as polaritons. When the strength of the coupling between the two becomes a significant fraction of the resonant frequency such that the frequency splitting is 10% of the resonant frequency it is said to be in the USC regime. For quantum computing platforms, the stronger the coupling the more efficient qubit-photon coupling can become which provides shorter operation times. The USC regime also allows the possibility of replacing quantum gates just by their very nature due to the natural evolution of a USC system. [3] In quantum information technology, particularly quantum computation, the core idea is to use multiple interconnected quantum systems to perform calculations, enabling the use of numerous qubits. The strength of the coupling between qubits determines the speed at which a quantum computer can process information. Exploring this phenomenon in the terahertz (THz) region is crucial, as it provides a greater communications bandwidth compared to microwave frequencies. FW-BIC's occur in cavities as a function of continuous parameter (i.e. the length of the ribbon as it is varied in the cavity). This interference induces an anti-crossing which results in part of the polariton to vanish becoming an FW-BIC. [4,5] FW-BIC's have found many applications in laser, demultiplexers and filters. [4]

Figure 1(a) shows a unit cell of the metasurface consisting of a 200 nm thick Al thin film that consists of the cavity-dipole system on a 150 μm thick quartz substrate. The cavity-dipole system is comprised of a cavity that is 280 μm x 30 μm and a ribbon that is 10 μm wide with its length parametrically varied from 50 to 270 μm. Numerical calculations were performed using ANSYS HFSS to predict the spectral response of the structure which was illuminated at normal incidence under a TE polarized wave. Periodic boundary conditions are applied to mimic the periodic unit cell. The ribbon displays a dipole resonance. As the ribbon is varied parametrically the dipole resonance changes as well. The dipole resonance sweeps the frequency range that overlaps with the second and third cavity modes. This effect causes two anti-crossings to occur in our metasurface. The contour

plot of Fig. 1(b) shows anti-crossing at zero-detuning to be at ~0.784 THz, respectively with a rabbi splitting (ΩR) of 0.17 for the third cavity mode. The second cavity mode at 0.584 THz also has an anti-crossing with the with a rabbi splitting (ΩR) of 0.19 showing that this structure results in multimode USC. The near field coupling strength derived from the two-band Hamiltonian show FW-BIC at 0.72 and 0.51 THz. We show an enhanced light-matter interaction that can be utilized for various optical applications in a small, compact device.

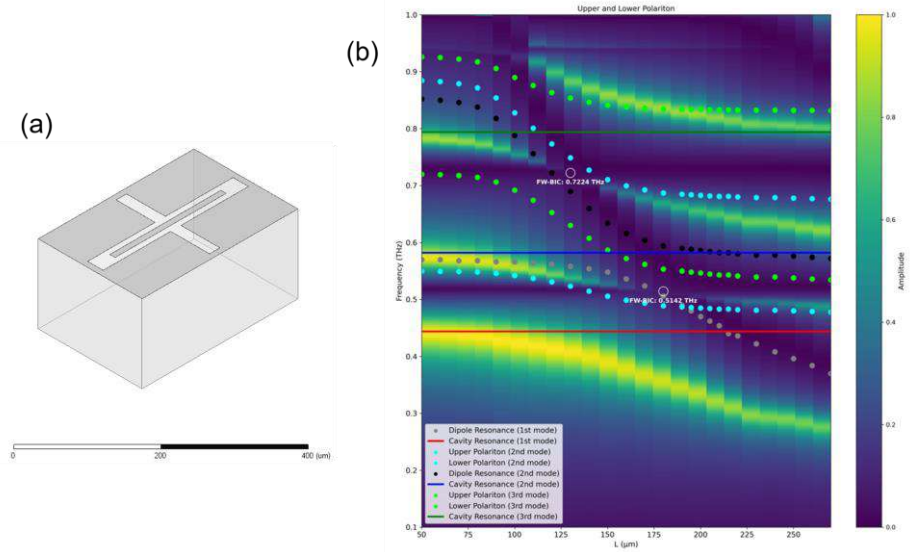

Figure 1: (a) This is the unit cell of the metasurface. (b) Contour plot of the transmission of the metasurface as the ribbon is parametrically varied. Green and light blue dots indicate the upper and lower polaritons for the third and second cavity modes.

Abstract: 300-GHz-band transmission-type metasurfaces for signal coverage extension in wireless communication and high-resolution sensing applications were designed, fabricated, and evaluated. Gradient beamforming devices with steering angles between 18° and 38° and collimating lenses based on 3-bit quantization were fabricated as self-standing devices which makes them perfect candidates for future sub-THz applications.

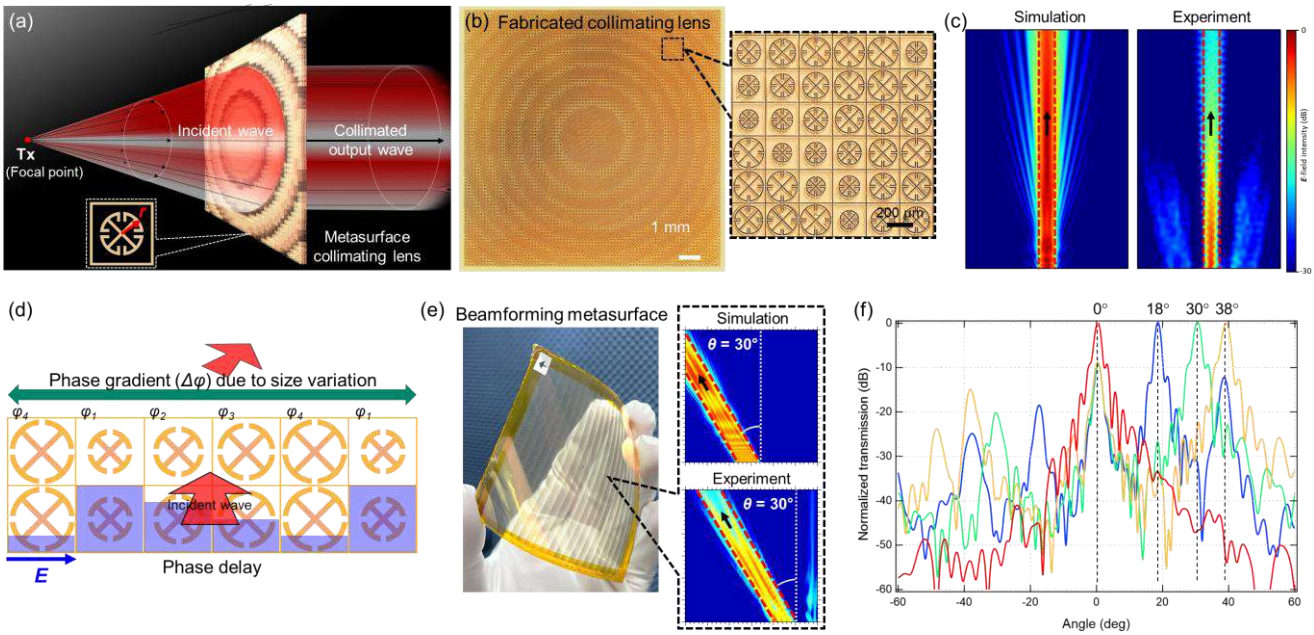

Fig. 1. (a) Schematic of operating of collimating metasurface lens. (b) Fabricated metasurface lens and (c) obtained in simulation and experiment near ***E*** field results. (d) Schematic of operation of gradient beamforming metasurface. (e) Fabricated metasurface beamformer and near ***E*** field results for beam steering angle of 30°. (f) Far-field characteristics for beamforming metasurfaces at 300 GHz band.

With advancements in high-frequency semiconductor technologies, major attention has been brought to sub-terahertz waves (millimeter-wave) due to their unique characteristics, like high directivity, wide bandwidth, or very distinctive absorption spectra. Millimeter waves, especially between 30 and 300 GHz, became a major development target for high-capacity wireless communication networks with data rates over 100 Gb/s, and high-resolution sensors for short-range applications and object recognition [1,2]. However, an increase in operation frequencies generally leads to the degradation of signal-to-noise ratios (SNR) and data rates in the system, due to strong atmospheric attenuation, non-line-of-sight propagation (high linearity), and free space path losses [3]. To cope with these challenges, in both wireless communication and radar sensing, various beamforming and beam shaping techniques were developed to allow for desired beam radiation patterns, beam scanning, or spectral selectivity. Among these techniques, metasurface-based devices, both passive and active, have been intensively studied as an enabling technology and an alternative to complex conventional designs [4].

In this work, we present a diversity of devices at the 300 GHz band, including gradient beamforming metasurfaces for signal coverage expansion in wireless communication and multiple types of lenses for precise beam collimation and focusing. All the devices were fabricated using an in-house developed process to allow for multilayer metasurface structures that exhibit superb characteristics.

Fig. 1(a) shows an operation schematic of a metasurface lens composed of continuous 2π phase controllable multilayer metamaterial cells based on Jerusalem cross geometry that were organized into radial patterns with 3-bit quantization (eight steps) with phase step $\Delta\varphi = 45°$ between each zone. The radius of each zone was optimized to provide beam collimation of the incident wave from the transceiver (Tx) antenna placed at a close distance (20 mm) from the device. An example of a fabricated device operating at 300 GHz is shown in Fig. 1(b). As shown, radial zones are clearly defined in the image, while the inset confirms the high quality of the fabrication and the high level of alignment of each metamaterial layer (5 layers in total). The quality of beam collimation was evaluated by the electric near-field distribution maps, showing good consistency between the experiment and the simulation results. The data shown in Figs. 1(a-c) relates to the control of the beam collimation for high-resolution sensing applications in 300 GHz.

Fig. 1(d) shows a schematic of a phase gradient beamforming metasurface used for beam forming of the incident wave during wave transmission through the device. Similar to the sensing, the designed cells exhibit continuous 2π phase controllability as a response to radius variation. By the combination of different-sized metamaterial cells, the metasurface exhibits a desired transmission phase gradient across its surface, allowing for bending the beam into a predesigned direction (0 ~ 38° in this work). Fig. 1(e) shows fabricated gradient beamforming metasurface and near-$\boldsymbol{E}$-field results confirming beam steering at 30°. The obtained experimental results were in good agreement with the simulation. Additionally, as shown, fabricated metasurface devices exhibited good optical transparency and flexibility, expanding the range of potential use cases in wireless communication applications. Fig. 1(f) shows far-field results obtained for various beamforming angles in this work at 300 GHz. The main lobes in the graph correspond to the designed beam steering angles for all metasurface devices.

In this study, transmission-type metasurface devices for wireless communication and sensing are discussed and combine low loss, good transmission efficiency, broadband operation, and good control of output wave characteristics at 300 GHz. Additionally, good flexibility, optical transparency, and self-standing design were achieved making the presented devices a prospecting technology for future applications in sub-THz.

Tunable beamsplitter based on continuous transition between a planar metasurface and a Brewster metafilm

Yasuhiro Tamayama[1*], and Yugo Shibata[1]

[1] Department of Electrical, Electronics and Information Engineering, Nagaoka University of Technology, Japan
*corresponding author: tamayama@vos.nagaokaut.ac.jp

Abstract: We develop a method for realizing a beamsplitter with a tunable splitting ratio using a metamaterial with deep subwavelength thickness. We numerically verify that the splitting ratio can be controlled by the arrangement of the constituent meta-atoms without changing the structure of the meta-atoms.

Controlling the reflectance and the transmittance is one of the most fundamental issues in the application of electromagnetic waves. It has already been shown that an arbitrary complex reflectance can be achieved in a metasurface with a ground plane and that an arbitrary complex transmittance can be achieved in a Huygens metasurface [1]. In addition to the control of either the reflectance or the transmittance, simultaneous control of the reflectance and the transmittance is also important. In this study, we develop a method for controlling the absolute values of the reflectance and the transmittance simultaneously in a broad frequency range using metamaterials.

First, we theoretically analyze the reflectance and the transmittance of a single-layer resonant metamaterial. Based on the coupled mode theory [2], the reflectance and the transmittance is calculated to be

$$r = -\frac{2k}{k^2+1}\frac{\gamma_\mathrm{r}}{-\mathrm{i}(f-f_0)+\gamma_\mathrm{r}+\gamma_\mathrm{nr}}, \quad (1)$$

$$t = 1-\frac{2}{k^2+1}\frac{\gamma_\mathrm{r}}{-\mathrm{i}(f-f_0)+\gamma_\mathrm{r}+\gamma_\mathrm{nr}}, \quad (2)$$

where f is the frequency of the incident wave, f_0 is the resonance frequency of the metamaterial, γ_r (γ_nr) is the radiative (non-radiative) loss of the metamaterial, k is the ratio of the radiation from the metamaterial in the propagation direction of the reflected wave to that of the transmitted wave. In the case of γ_nr =0, the absolute value of $r(f=f_0)$ [$t(f=f_0)$] can be varied in the range from 1 to 0 (0 to 1) by varying k in the range from 1 to 0. Assuming that the constituent meta-atom acts as an infinitesimally small dipole, k is equal to $\sin(45^\circ-\theta)/\sin(45^\circ+\theta)$ in the configuration of Fig. 1. Thus, k can be controlled in the range from 1 to 0 by varying θ in the range from 0° to 45°. Note that in the case of θ=0° (θ=45°), the single-layer metamaterial corresponds to a planar metasurface (Brewster metafilm [3]).

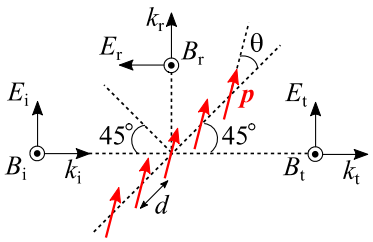

Fig. 1. The relationship between the electromagnetic fields and the electric dipoles induced in the meta-atoms. In the numerical simulation, d=16mm.

Now we verify the above theory numerically. We use a dipole resonator shown in Fig. 2(a) as the constituent meta-atom. The dipole resonator is assumed to be fabricated on a dielectric substrate (FR-4) and covered by the same dielectric as shown in Fig. 2(b) to simply decrease the resonance frequency in a realistic manner. We numerically analyze a metamaterial composed of the dipole resonator arranged as shown in Fig. 1. The calculated reflection and transmission spectra are shown in Figs. 3(a)-3(c). The absolute value of the reflectance (transmittance) at the resonance frequency decreases (increases) with increasing θ as shown in Fig. 3(d).

We gather from the above result that a tunable broadband beamsplitter may be realized using a metamaterial with deep subwavelength thickness that exhibits high reflectance in a broad frequency range for θ=0°. Then we

design and analyze a metamaterial composed of the structure shown in Fig. 2(c). Although this structure is a two-layer structure, the thickness is much smaller than the wavelength. The reflection and transmission spectra of the metamaterial for θ=0°, 15°, 24°, and 33° are shown in Fig. 4. The absolute value of the reflectance is high in a broad frequency range for θ=0° and broadband beamsplitters with different splitting ratio are realized by only varying θ.

In conclusion, we developed a method for realizing a tunable broadband beamsplitter based on the continuous transition between a planar metasurface and a Brewster metafilm. This result would be useful for realizing compact broadband beamsplitters with low losses especially in the low frequency region such as the microwave and the terahertz regions.

Plasmonic Enhanced Si-based Hot Electron Photodetector for SWIR Range

D.Cristea [*], R.Tomescu , G. Craciun and A.Dinescu

National Institute for Research and Development in Microtechnologies - IMT Bucharest, Romania
[*]corresponding author: dana.cristea@imt.ro

Abstract: We explored various architectures for plasmonic-enhanced Si Schottky photodetectors for SWIR, aiming at enhancing light absorption, hot electron generation and collection. The combination of grating-like electrodes with a nanostructured thin metal layer demonstrated the most promising results, with responsivities reaching the range of tens of mA/W at telecom wavelengths.

SWIR photodetectors are required in a wide range of applications with high societal impact, such as remote monitoring and surveillance, imaging systems, firefighting, sensing (e.g. humidity, temperature, gas, bio-chemical), contaminant detection, optical metrology, optical communications [1-3]. Despite the recent development of various photodetectors based on a range of materials (InGaAs, Ge, InAs, colloidal quantum dots, 2D metal chalcogenides, polymers, etc.) [1], all-Si photodetectors remain of significant interest because they can be easily integrated with Si electronic circuits [2,5]. Silicon becomes transparent to photons with energies below its 1.12 eV bandgap. However, the internal photoemission (IPE) process in a Schottky barrier enables sub-bandgap photodetection making thus silicon devices suitable for operation in the SWIR range [2-5]. IPE-based devices typically consist of a metal surface in contact with a semiconductor forming a Schottky barrier. Photons are absorbed by the metal and excite hot electrons. The electrons with energy higher than the Schottky barrier and sufficient momentum in the direction of the Schottky barrier can be injected into the silicon and contribute to the photocurrent. Thus, hot-electron devices on Si offer an alternative to the existing technologies for SWIR detectors, which require either expensive epitaxial growth or bonding of multi-layer structures, or quantum dots based on toxic materials (Pb, Hg). The key benefits of these photodetectors include high speed, simple fabrication process, and small dimensions, which are comparable to those of highly integrated electronic circuits. The main drawback of the internal photoemission process over a bulk metal/semiconductor Schottky junction is the low efficiency due to the low absorption of incident light by the metal, the broad hot electron energy distribution, and the momentum mismatch of electron waves between the silicon and the metal. However, plasmonic nanostructures have been shown to improve light absorption and enhance the electric field, leading to a more efficient generation of hot carriers [4,6]. Furthermore, the energy levels of the hot carriers generated by plasmon decay are higher than those generated by direct light absorption [6].

In recent years, a number of solutions for improving the responsivity of plasmonic Si photodetectors have been proposed, including the use of nanoparticles, thin/nanostructured metal layers [2,3,9], Si surface nanostructuring [5,10,11] and complex 3D structures/metasurfaces [13]. However, the responsivity remains still low (units of A/W for λ=1300-1500 nm).

In order to enhance light absorption, hot electron generation and collection, we conducted a series of experiments on different architectures for the front-side and backside electrodes. One solution that was pursued involved the use of plasmonic nanostructures, which were obtained by means of vacuum deposition of very thin Ag layers (15–50 nm), followed by thermal annealing. Nanostructured layers composed of flattened nano-hemispheres have been obtained. The diameter of these nanostructures varies between 10 and 500 nm, depending on the initial thickness of the Ag layer and the annealing process parameters. The nanostructured Ag

layer acts as plasmonic metasurface that improves both light absorption and the efficiency of hot electrons generations. In addition, experiments have been conducted with very thin discontinuous Ag and Au layers (2-6 nm in mass equivalent) composed of nanoparticles partially interconnected. Devices with Ag and Au nanostructured layers on n-Si demonstrate high responsivities, reaching 7-12 mA/W at telecom wavelengths for both front and back-side illumination. The second approach involved the combination of grating-like Au electrodes with as-deposited, very thin nanostructured Au or Ag layers. This approach yielded a 5-fold improvement of the responsivity, likely attributable to enhanced absorption coupled with improved collection of the carriers at the electrodes.

Similar experiments were conducted with Al plasmonic structures on p-Si. The responsivity was slightly higher, but also the dark current was higher (lower barrier). The next step is to place plasmonic nanostructures on both front and backside of the chip.

Tailoring the RF fields in MRI: A new compact multi-layer metamaterial design combining a hexagonally-structured artificial dielectric with electric and/or magnetic dipoles

Rita Schmidt [1,2]

[1]Department of Brain Sciences, Weizmann Institute of Science, Israel,
[2]The Azrieli National Institute for Human Brain Imaging and Research, Weizmann Institute of Science
[*]corresponding author: rita.schmidt@weizmann.ac.il

Abstract: We established a new framework of MRI-beneficent artificial materials to tailor the RF transmit and receive fields, combining an artificial dielectric with a set of electric and/or magnetic dipoles. This combination provides high flexibility to plan the possible enhancement, as well as a higher efficiency and a very compact structure.

Magnetic Resonance Imaging (MRI) has become a staple of medical diagnostics, providing indispensable diagnostics information. Its influence can be extended even more by boosting the sensitivity, which would translate into shorter scan duration and greater scan resolution. In recent years, metamaterial designs have been developed in the field of MRI to increase SNR and efficiency for passive designs and for new RF coil's designs[1-5]. In our lab, we explored a hybrid metamaterial-based structures, combining a high-permittivity dielectric layer and a set of electric and/or magnetic dipoles[4]. We implemented this design in MRI applications achieving local signal enhancement in the vicinity of the structure. Our recent works[6,7] also showed that non-uniform distribution of the copper strips can be utilized to further extend the degrees of freedom to tailor the resulting RF transmit field and to reduce the power deposition.

Taking the next step forward, we recently replaced the high permittivity dielectric layer with artificial dielectric (AD) design, introducing a new framework to design a compact and flexible metasurfaces for MRI. In this design, the AD comprises of shifted short copper strips arranged in hexagons and a dielectric (relative permittivity, εr=2.6) substrate in-between (Fig.1). Introducing a hexagonal arrangement of the sub-units achieves an optimally condensed distribution and thus provides a wide range of artificial dielectric properties. As was shown before[8], the combination of overlapping copper strips generates a network of capacitors. We show that the AD structure can also be combined with another layer of electric and/or magnet dipoles, which can be used to control the resonant frequency and the achieved RF transmit field enhancement. To achieve much smaller dimensions (16x11.2 cm^2), AD layer was attached to two additional AD layers with diagonally shifted configurations (See Fig.1B).

To characterize and examine the proposed structures, EM simulations, including eigen mode solver and time domain, and measurements in 7T MRI were performed. All the simulations were carried out using CST Microwave Studio, Darmstadt, Germany. The most relevant resonant mode of interest for MRI - the lowest transverse-electric (TE) mode (with large penetration depth) was examined. Similar distribution was achieved by the TE_{01} mode with an actual dielectric layer and with an AD (Fig.2). A resonant structure at ~298 MHz was achieved for all configurations (Fig.2). A time domain simulation with an RF coil and a phantom showed B_1^+ field enhancement of ×1.25, ×1.35, and ×2.35 for AD, dielectric and the combined resonant "Triple Hexa" setup, respectively. Scans were performed on 7T Terra, Siemens, with an 8Tx/32Rx Nova coil and a cylindrical oil phantom. The MRI scan with the "triple-Hexa" showed 4-fold enhancement for the square root of the image intensity (Fig.3), which can

be approximated as B_1^+ enhancement (assuming the signal is proportional to B_1^{+2}).

This study shows a new design of a metamaterial that can provide very compact resonant structures at 7T MRI. Another advantage of this design that no lumped elements are required. The combined design provides high flexibility to plan a range of possible enhancements.

Breaking the Diffraction Limit: Far-Field Super-Resolution Imaging Via Metasurfaces and Holography

P. Salami[1] and L. Yousefi[2*]

[1]School of Electrical and Computer Engineering, College of Engineering, University of Tehran, Tehran, Iran

Abstract: In this presentation, we discuss the innovative methods we have developed to surpass the diffraction limit using metasurfaces. By designing metasurfaces to transform evanescent waves into propagating modes and utilizing holography, we achieve super-resolution imaging. Full-wave simulations demonstrate that our proposed techniques can retrieve feature sizes as small as λ/14.

Irregularities on a surface smaller than the wavelength of light generate evanescent waves that decay rapidly as they move away [1]. The loss of this information enforces the diffraction limit, restricting optical systems from resolving details smaller than $\lambda/2NA$, where λ is the light wavelength and NA is the numerical aperture [2].

To overcome this barrier, near-field techniques like NSOM utilize probes to capture evanescent waves, achieving nanometer resolution [3]. However, these methods are slow and have a limited field of view. To enable far-field imaging, approaches such as hyperlenses and superlenses have been introduced [4]. Hyperlenses, composed of hyperbolic metamaterials, magnify sub-wavelength details but are challenging to fabricate due to their curved structure. Superlenses use gratings to convert evanescent waves into propagating modes, but multiple diffraction orders can create ambiguities in imaging, requiring the placement of a superlens before the grating to resolve this issue.

To overcome these challenges and remove the need for a superlens in far-field superlens approach, we employed plasmonic and dielectric metasurfaces [5,6] (see Figs. 1(a) and (b)). These metasurfaces manipulate the amplitude, phase, and polarization of incident waves, enabling the conversion of evanescent waves into propagating modes for sub-wavelength imaging (see Figs. 1(c) and (d)).

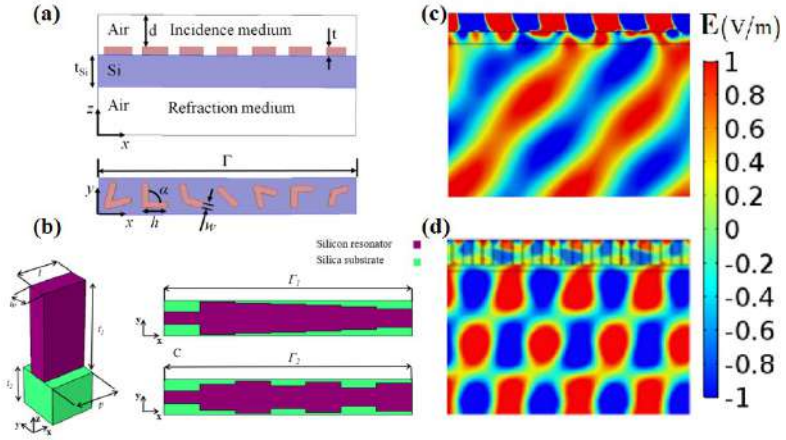

Figure 1. (a) Plasmonic [5], and (b) first and second order dielectric [6] metasurfaces used for sub-wavelength imaging. (c) Plasmonic [5], and (d) second order dielectric [6] metasurfaces convert evanescent waves with transverse wavenumbers of $1.7k_0$ and $2.6k_0$ into propagating modes, respectively.

Metasurfaces introduce a shift in the transverse wavenumber of incident waves, transferring evanescent waves with large transverse wavenumbers into the propagating region. Our previous studies [5,6] showed that in sub-wavelength imaging, scattered waves from the sub-wavelength features of the sample interact with only a few unit cells, preventing the excitation of higher-order modes. The typical reconstructed sub-wavelength images obtained using plasmonic [5] and high-order dielectric [6] metasurfaces, are shown in Figs. 2(a) and (b), respectively.

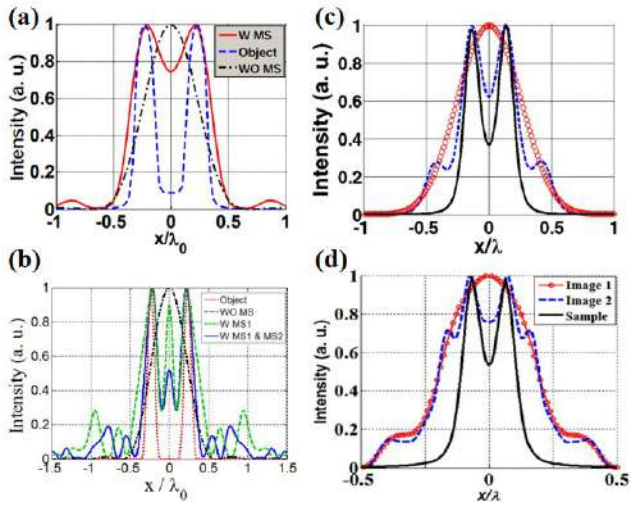

Figure 2. (a) λ/3.4 and (b) λ/5.5 resolution achieved using plasmonic and dielectric metasurfaces, respectively. (c) λ/7 and (d) λ/14 resolution achieved using one-step and two-step holography-based techniques, respectively.

For removing the need for nanostructures in sub-wavelength imaging, we propose holography-based techniques in Refs. [7,8]. These methods demonstrate that interference between a known reference wave and waves scattered from the sample, can shift sample angular spectrum, converting a range of evanescent waves into propagating ones. By recording interference patterns using photographic emulsions and applying reconstruction waves, scattered wavefronts are analyzed. Combining this data with the propagating range of sample angular spectrum enables sub-wavelength image reconstruction (see Figs. 2(c) and (d)).

Abstract: Measurements demonstrate that a terahertz collimating metalens antenna based on a polarization-independent isotropic metasurface with a high refractive index and low reflectance collimates terahertz waves from a resonant tunneling diode (RTD) in the 0.3-THz band. These results could pave the way for integrating metalens antennas with RTDs as on-chip devices.

The terahertz waveband is a promising candidate as a carrier frequency for next-generation wireless communications [1]. Various attractive terahertz continuous-wave (CW) sources have been developed [2,3], and optical elements for the collimation of terahertz waves are essential to propagate terahertz waves over long distances. We have reported collimating metalens antennas [4,5] that collimate terahertz waves for propagation toward the far field. However, the previously reported metalens antennas are made with a polarization-dependent metasurface with a high refractive index and low reflectance, and metasurfaces with polarization-independent isotropic optical properties would be very adaptable for integration with terahertz CW sources. In this paper, we propose a terahertz collimating metalens antenna based on a polarization-independent isotropic metasurface with a high refractive index and low reflectance in the 0.3-THz band.

Figures 1 (a) and (b) show terahertz collimating metalens antennas with 10- and 1.0-mm focal lengths. Figure 1(c) shows a cross-section view of a terahertz collimating metalens antenna composed of a dielectric substrate and circular metal disks. The collimating metalens antennas are fabricated by etching a dielectric substrate (cyclo-olefin polymer film) coated with metal (copper) on the front and back of the substrate. Figure 2 shows the experimental system to measure the directivity of a terahertz collimating metalens antenna mounted on an RTD. The distance h between the metalens antenna and receiver is 65 mm, longer than the far-field distance of 44 mm for Fig. 1(a) and 6.7 mm for Fig. 1(b). Figures 3 (a) and (b) show the measured directivity of the metalens antenna with a 10-mm focal length mounted on the RTD. The collimating metalens antenna enhances the directivity of the RTD 3.1 times for a rotation angle γ of 0 degrees and 2.7 times for 90 degrees. The measurements are normalized with the maximum directivity of the RTD set to 1.0. Figures 4 (a) and (b) show the measured directivity of the metalens antenna with a 1.0-mm focal length mounted on the RTD. The collimating metalens antenna enhances the directivity of the RTD 1.6 times for a rotation angle γ of 0 degrees and 1.7 times for 90 degrees. The measurements are normalized with the maximum directivity of the RTD set to 1.0. The terahertz collimating metalens antennas collimate terahertz waves with the polarization directions along the x- and y-axes radiated from the RTD.

The metalens antennas with 10- and 1-mm focal lengths are fabricated and mounted on a resonant tunneling diode (RTD) to enhance the directivity. The metalens antennas could be integrated with various terahertz CW sources for applications in the terahertz band in next-generation (6G and 7G) wireless communications and advanced imaging applications.

Abstract

The lateral arrangement of self-assembled VO2 nanoparticles and gold nanostructures fabricated by electron beam lithography is presented as a suitable platform for hybrid tunable plasmonic devices. Two specific tunable devices are demonstrated: Electric-magnetic switches and resonance-energy switches.

Vanadium dioxide (VO_2) exhibits a metal-insulator transition near room temperature (68 °C), which can be exploited in tunable plasmonic devices with compelling functions. However, devices based solely on VO_2 suffer from a large optical absorption and low chemical stability of VO_2 [1].

In our contribution, we present a hybrid material platform that combines high-quality crystalline self-assembled VO2 nanoparticles [2] with lithographically defined gold nanostructures in a lateral arrangement [Fig. 2(a) shows an example of a fabricated device]. In this way, we benefit from both the tunability of VO_2 and the high conductivity of gold. Lithography is performed only on gold, which brings the desired design flexibility while preventing damage to VO_2. Finally, the lateral arrangement minimizes the amount of VO_2 and thus contributes to the high quality of the devices.

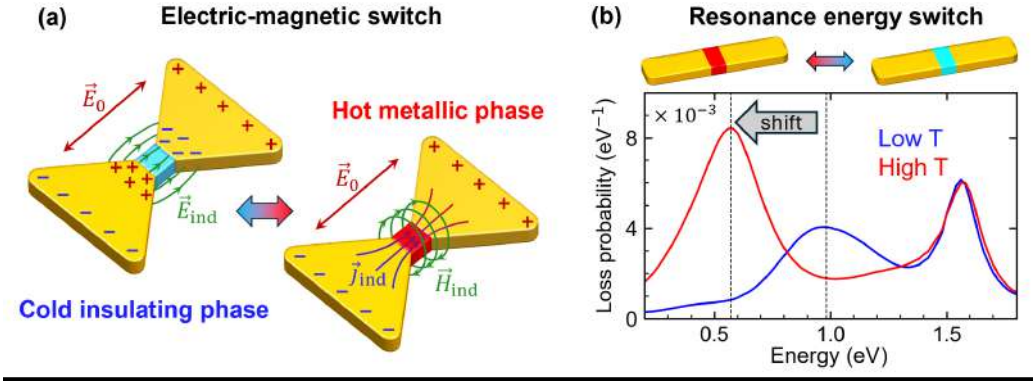

Figure 1: a) Conceptual design of the electric-magnetic switch. Gold wings (yellow) are connected with a VO_2 bridge (cyan or red). When cold, the bridge is insulating, resulting in charge accumulation near the bridge and a formation of the electric hot spot (as in the bowtie plasmonic antenna). When hot, the bridge is conducting, resulting in the funneling of the electric current and a formation of the magnetic hot spot (as in the diabolo antenna). (b) Conceptual design of the resonance energy switch (top). It is designed as a dimer of gold nanorods connected with a VO_2 bridge. A low-temperature dimer of two short nanorods separated by the insulating bridge transforms upon heating into a single nanorod with gold part connected with the conducting bridge. This process is accompanied by a pronounced shift in the plasmon resonance energy, as demonstrated in the calculated electron energy loss spectra (bottom).

We demonstrate two tunable plasmonic devices based on the above-mentioned material platform: (1) Electric-magnetic switches, in which either an electric or magnetic hot spot is formed, following a design from Ref. [3]. Such switches might find application e.g. in THz spectroscopy of magnetic transitions [4], to which they can introduce a temporal resolution or facilitate nonlinear spectroscopy by promoting either electric or magnetic transitions. (2) Resonance-energy switches, in which the spectral profile of the scattering or absorption is controlled, with possible applications in fine tuning of thermochromic smart windows. The concept of the switches is demonstrated in Fig. 1.

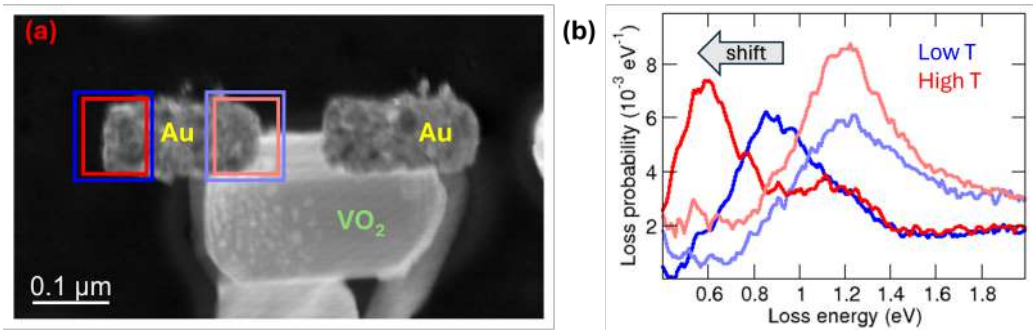

Figure 2: a) Annular dark-field image of a hybrid plasmonic device acting as a resonance-energy switch. A VO_2 nanoparticle and gold nanorods are indicated. (b) Electron energy loss spectra of the same switch taken at the low temperature where VO_2 is insulating (blue) and the high temperature where VO_2 is metallic (red). The energy shift observed for one of the plasmon resonances is indicated with the gray arrow. The color of the spectra corresponds to the color of the squares in panel (a) indicating the regions where the spectra were retrieved.

Both devices were characterized by analytical electron microscopy [in particular, electron energy loss spectroscopy] and electrodynamic simulations. A proof of concept for the resonance-energy switch is in Fig. 2. The observed shift of the lowest plasmon resonance shown in Fig. 2(b) agrees remarkably well to the prediction of Fig. 1(b).

Abstract: Nanostructured multilayer 2D materials are a promising alternative to traditional bulk nonlinear materials for on-chip photonics. Here we present a universal approach for patterning such materials based on Focused-Ion-Beam lithography. We fabricate high-quality microdisk resonators and other photonic nanostructures and characterize them as a platform for linear and nonlinear optics.

Van der Waals (vdW) materials are promising candidates for next-generation nanophotonics and optoelectronics thanks to their exceptional optical, electrical, thermal, and mechanical properties arising from their unique anisotropic structure, in which two-dimensional sheets of covalently-bound atoms are held together by relatively weak vdW forces to form multi-layer structures and bulk crystals. Overcoming these vdW interactions allows layers to be peeled off by mechanical exfoliation, resulting in flakes with controllable thickness down to a single atomic layer. The pristine dangling-bond-free surfaces of these layers enable the arbitrary stacking of heterogeneous materials without being constrained by lattice mismatch. Such heterostructures have been used to create optoelectronic devices with unprecedented functionalities [1, 2].

Even in bulk form, vdW materials exhibit monolayer-like excitonic behavior and in many cases their nonlinear optical performance far exceeds those of traditional platforms [3]. However, the potential of vdW materials as a platform for integrated photonics remains largely unexplored, as the fabrication of high-quality nanostructures out of these materials using traditional nanopatterning approaches poses significant challenges [4].

In this work we demonstrate a versatile and universal (material agnostic) approach for high-quality patterning of vdW multi-layer flakes and their heterostructures based on Focused-Ion-Beam lithography. Crucially, we employ a protective layer to minimize unwanted damage and parasitic ion implantation during milling. Our technique enables us to pattern a wide range of fundamental photonic building blocks such as waveguides, resonators, photonic crystals, and metasurfaces (Figure 1), which serve as a robust platform for exploring both linear and nonlinear optical phenomena. By controlling both the in-plane (via patterning) and out-of-plane (via stacking) structure, we are able to create metamaterials with precisely-tailored optical properties. This approach unlocks the untapped potential of vdW-based metamaterials for high-performance integrated nonlinear photonics and optoelectronics.

Abstract: We observe circularly polarized NIR-to-visible upconversion luminescence (UCL) from single β-$NaYF_4$:Yb^{3+}:Tm^{3+} upconverting nanoparticles (UCNPs) supported on self-assembled chiral metasurfaces[1]. A circular-polarized luminescence microscope images the left and right circularly polarized emission from single particles randomly placed on the substrate. We use time- and energy-resolved single particle imaging to assess the plasmon-enhanced radiative decay and polarization of upconversion luminescence from nanoparticles supported on self-assembled metasurfaces, composed of self-assembled tetrahedral Au nanoparticles. We obtain a statistical description of UCL emission enhancement in the Tm-doped UCNPs and map out the statistical distribution of excitation and luminescence enhancement on plasmonic substrates[2–4]. We use both wide field and confocal scanning spectroscopic imaging of single UCNPs on and off the plasmonic substrates in combination with energy and time resolved spectroscopy, and compare these results to a coupled rate equation analysis to elucidate the energy transfer upconversion enhancement mechanisms. The results obtained are compared to Finite Difference Time Domain (FDTD) calculations of the fields near the plasmonic substrate.

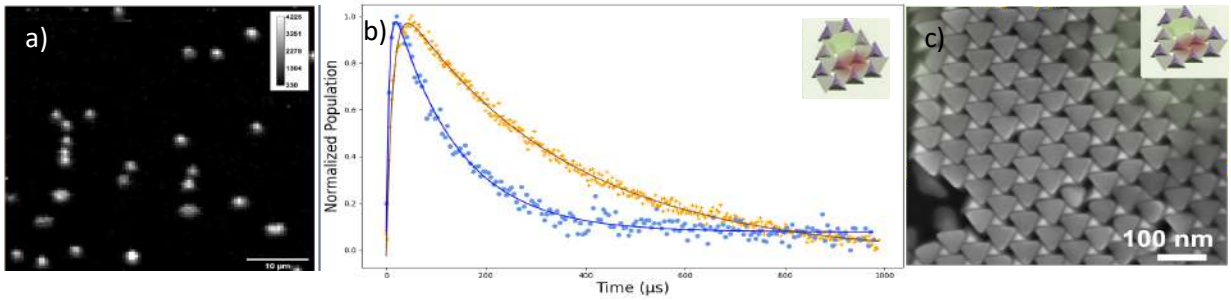

Figure 1: (**a**) Single particle upconversion luminescence (UCL) image (**b**) luminescence decay of isolated and plasmon-coupled upconverting nanoparticle (schematically shown in inset). (**c**) Chiral metasurface induces circularly polarized UCL (CP-UCL) (schematically shown in inset).

Relative illumination engineering of metalens

Qiu-Chun Zeng[1,2], Chen-Yi Yu[2], Wei-Lun Hsu[2], Che-Chin Chen[1], and Chih-Ming Wang[2,*]

Abstract: The relative illumination of traditional lenses generally follows the Cosine Fourth Power Law. We proposed a metalens consisting of mixing-pitch meta-units to modulate the relative illumination. Our experimental results show that the relative illumination of our metalens at 30° is 4-folds higher than that at 0°. Our metalens offers promising potential for applications requiring specific illumination control, such as wide-angle imaging and oblique detection.

Machine vision is increasingly prevalent in daily life, with image input being a core component [1]. However, metalens-based imaging systems often suffer from strong relative illumination variations, causing the image center to appear significantly brighter than the edges. Most research on metalenses has focused on focusing quality and imaging performance within imaging optics [2-3]. In this work, we extend their application to non-imaging optics by leveraging metasurface amplitude modulation for illumination control. Traditional lenses follow the Cosine Fourth Power Law [4-5], causing illumination to drop at large field angles. Here, we employ a mixing-pitch meta-unit design to adjust relative illumination at different angles [6]. Experiments show that relative illumination at a 30° incident angle is twice as high as at 0°, making it useful for oblique image detection and wide-angle illumination compensation.

We investigate two metalens designs: single-pitch and mixing-pitch, both designed for 940 nm and using a telecentric optical setup. In the single-pitch case, Figures 1(a) and 1(b) show the simulated and measured focal spots at AOI = 0° and 45°, both 1.98 μm in size. The spots are symmetric due to the zero chief ray angle at all AOIs, enabling consistent imaging quality. The modulation transfer function (MTF) in Figure 1(c) confirms stable imaging across AOI = 0° to 60°, achieving 150 lp/mm at MTF = 0.3.

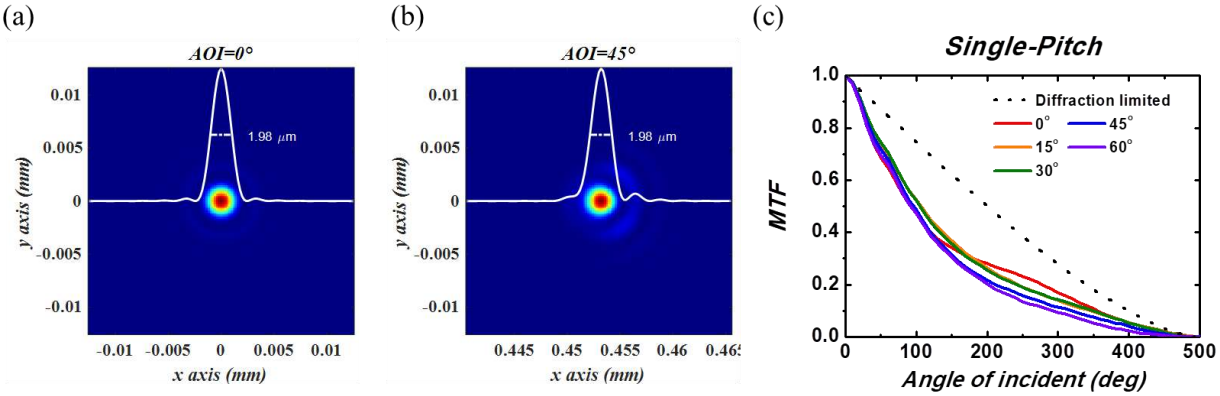

Figure 1. Simulated focal spot diagrams of the single-pitch metalens at an angle of incidence (AOI) of (a) 0° and (b) 45°. (c) Measured MTF curve for AOI values ranging from 0° to 60°.

For the mixing-pitch metalens, Figures 2(a) and 2(b) show smaller focal spots of 1.59 μm and 1.79 μm at AOI = 0° and 45°, respectively, improving resolution. The MTF diagram in Figure 2(c) shows a resolution of 170 lp/mm at MTF = 0.3, though a minor low-frequency drop is observed at AOI = 0°.

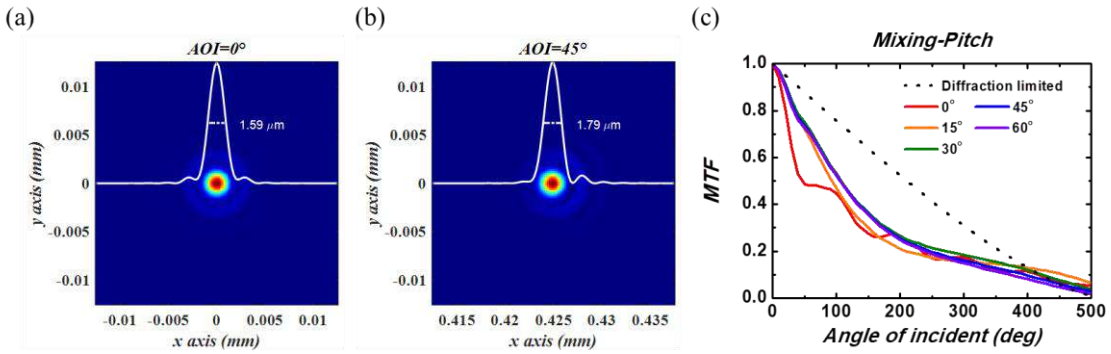

Figure 2. Simulated focal spot diagrams of the mixing-pitch metalens at an angle of incidence (AOI) of (a) 0° and (b) 45°. (c) Measured MTF curve for AOI values ranging from 0° to 60°.

Distortion characteristics across these cases are compared in Figure 3(a). The telecentric system exhibits -27% distortion at AOI = 40°, with the mixing-pitch metalens showing similar behavior. Relative illumination, a key factor in metalens applications, decreases with increasing AOI, causing uneven brightness. As shown in Figure 3(b), the telecentric metalenses exhibit a significant illumination drop. However, the mixing-pitch metalens effectively mitigates this issue. This improvement is due to using larger-period meta-atoms at the lens center, reducing central illumination and enhancing overall brightness uniformity.

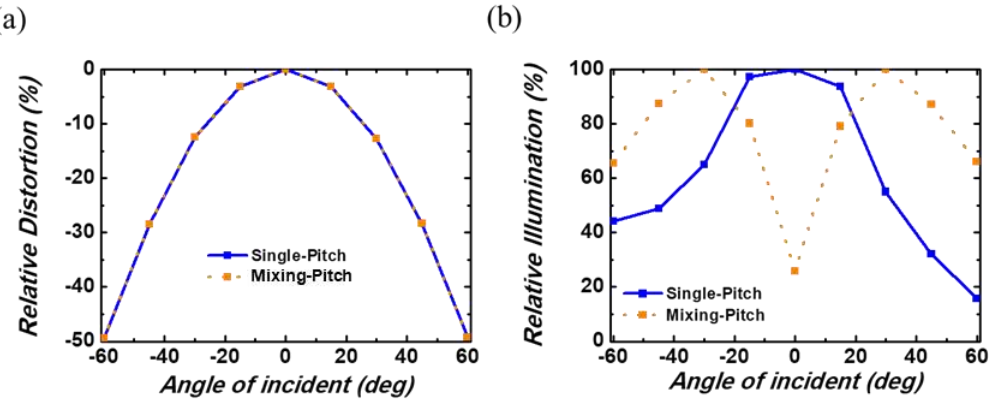

Figure 3. (a) Relative distortion and (b) relative illumination characteristics of the two metalens designs.

Abstract: The method for structuring and oxidizing metallic layers on glass, creating transparent oxide metasurfaces with periodic patterns, is presented. Sub-micrometer periodicity gratings are formed using laser interference patterning of tantalum layers, followed by thermal oxidation. Applications of such metamaterials in laser optics will be discussed.

The topic of photonic crystals has been booming over the past decade. Various technologies can be combined to achieve fascinating phenomena in light-controlling meta-structures and photonic crystals. A conceptually novel mechanism of spatial filtering in the near-field domain has already been demonstrated using a nanostructured multilayer coating: a 2D photonic crystal structure with periodic index modulation along the longitudinal and transverse directions relative to the beam propagation [1,2]. Such a structure is built on a nano-modulated substrate, which provides transverse periodicity. The fabrication of complex periodic structures based on coatings involves dual challenges: the development of advanced technologies for both layer deposition and substrate preparation. Even though controlling the growth of layers with periodic patterns is challenging, ensuring the optical quality of substrates with submicron periodicities is also a very difficult task.

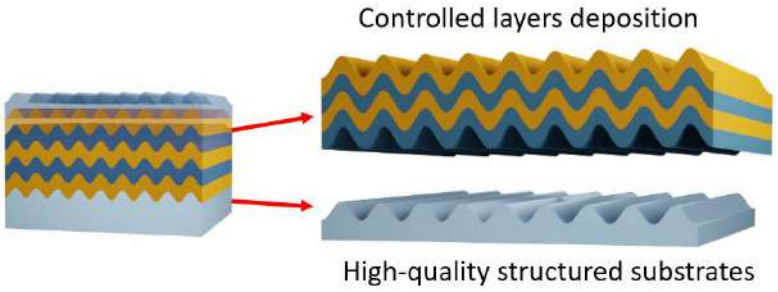

Fig. 1. The schematic representation with highlighted complexity of photonic structure fabrication by coatings.

Nano- and micro-structuring of glass surface for IR and visible spectrum applications is challenging due to the need of submicronic structures which involve complicated fabrication processes, especially while maintaining high surface quality in glass. The method proposed in this work involves the structuring and subsequent thermal oxidation of a thin metallic layer on a glass substrate [3]. Annealing of the structured metal layer produces a transparent fully inorganic oxide surface with periodic patterns, avoiding the subtleties of glass structuring.

In this work, a new method for the formation of sub-micrometer non-absorbing gratings with 750 nm periodicity is presented by direct laser interference patterning (DLIP) of thin tantalum layers on fused silica substrates followed by thermal oxidation by annealing. This method aims to improve the field of laser optics by providing a scalable and efficient method for the creation of precise metal-oxide photonic structures.

The patterned tantalum thin film sample was annealed using earlier estimated parameters: 2 ºC per minute heating rate up to 600 ºC, held for an hour, and cooled down to room temperature along with the furnace pace. Afterwards, captured surface morphologies of structured areas showed increased modulation depths and fill factor (Fig. 2). As it is inevitable during the oxidation process, attachment of oxygen atoms to metal causes material volumetric expansion.

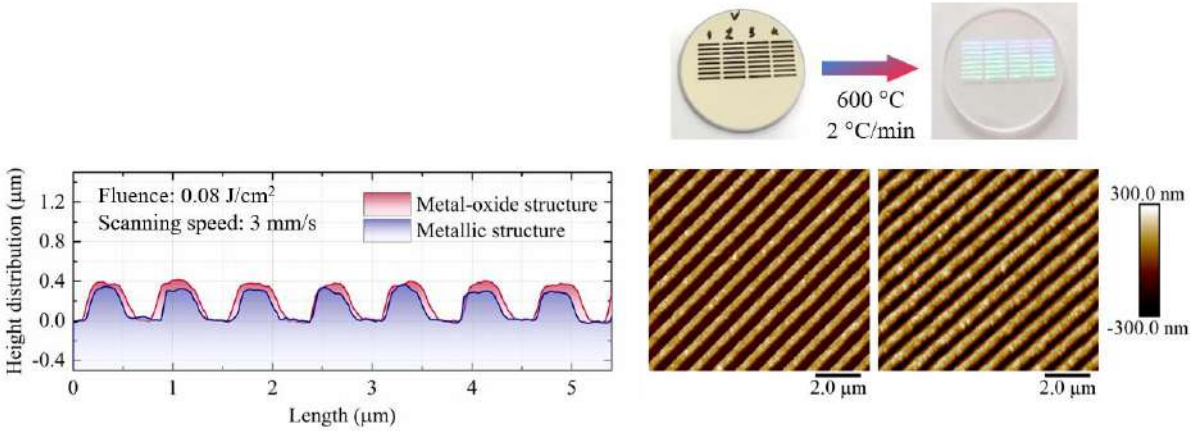

Fig.2. The comparison of 2D surface patterns before and after thermal oxidation.

This method could be expanded for fabrication of different periodicity or even 2D structures, such as meta surfaces suitable for at least to IR spectral band. Slightly smaller periodicities can be relatively easily achieved and much smaller (i.e. by factor of 10) periodicities cannot currently be easily fabricated using this method. DLIP can provide 2D patterns, therefore, this method can be used for 2D non-absorbing gratings.

In this work, a novel method for inorganic periodic structures formations is presented. Such surfaces are needed for 2D photonic structures fabrication based on coatings. The fabrication method proposed in this work involves the structuring and subsequent thermal oxidation of a thin metallic layer on a glass substrate. Annealing of the structured metal layer produces a transparent fully inorganic oxide surface with periodic patterns, avoiding the subtleties of glass structuring. The formation of sub-micrometer non-absorbing gratings with 750 nm periodicity is presented by direct laser interference patterning (DLIP) of thin tantalum layers on fused silica substrates followed by thermal oxidation by annealing.

During the conference presentation, the proposed technology will be discussed in a frame of fabrication process, applications and resistance to laser radiation. Additional insights on how coating technologies can improve the formation of periodic structures will also be shared.

Aluminum Nanoparticles for Photobleaching Resistance of Quantum Dots in Solution

Jérôme Plain[1*], Théo Duarte[1], Silvère Schuermans[1], Thomas Lerond[1], Jérôme Martin[1], Davy Gérard[1], Thomas Maurer[1], and Julien Proust[1]

[1]L2n, Université de technologie de Troyes and CNRS, Troyes, France

Abstract: We investigated aluminum nanoparticles (2–20 nm) synthesized via ion reduction in alkane solvents. Extinction spectroscopy revealed UV-range plasmon resonances matching Mie theory. These nanoparticles enhanced quantum dot emission by 1.75× and reduced photobleaching, absorbing emitted light. They hold promise as building blocks for nanophotonics and protecting emitters from degradation.

This study presents a novel method for synthesizing tiny aluminum nanoparticles (Al NPs) with diameters ranging from 2 to 20 nm and explores their potential applications in nanophotonics, particularly for enhancing the photobleaching resistance of quantum dots.

The synthesis process involves the reduction of aluminum ions in trace amounts of water present in alkane solvents like hexane or dodecane. This bottom-up approach allows to produce significant quantities of small, crystalline Al NPs that can serve as building blocks for more complex UV-dedicated plasmonic structures. The method is straightforward, cost-effective, and can be conducted in a standard chemistry laboratory without the need for expensive equipment.

Transmission Electron Microscopy (TEM) analysis revealed two families of Al NPs: a dominant population (99.9%) with an average diameter of 2.0 nm and a standard deviation of 1.2 nm, and a smaller population (0.1%) with an average diameter of 20 nm and a standard deviation of 10 nm. The size distribution of the nanoparticles can be controlled by modifying the water content in the solution, either by changing the alkane solvent or adjusting the temperature during synthesis.

Optical characterization of the Al NPs in hexane showed sharp extinction peaks in the UV range, indicating the presence of Localized Surface Plasmon Resonances (LSPRs). Two distinct peaks were observed: one at 206 nm (FWHM 25 nm) associated with the 2 nm nanoparticles, and another at 249 nm (FWHM 32 nm) corresponding to the dipolar LSPR of the 20 nm nanoparticles. Mie theory calculations confirmed that the particles are purely metallic, with the alkane solvent successfully preventing oxidation.

The study demonstrates the potential of these Al NPs for enhancing the photobleaching resistance of quantum dots in solution. The particles allowed for a global increase in the number of photons emitted by a factor of up to 1.75 compared to quantum dots alone. This enhancement is attributed to the high absorption of the Al NPs in the near UV region, which increases the absorption cross-section of nearby quantum emitters.

The unique properties of these Al NPs make them promising candidates for various applications in UV plasmonics and nanophotonics. Their ability to support LSPRs in the UV range opens possibilities for

developing new UV-LSPR-based nanotechnology, including highly sensitive UV Surface Enhanced Raman Spectroscopy (UV-SERS), high-energy LSPR-based nano-lasers, plasmonic photocatalysis, and UV optical lithography and data storage.

Furthermore, the compatibility of these Al NPs with UV excitation and emission of photo-emitters such as quantum dots and wide bandgap semiconductors suggests potential applications in developing nano-optical devices that leverage exciton-plasmon interaction mechanisms. The ability to control the size distribution of the nanoparticles also allows for tuning their optical properties, potentially extending their usefulness across a broader spectral range.

In conclusion, this study presents a significant advancement in the synthesis of small, crystalline aluminum nanoparticles and demonstrates their potential for enhancing the photobleaching resistance of quantum emitters. The method developed here provides a valuable tool for researchers in the fields of plasmonics and nanophotonics, particularly those focused on UV applications. Future work may explore the integration of these Al NPs into more complex nanostructures and investigate their performance in various optical and sensing applications.

Chalcopyrite – Noble Metal Hybrids as Catalytic Nanoscale Metamaterials with Enhanced Interfacial Excitation Transfer

B.M. Reinhard[1,*]

[1]Boston University, Department of Chemistry and The Photonics Center, Boston University, Boston, MA 02215, United States

[*]corresponding author: bmr@bu.edu

Abstract: Chalcopyrite ($CuFeS_2$) nanocrystals provide collective quasistatic resonances in the visible where they can couple with plasmonic resonances of metal nanoparticles. Hybrid chalcopyrite – noble metal nanoparticles are introduced as catalytic nanoscale metamaterials that utilize energy and charge transfer mechanisms to generate excited charge carriers and provide chemical reactivity.

Chalcopyrite nanocrystals provide a quasistatic resonance in the visible range (~490 nm) of the electromagnetic spectrum that is associated with collective oscillations of bound electrons.[1] Integration of these nanocrystals into hybrid structures with noble metal nanoparticles provides unique opportunities for realizing new materials in which the building blocks are resonantly coupled or, alternatively, off-set to generate bi-resonant nanostructured metamaterials. Both types of structures have been implemented and direct energy transfer and photoelectrocatalytic properties have been investigated.[2,3]

Chalcopyrite nanocrystals can be incorporated into the evanescent field around noble metal nanoparticles by assembling a lipid coating around the metal nanoparticle that serves as matrix for chalcopyrite nanocrystals with a hydrophobic ligand shell. Two classes of chalcopyrite nanocrystal – noble metal nanoparticle hybrids will be discussed in this presentation: i.) Chalcopyrite nanocrystals with Au nanorods ($CuFeS_2$ NC – Au NR)[3] and ii.) Chalcopyrite nanocrystals with Ag nanospheres ($CuFeS_2$ NC – Ag NP)[2]. The vertical and longitudinal plasmon resonances of the Au nanorods used in ref[3] peaked at around 530 nm and 745 nm, respectively. The chalcopyrite nanocrystal resonance overlaps only with the vertical but not with the longitudinal plasmon mode of the Au nanorod. These bi-resonant hybrid nanostructures were found to enhance the hydrogen evolution reaction (HER) when excited at 730 nm in an acidic electrolyte and the oxygen evolution reaction (OER) when excited at 530 nm in a basic electrolyte.

A systematic investigation of the photoelectrocatalysis obtained with these materials indicated that the detected reactivity is consistent with a hot electron transfer in different directions based on the chosen excitation wavelength.[3] Excitation of the longitudinal resonance triggers the formation of hot electrons in the Au NRs. These hot electrons can be transferred to the chalcopyrite nanocrystals where they can trigger the HER ($2H^+ + 2e^- \rightarrow H_2$). Alternatively, excitation of the quasistatic resonance in the chalcopyrite nanocrystals results in the formation of hot electrons in the nanocrystals that can transfer to the Au nanorods in a process that generates reactive holes on the nanocrystals to facilitate the OER ($4OH^- - 4e^- \rightarrow 2H_2O + O_2$) on the nanocrystal surface. In addition to the generation of hot electrons and holes on the chalcopyrite nanocrystals, the specific surface properties of the $CuFeS_2$ nanocrystals also play a role in driving the chemical reactivity of the hybrid materials and will be discussed.

The presence of a quasistatic resonance in the nanocrystals that overlaps with the plasmon resonance of metal nanoparticles also provides opportunities for engineering direct energy transfer between the building

blocks. This was investigated through single particle spectroscopy of $CuFeS_2$ NC – Ag NP hybrids.[2] Single particle lineshape analysis revealed a broadening of the silver nanoparticle spectrum that was indicative of a decrease in plasmon lifetime due to the presence of the chalcopyrite nanocrystals. Importantly, the spectral broadening was observed to depend on the energetic overlap between the silver nanoparticle plasmon resonance and the quasistatic chalcopyrite nanocrystal resonance.[2] An analysis of the single particle data will be presented and examined in this presentation.

Overall, the experiments performed so far suggest that chalcopyrite nanocrystal – noble metal nanoparticle hybrids facilitate light driven and wavelength-dependent charge and energy transfer that can be utilized to drive energy-relevant chemical transformations. This presentation will develop the framework of the relevant interactions between the building blocks and highlight potential strategies to optimize the photocatalytic properties of these intriguing nanoscale metamaterials.

Abstract

We improve quality factors (Q) of conducting polymer plasmonics by one order of magnitude through coupling with collective lattice resonance, and such nonlocal narrow resonance allows large extinction modulation depths during dynamic switching, which puts forward a key step in smart organic metasurfaces.

1 Summary

Conducting polymers with tunable redox states support dynamic switching of surface plasmon resonances for intelligent nano-optic metasurfaces. However, current polymer plasmons suffer from weak resonance intensities and low quality factors (Q < 2). Here, we achieve narrow conducting polymer plasmonics by coupling with collective lattice resonance (CLR) based on poly(3,4-ethylenedioxythiophene) (PEDOT) nanoantennas. We analyze the CLR-matching relationship between array factors of lattice and isolated polarizabilities of PEDOT nanoantenna units, and fabricated PEDOT arrays with well-matched sizes between array periodicities and nanoantenna dimensions, by using electron-beam lithography. The PEDOT arrays exhibit mid-infrared surface plasmon resonance (at the wavelength ranges of 2-4.5 μm) with linewidths of 0.3-0.5 μm, and Q can be up to 10-12, as one order of magnitude higher than previous works [1-4] (Q = 1-2). Furthermore, we can modulate large extinction depths of narrow plasmonic resonance (between ~5% and ~45%) through redox reactions of PEDOT materials. By addressing problems of broad and weak plasmonic resonances from conducting polymer nanoantennas, this work not only offers significant advances in the emerging field of nonlocal metasurfaces, but also shows feasibility of organic electronic materials for practical applications in active nano-optic systems.

Bound-state-in-the-continuum dielectric bowtie metasurfaces for strongly enhanced light-matter interaction

Abstract: Dielectric bowtie cavities allow confining light well below the diffraction limit without absorption and therefore enable greatly enhanced light-matter interactions. Here we present theoretical results showing that this enhancement may be harnessed in metasurfaces that support bound states in the continuum laterally confined to dielectric bowties.

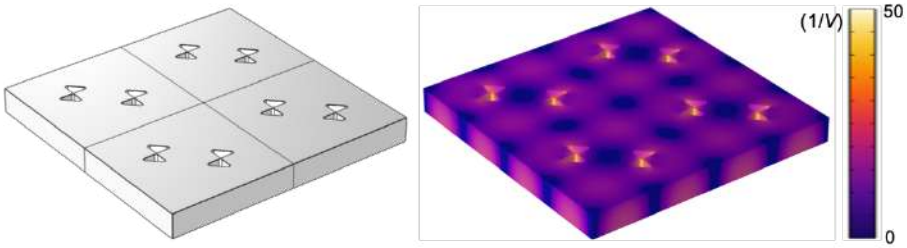

Figure 1. Left: Geometry of a metasurface with bowtie unit cells. Right: Simulated bound-state-in-the-continuum mode confining light more than 50 times below the diffraction limit in the silicon bridges at the center of the bowties.

The advent of dielectric bowtie cavities (DBCs) opens prospects for enhancing light-matter interaction[1] beyond what was previously considered possible owing to subdiffraction mode volumes[2-8]. Previous experimental works have considered single bowtie cavities, either realized by high-resolution nanofabrication[4,7] or self-assembly[5], while theoretical works span various inverse-design methods, nanobeam cavities, or topological building blocks, but a direct observation of increased spontaneous-emission rates have so far not been reported. Here we utilize a bowtie as a building block for a metasurface supporting as shown in Fig. 1. The structure supports bound states in the continuum[9] as shown in Fig. 2. In my talk, I will discuss recent theoretical results as well as experimental efforts towards measuring enhanced spontaneous-emission rates in bowtie structures.

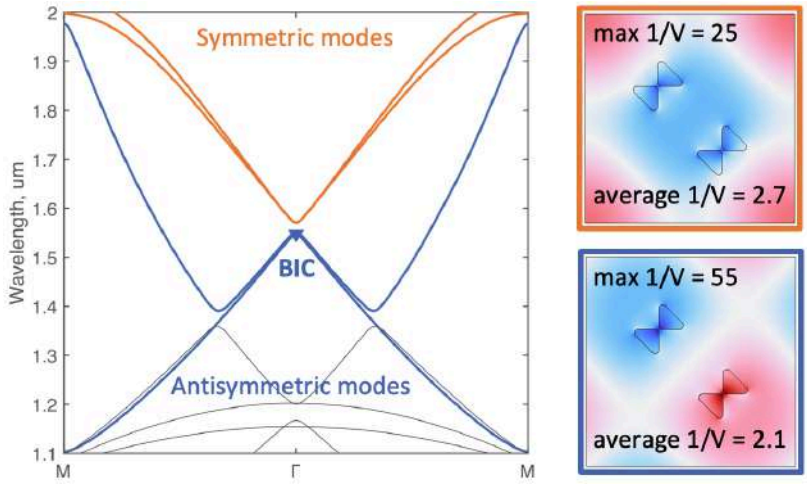

Figure 2: Calculated band structure exhibiting both symmetric and antisymmetric modes, and the latter includes a bound state in the continuum (BIC) with strong field enhancement in the bowtie region.

Abstract: Plasmonic effects enhance light-matter interactions for advanced metamaterials with tunable properties and broad spectral responses. Noble metals limit modulation beyond the visible range. This work develops novel meta-structures using alternative plasmonic materials (transparent conductors, nitrides, oxynitrides) to achieve customizable plasmonic properties from visible to infrared for extreme light control.

Optimizing solar energy conversion processes requires materials capable of harnessing the entire solar spectrum, from the visible (VIS) to the infrared (IR). In this context, plasmonics enables advanced control of light-matter interactions through plasmonic resonances [1]. Traditionally, noble metals such as gold (Au) have dominated due to their high-quality resonance in the VIS range, but their limited plasmonic tunability has driven research towards alternatives [2]. Transition metal nitrides, such as TiN, stand out due to their cost-effectiveness, thermal stability, and CMOS compatibility, offering tunable plasmonic responses in the VIS-NIR through compositional variations [3]. At the same time, oxynitrides (TiO_xN_y) are emerging as promising materials because they exhibit two epsilon-near-zero (ENZ) points, granting them a Double Epsilon-Near-Zero (D-ENZ) character. This property is highly beneficial for advanced optical phenomena, such as multiple resonances and enhanced nonlinear optics [4]. Another promising class of materials is represented by transparent conducting oxides (TCOs), such as Ta-doped TiO_2 ($Ta:TiO_2$), whose carrier concentration can be modulated to extend plasmonic properties into the IR range [2]. In this scenario, research focuses on developing metastructures based on alternative materials to enable multifunctional properties for applications in optoelectronics, biosensing, and nanophotonics. Hyperbolic Metamaterials (HMMs) are a key approach, as they feature anisotropic permittivity by alternating conductive ($\varepsilon_1 < 0$) and dielectric ($\varepsilon_1 > 0$) layers, enabling high-wavevector propagation and new light-confinement strategies [5].

In this study, thin films and multilayers based on $Ta:TiO_2$, TiN, and TiO_xN_y were developed and characterized using pulsed laser deposition (PLD) on cost-effective substrates (Si, glass). This technique allows precise control over composition and morphology during both growth and post-deposition treatments.

TiN/TiO_2 multilayers (**Fig.1(a)**) were explored as new candidates for HMMs, merging TiO_2 wide-bandgap semiconductor properties and TiN thermal stability. Optical characterization via spectroscopic ellipsometry revealed a broadband hyperbolic response between 600 and 2100 nm.

For oxynitrides, synthesis was optimized to incorporate oxygen while maintaining the TiN structure and preventing its transition to TiO_2. This challenge was addressed by fine-tuning deposition parameters such as base vacuum, oxygen and H_2-N_2 pressure. The resulting films exhibited a D-ENZ character, with tunable ε_1 crossings between 400 and 1700 nm (**Fig.1(b)**), opening new possibilities for their integration into multilayered broadband and multi-resonant HMMs, as it will be explained later.

With the final goal to extend plasmonic and optical functionalities of nanostructures far in the IR, Ta-doped TiO_2 TCO compact-conducting and porous-insulating films, obtained by varying solely the deposition pressure during PLD synthesis (1, 3, 6 Pa O_2) at fixed Ta doping content (5% or 10% at.), have been fully investigated from a material science perspective. The obtainment of metal-like and dielectric properties (**Fig.1(c)**) is allowed by the possibility to impose optoelectronic modification to the TCO upon tuning finely the oxygen content directly in the deposition process, that modifies morphology and stoichiometry, due to the inherent charge carrier density tunability owned by TiO_2-based TCOs. These results are fundamental to confirm the possibility to engineer HMM in the IR, which is impressive and quite unusual for a TCO (usually accomplished for AZO and ITO in the NIR up to 2 μm). Indeed, the next challenge is the experimental development of original nanostructures potentially working as HMM in the IR. Multilayers for this purpose have been synthetized with a simple one-step production by alternating metal-like (compact, crystalline) and insulating (nano-porous, amorphous) layers of the same Ta:TiO_2 TCO material, by varying the background pressure (1-6 Pa O_2) during the PLD deposition. As last but interesting remark, multilayers combining TiN, TiO_xN_y and Ta:TiO_2, definitely deserve additional research efforts, since it seems promising for achieving an exceptionally wide HMM behaviour, in multiple ranges, from VIS (TiO_xN_y is metal-like) to IR (Ta:TiO_2 is metal-like) (**Fig. 1(d)**).

Concluding, TCO (Ta:TiO_2) and nitride-based (TiN) alternative plasmonic nanomaterials merging multifunctional, tunable and broader plasmonic responses have been experimentally realized and characterized according to the tailored application. This work surely provides a starting guideline for designing real devices implementing cutting-edge alternative plasmonic materials, where the expected enhancement of light-matter interactions is at the core for technologically-relevant applications (thermal management in photovoltaics, plasmon-mediated broadband solar absorption/manipulation and photocatalysis).

Geometric approach based on optimal toric packings for photonic crystals and metamaterials design.

Alexander Itin[1]

Abstract

We introduce new classes of nanostructures—optimal toric packings of particles and their Voronoi tessellations—that exhibit remarkable properties for photonic and potentially for plasmonic/phononic crystals design. These structures connect the classical problem of optimal packings on tori with the development of optimized photonic architectures.

1. Introduction

Design of photonic crystals [1, 2, 3] with large bandgaps above a specified band is a well-known problem with diverse applications. Usually, such a design is achieved numerically using optimization methods or machine learning (ML) techniques. Optimality of the final designs is not easy to determine: combinatorial complexity of the design space is too large. Therefore, despite advances in numerical and ML techniques [4, 5], theoretical understanding of design principles of photonic bandgap structures remains being an important topic, and may be useful for many adjacent areas of scientific knowledge (e.g. plasmonics, phononics, and magnonics). In fact, in the field of photonic crystals, approximate design principles do exist thanks to insightful classic work of O.Sigmund and K. Hougaard [6]. Their conjecture linked optimal structures for bandgaps between bands n and n+1 to centroidal Voronoi tessellations (CVT): rods being placed at locations of CVT generators (in the case of transverse magnetic (TM) polarization), and walls of the CVT (in the case of transverse electric (TE) polarization). We found another mathematical approach [7]: optimal disc packings in square and triangular tori. While geometric idea behind CVT is some kind of uniformity in distribution of optical elements (coincidence of Voronoi tesselation generators with corresponding cell center of mass), optimal disk packings realise a simpler geometric objective: maximisation of minimal distance between the elements. Arrays of particles placed at the centers of optimally packed discs on tori and nets formed by walls of their Voronoi tessellations produce qualitatively different structures that sometimes significantly enlarge bandgaps. The new classes of periodic structures might have many applications in photonics and beyound. Optimal packing problems have arisen throughout the history of humankind, one of the most famous example is probably the Kepler problem concerning densiest arrangement of (many) identical spheres, where a close-packed structure was conjectured to be a solution [8]. It took more than 300 years to prove 2D version of the Kepler conjecture, and then much more difficult 3D case [8]. These results were about infinite space. We use somehow related and much more recent results for finite spaces [9]: optimal packings in "containers" with periodic boundary conditions. Indeed, even though a photonic crystal occupies an infinite space, it is obtained by periodic arrangement of a finite elementary unit cell. Considering a square or rhombic unit cell with periodic boundary, one obtains a square torus or triangular torus geometry, correspondingly [7]. Several mathematical and numerical methods had been used to find point configurations maximising minimal distance between points [9, 10, 11, 12]. In [7], we compared symmetry constrained CVT recipes of [6] with toric optimal configurations (OP). Here, we additionally study toric CVT configurations (tCVT, with generators of centroidal Voronoi tesselations being distributed on tori *without* symmetry restrictions). Part of the achieved advantage of OP over CVT comes from absence of symmetry restrictions. It is therefore logical to study also tCVT without those symmetry restrictions. We find that they are able to outperform toric OP in certain (rare) cases.

2. CVT, toric CVT, and toric OP configurations for photonic bandgap structures

.

Toric optimal packing configurations studied in [7] are illustrated on Fig. 1. CVT configurations of [6] with symmetry restrictions are shown on Fig. 2 and toric CVT configurations (without symmetry restrictions) are shown in Fig. 4. Here we illustrate only the square lattice geometry, for the triangular lattice case see [6, 7]. Bandgaps of optimised structures are shown in Fig. 3. Permittivity of the inclusions is the same as in Ref.[6]: $\varepsilon = 11.56$, while host media is air with $\varepsilon = 1$. 1-parameter optimisation (with only radius of rods or width of wires being the optimisation parameter) was applied to OP structures and obtained in this way OP_1 structures were compared with topology optimised (TO) structures of [6] (CVT_{top}), and with 1-parameter optimised CVT and tCVT structures (CVT_1 and tCVT_1, correspondingly). If 1-parameter optimisation is comparable with or better than TO (which involves hundreds of parameters), it is a clear sign of success. Indeed the

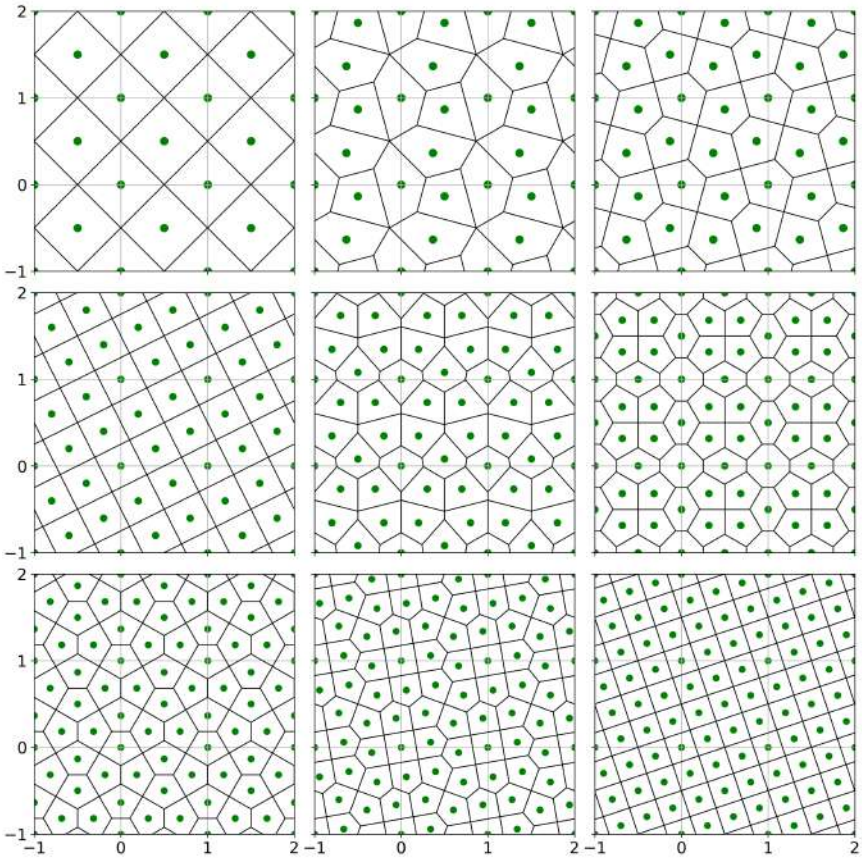

Figure 1: Optimal packing configurations (green dots) and their Voronoi tesselations (black lines) from N=2 (top left) to N=10 (bottom right). Each panel shows 3x3 supercell (numbers just mark the unit cells)

OP_1 structures clearly have certain advantages compared to classic CVT structures of [6]. In square lattice geometry, bandgaps of CVT structures for TE modes cannot reach levels that are achieved in triangular lattice geometry (approx. 52 %). However, for OP_1 structures, surprisingly, it is possible. In some cases OP_1 structures for TM modes also outperform CVT_{top}. One of the most peculiar structures arises at N=4 and N=8: for TM modes, arrays of points form one of the Archimedean square-triangular patterns, and for TE modes its corresponding Voronoi tesselations form Cairo pentagonal tiling [14, 15]. For triangular lattice geometry, the optimal packing recipe allows to predict "magic" band numbers where maximal bandgaps can be achieved [7]. Toric CVT structures (without symmetry restrictions) are shown in Fig. 4. We use results of [13] where toric CVT configurations were achieved using L-BFGS method. These structures, unlike OP, are not unique: there could be many different realisations, in particular it is possible to find fully hexagonal patterns in most cases. In some cases (e.g. N=5), toric CVT configurations coincide with toric OP structures. We chose fully hexagonal toric CVT patterns where it was possible, and found that for N=4 and N=8 they outperform toric OP structures (Cairo pentagonal tilings). At the same time, neither CVT nor toric CVT property, even being supplied with fully hexagonal patterning, is not enough to ensure optimal photonic bandgap: hexagons should also be somehow "round", e.g. for N=7 tCVT performs considerably worse than either OP or CVT (Fig 3c).

3. Further connections to art, math, and physics

.

Cairo tesselation [14, 15] is encountered in architecture, decorative design, and crystallography, but was not used in photonic crystals yet, to the best of our knowledge. In architecture, it can be found in Cairo (obviously), but also in Hamburg ([14, 15], see also Fig.6) and some other cities.

Mathematically, it is connected to one of the 11 Archimedean tilings via duality (see Fig.5). Archimedean tilings were already studied from the point of view of photonic structure design, but not from the point of view of optimal packings.

When discussing low-contrast limit of photonic bandgap structures, some kind of optimal packings in reciprocal space appear [17, 18].

Some of the structures of [7] may hopefully find applications in topological photonics and plasmonics: e.g. Ref.[16] studied lasing in arrays of quadrumers, while our N=4 configurations provides another route for packing of quadrumers on lattice.

There are certain connections with phononic structures

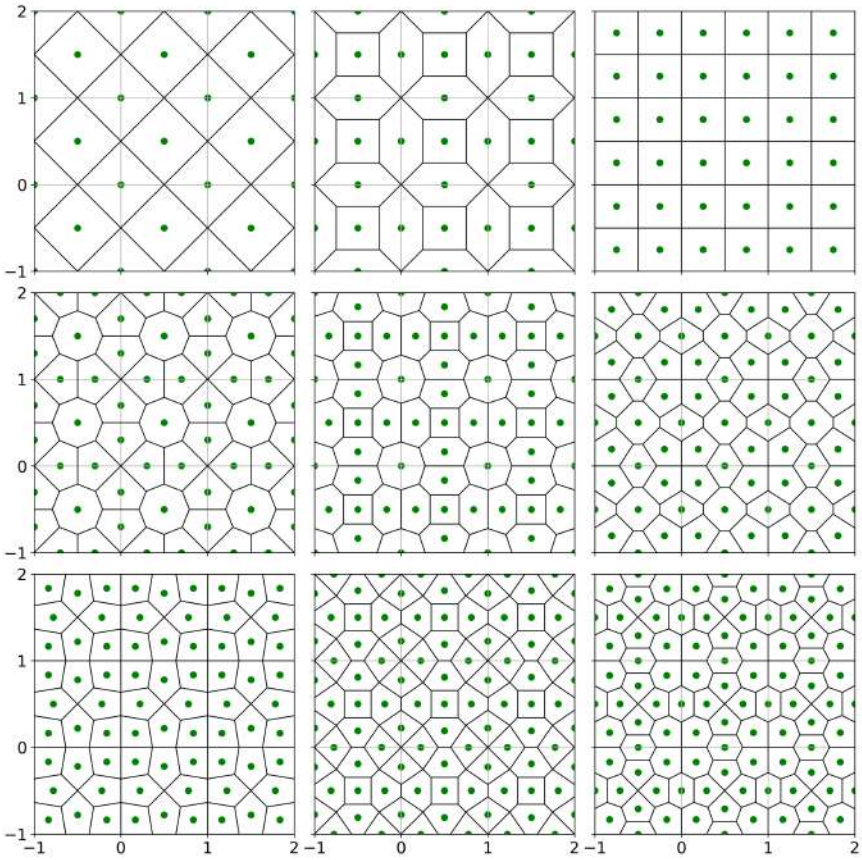

Figure 2: Centroidal Voronoi tesselations with symmetry constraints (black lines) and their generators (green dots) from N=2 (top left) to N=10 (bottom right). Each panel shows 3x3 supercell (numbers just mark the unit cells)

studied in [19].

4. Conclusions

. Splitting the process of topology optimisation on two steps, as suggested in [6], with the first step being purely geometric one, is very attractive and inspirational idea. So far systematic applications of this approach have been done in photonics, but it should be possible to extend to other realms of physics: plasmonics, phononics, etc. A peculiar historical fact is worth noting: in the very same year the first bandgap structure was ever discussed [3] (1887), a study appeared on an optimal geometric structure realising tiling of space [20]. These two scientific fields remain being intrinsically connected, providing interesting new findings. In [7] and here we considered toric optimal packing configurations and toric CVT configurations which sometime demonstrate certain advantages compared to classic CVT configurations of [6].

Abstract: We report the design and anticipated fabrication of Germanium metalenses on Ge and ZnSe platforms in the long-wavelength infrared (12–15 μm). Integrated into indirect absorption spectroscopy systems, they enable miniaturization for BTEX detection (Benzene, Toluene, Propane), addressing the need for compact optical components in the LWIR range.

Many Volatile Organic Compounds (VOCs) have strong fundamental vibrational absorption bands in the long-wavelength infrared (LWIR) region, making this spectral range particularly advantageous for their detection [1]. The pronounced absorption features in this range enable highly sensitive and selective VOC identification, even in complex gas mixtures, overcoming the limitations of shorter-wavelength methods.

Recent advances in indirect spectroscopy, such as photothermal [2] and photoacoustic spectroscopy [3], offer high selectivity and sensitivity. However, miniaturization remains challenging due to the limited availability of mid-IR optical components, including sources, detectors, and efficient beam-shaping elements. While recent developments in high-power LWIR sources [1] open new possibilities, conventional optics remain constrained by diffraction limits and bulky designs.

Metastructures [4], particularly long-wavelength metalenses [5], present a promising solution by enabling compact, high-performance optical elements for mid-IR applications [6]. These structures enhance light-matter interactions, surpass the limitations of traditional optics, and facilitate system integration for next-generation LWIR spectroscopy. In this work, we explore engineered meta-optics for focusing and collimation, designed to operate at the absorption bands of three VOCs, advancing miniaturized sensing technologies.

The selected absorption bands for Propane (13.36μm), Toluene (13.71μm), and Benzene(14.85μm) are highlighted in Fig. 1(a) with color-coded dashed lines. To increase the fabrication possibilities of the proposed design for indirect LWIR spectroscopy, two alternative platforms are considered. The first approach involves Ge on ZnSe, whose refractive index contrast is shown in Fig. 1(a). The second consists of a monolithic unit cell based entirely on Ge. Both systems have good compatibility with available photolithography-based fabrication processes and are derived from the structure presented in Fig. 1(b). As illustrated in Fig. 1(b), the design consists of Ge nanopillars with a thickness of t=7μm and a unit cell periodicity of P=5μm while the in-plane geometry is varied through the ratio d/P, where d represents nanopillar diameter. P is guaranteed to be subwavelength, $P<\lambda/n_{\mathrm{ZnSe}}$, to ensure the contribution primarily comes from the zeroth diffraction order. Additionally, $P<\lambda/2NA$ is set to allow high numerical aperture (NA). A minimum feature size of 1 μm is also ensured for fabrication.

Rigorous Coupled Wave Analysis (RCWA) is used to compute the amplitude and phase response that characterize the proposed Ge/ZnSe platform under normal incidence within the wavelength range of 13.3–14.9 μm. Fig. 1(c–e) illustrates that, in all cases, the phase response reaches at least 2π, while the amplitude response appears to be decoupled from the phase response, with transmission exceeding 90%.

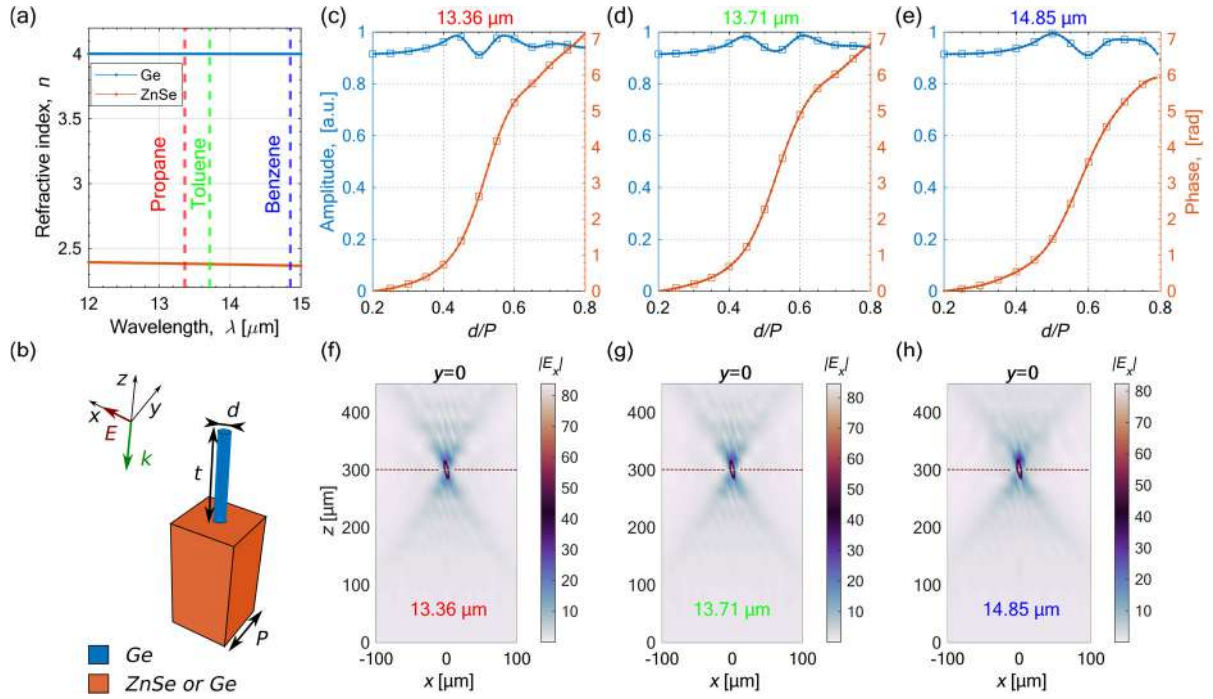

Fig. 1. (a) Refractive index of Ge and ZnSe. (b) Ge unit cell on a ZnSe substrate or bulk Ge. (c-e) Simulated amplitude and phase as a function of the filling fraction (d/P). The meta-atom response is computed when illuminated at the absorption band wavelengths in (a): Propane, Toluene, and Benzene. (f-g) Cross-section of the simulated diffracted beam along the z-axis for a metalens designed with a 300 μm focal length, 700μm diameter and NA = 0.8.

The composed meta-element library is then used to design three different high-NA (0.8) metalenses with a focal length of 300 μm, optimized for the absorption wavelength of the target VOCs, as shown in Fig. 1(f–h).

The monolithic unit cell, despite having a limited amplitude transmission as low as 60%, still exhibits 2π phase coverage for the two lowest wavelength bands. However, when implemented in a metalens design, its focusing efficiency is estimated to be lower than the 90% achieved with the bi-material unit cell. Fabrication in bulk Ge, requires a smaller P value, if not increases secondary diffraction effects, potentially reducing overall efficiency. However, single-material systems offer simpler fabrication compared to Ge grown on ZnSe.

With ongoing fabrication, we aim to integrate these metadevices into photothermal and photoacoustic spectroscopy, leveraging their compactness and flexible optics to overcome LWIR limitations.

Abstract: We have investigated local photo-bleaching in TDBC dye layers for grating and strong coupling applications. This method allows to be modulate the refractive index both locally and spectrally, enabling the patterning of micro-devices with spectral modulation. We will present fundamental properties and fabricated devices, highlighting the high potential of such material.

Tetrachloro Diethyl Benzimidazo Carbocyanine (TDBC) layers are highly promising for photonic applications due to their significant oscillator strength, narrow absorption spectrum, local photo-bleaching capabilities, and cost-effective fabrication. They were primarily utilized in aggregation and strong coupling studies [1], but also in other works like light concentration [2] and absorption enhancement [3]. However, the intrinsic properties of TDBC layers are not yet fully understood and require further investigations to fully harness their potential, especialy regarding their bleaching properties (i.e., photochemical alteration of a molecule that renders it non-fluorescent) and the fabrication process [4].

Over the past few years, we have studied various TDBC micro-devices, demonstrating that micro-structures with resolution~~s~~ down to 1 µm can be successfully fabricated for strong coupling applications [5] and grating fabrication [6]. Additionally, we have investigated the intrinsic properties of the material. Using Raman spectroscopy, we have shown that even a slight change in the molecule can result in a significant modification of the oscillator strength [7].

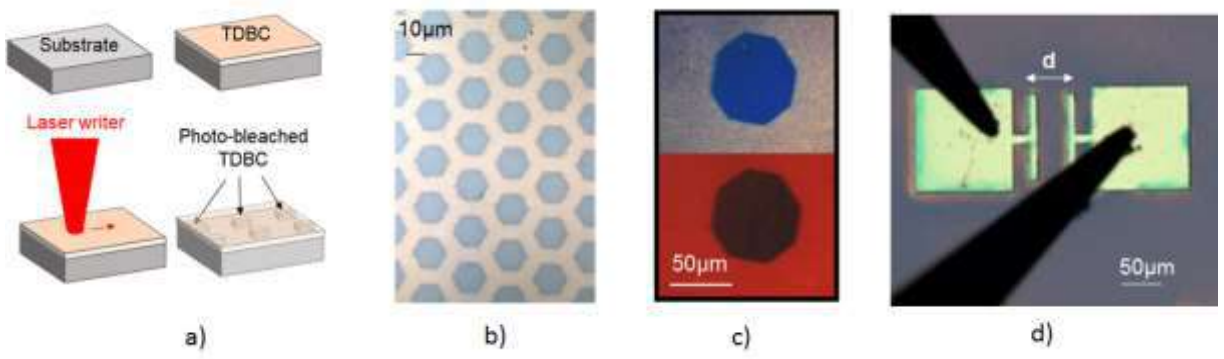

Figure 1 : a) process flow of the local photo-bleaching using a laser writer; fabricated sample observed with an optical microscope in b) bright field on Ag and in c) bright field and fluorescence on SiO_2; d) electrical characterization

Figure 1-a illustrates the process flow used to locally bleach such layers. TDBC layers, 17 nm thick, are spin-coated onto substrates and then exposed using a laser writer (µPG Heidelberg) [5,6] or fluorescence microscope. Figures 1-b and c show examples of fabricated structures with polygons exposed on Ag layer or SiO_2 substrate,

respectively. Images were captured using an optical microscope in both fluorescence and bright field (BF) modes. In the BF image, we can see that the refractive index is modulated at the microscale, as the TDBC becomes transparent in the bleached regions. In fluorescence mode, no emission is detected in the bleached regions, as expected. Furthermore, we investigated how the refractive index changes as a function of the bleaching. The Drude-Lorentz model, which is widely used in the literature, involves four constant material parameters: f_{osc} (the oscillator strength), Eg (the energy of the HOMO-LUMO transition), ΔE (the absorption spectral width), and ε_0 (the constant part of the dielectric function). After bleaching, only the fundamental transition around the 590 nm wavelength range is modified in the refractive index [9].

Finally, we explored different new significant parameters such as layer thickness influence, surface roughness, layer conductivity (Figure 1-d), the use of PDAC (Poly Diallyldimethyl Ammonium Chloride) as a hang layer highlighting the need for more investigation of these layers to fully leverage the potential of this promising material for future applications.

Abstract: We report a combined experimental-theoretical investigation on nanoscale light-matter interaction in quasi-3D photonic crystals of gold. Using ultrafast optical pulses we produce strongly localized surface plasmon resonances in the metal-dielectric interface, to enhance nonlinear frequency conversion from visible/NIR to ultraviolet ranges.

Plasmonic nanostructures under resonant conditions create strong spatial confinement of the electromagnetic field near the surface of the metal, which in turn enhances light-matter interaction and generates very large surface nonlinearities and enhanced frequency conversion, a fundamental step towards building coherent and efficient nano-scale UV light sources. The resonant properties are determined by the geometrical (shape, size, sharpness) and physical parameters (dielectric functions) of both the metal and surrounding dielectric materials [1-4].

In this work we explore crystals consisting of large area, periodically patterned arrays of cylindrical wells along x and y dimensions, with diameters of $d \sim 367\text{nm}$, imprinted in film of SU8 photoresist ($h_{SU8} \sim 390\text{nm}$), and center-to-center spacings of $p \sim 800\text{nm}$. The nanostructure is coated with uniform deposition of gold ($h_{Au} \sim 50\text{nm}$), coating both the top surface and the recessed regions, resulting in quasi-3D plasmonic crystals (Fig. 1(a)). The top layer is a 2D array of nano-holes in gold films, with a second, physically separate level of isolated gold disks at the bottoms of the embossed wells (Fig. 1(b)).

Our detection system and precise calibration enables us to detect and quantify third harmonic generation (THG) efficiencies, and corroborate our theoretical and experimental observations of shape, spectral width, and maximum amplitude of the spectral response. Fig. 1(c) shows the narrow spectral linewidth plasmonic resonance centered around 789 nm. The sharp dip in reflection is a result of complete absorption of incident light and its localization at the metal-air interface inside the holes (Fig. 1(d) inset). The spectral position of the resonance precisely depends on the geometrical parameters of the structure, such as p, d, h_{Au}, h_{SU8} and hence is highly tunable.

The spectral response of the TH emission ocurring in the UV (centered at 263 nm) is depicted in Fig. 1(d), the experimentally retrieved data as the curve with red dots, showing a maximum THG enhancement factor of 98. The theoretical prediction, calculated by FDTD (blue curve in Fig. 1(c)), shows a maximum enhancement of 108. The periodicity of the structure can diffract the generated TH. The total efficiency, which is the sum of the zeroth and first diffraction orders, when scaled to the TH reference signal originating from the unpatterned portion of the gold sample, measured exactly in the same experimental conditions, gives us the total enhancement factor of ~ 400 times.

ABSTRACT The basis of a scientific and technological breakthrough at the nanoscale is the use of new, previously unknown properties and functionality of materials. New devices require the development of new materials with atomically smooth interfaces. Therefore, this paper examines modern metamaterials based on porous anodic alumina (PAA), and presents prospects for the development of micro- and nanoelectronics, including a wide range of innovative nanodevices and miniature systems using PAA. The features of anodizing aluminum foil are considered. Nanosized layers and membranes based on PAA with ordered nanoscale capillaries with a pore diameter from 20 nm to 200 nm and an aspect ratio of up to 500 are obtained. Study of structure and morphology using AFM, SEM and RBS techniques. The results of studying the optical properties (in the range of 200 nm - 16 μm) made it possible to propose a method for diagnosing a porous structure based on an analysis of optical transmission spectra. Possible areas of application of structures based on PAA, including in popular new generation devices, have been demonstrated.

I. INTRODUCTION

To date, a number of effective methods for creating nanostructures have been developed, among them the methods based on the principle of self-formation are extremely important [1-9]. Self-formation methods include various mechanisms for ordering nanoparticles into structures with a given shape and size. The simplicity of electrochemical methods for obtaining porous materials and the ability to control their properties by changing the formation mode make them convenient objects for studying physical phenomena in nanostructures. The most studied materials obtained by the electrochemical etching method are porous silicon and porous anodic alumina (PAA) [9-15]. To date, the most widely accepted model of the formation of the porous structure of aluminum oxide is based on the hypothesis of the mechanism of formation of the ordered honeycomb structure of the PAA layer. According to this hypothesis, a possible source of forces arising between neighboring cells is mechanical stress associated with the increase in volume during the formation of aluminum oxide. More detailed theoretical ideas about pore formation can be found in the works.

In this work, the main emphasis is on the formation of nanoporous aluminum oxide. Membranes based on it are in demand in nanotechnology and microbiology [12, 16-17], nuclear physics [18-22], since they have a number of unique properties (high aspect ratio, optical transparency, biological inertness), as well as mechanical strength, thermal stability and chemical resistance.

The complexity of separating such porous anodic films from the substrate limits the prospects for their use as free membranes (masks, matrices) with the required topological and geometric parameters of pores. Thus, the formation of mechanically strong PAA membranes with ordered through pores - capillaries of micro- and nanoscales in thin (~10 μm) aluminum foil is an actual task.

The aim of this work is a comprehensive study of the processes of controlled formation and self-formation of nano- and microporous membranes based on aluminum oxide and the possibilities of using them as nanosized capillary matrices and masks for various purposes in micro- and nanoengineering.

II. EXPERIMENTAL

Since the aim of the work was to form through single-axis oriented capillary membranes based on aluminum oxide, the main object of the study was aluminum foil with a thickness of ~ 10 μm. Particular attention was paid to the technology of

preliminary preparation of its surface and the actual process of electrochemical anodization, as well as to the study of the structure, geometry and physical characteristics of porous membranes.

For the reproducibility of the membrane manufacturing technology, it is necessary to study the microstructure of the original aluminum foil, since the size and crystallographic orientation of the grains of the anodized foil determine the homogeneity of the layer and the shape of the pores. In the course of the work, special attention was paid to the technology of preliminary preparation of the surface of aluminum foil with a thickness of ~ 10 μm and the process of electrochemical anodization itself. The first stage of the study was the preparation of the foil within the framework of such processes as mechanical faceting (Fig. 1a) and surface polishing, as well as recrystallization during thermal annealing. Surface faceting largely determines the topological and geometric parameters of the pore formation process and the pore habit (Fig. 1b).

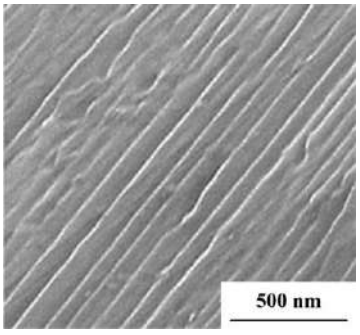

FIGURE 1. SEM images of aluminum foil after faceting process.

Using a local X-ray structural analysis method (inverse Laue imaging), a study of the recrystallization of aluminum foil and determination of grain orientation was carried out (Fig. 2).

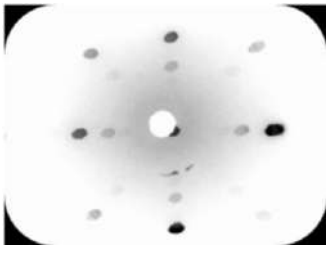

FIGURE 2. Reverse Lauegram of aluminum foil after annealing at T = 650 ºC for t = 6 h

The results showed that high-temperature annealing leads to the formation of single-crystal grains, and on the Lauegram taken in the center of the sample, clear reflections corresponding to the (100) orientation of this grain are observed.

In order to form PAA membranes, aqueous solutions of sulfuric and orthophosphoric acids with the addition of 10-15% glycerol were used as electrolytes in this work. The production technology is described in detail in [23], Table 1 provides generalized data, where U_A is the anodizing voltage, t is the time, T is the temperature, d_{pore} is the pore diameter, C_{pore} is the pore concentration.

TABLE 1. Aluminum anodizimg parameters

electrolyte	H_2SO_4+15% glycerol	H_3PO_4	H_3PO_4+10…15% glycerol
U_A, V	20–27	80	120–150
t, min	3…5	20	10…17
T, ˚C	5…7	-5…+5	0…7
d_{pore}, *nm*	20–30	80–100	180–220
C_{pore}, $1/\mu m^2$	350	50	20

To obtain through membranes, technological stages of chemical and electrochemical etching of samples from the back side were introduced.

The study of the parameters of the porous structures was carried out using scanning electron, atomic force and optical microscopy. A technique based on the analysis of optical transmission spectra in a wide range (from 200 nm to 15 μm) of wavelengths was also used.

IV. RESULTS AND DISCUSSION

A comprehensive study of PAA showed [15, 18, 23] that by varying the technological conditions of anodization (electrolyte composition, voltage/current density, temperature and process time), it is possible to control the structural parameters of the porous layer (Fig.3): pore diameter (from 20 to 200 nm), distance between pore centers (from 40 to 250 nm), and thickness of the porous layer (from 200 nm to 30 μm).

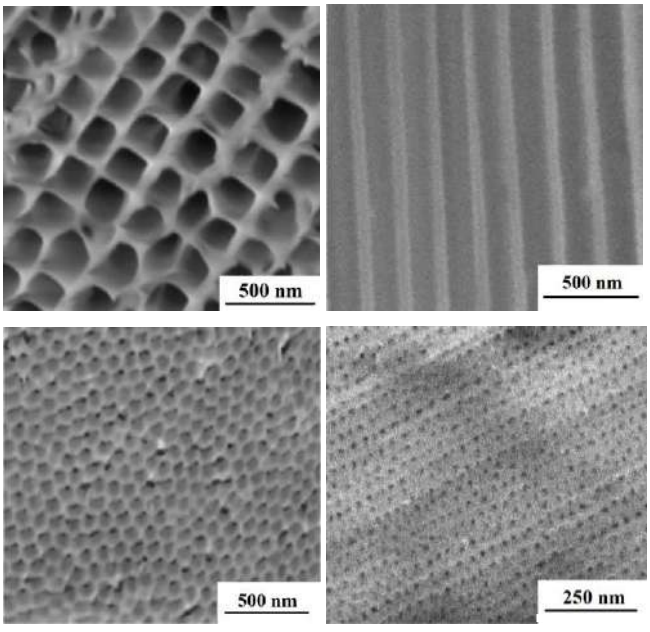

FIGURE 3. SEM images of PAA with different pore geometries

The results showed that by choosing the method of preliminary processing of the initial aluminum foil (faceting, polishing, thermal annealing), it is possible to control the shape of the pores: square, hexagonal, round.
The results of the study of optical transmission spectra are presented in Fig. 4 [24].

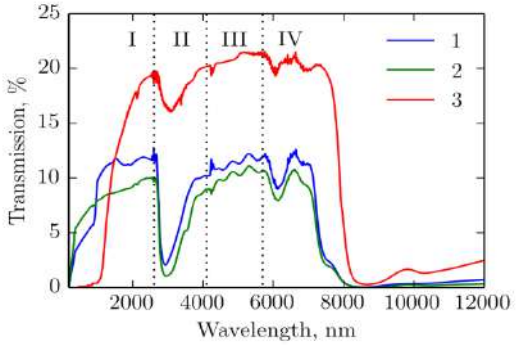

FIGURE 4. Optical transmission spectrum for PAA-based membranes in a wide range of wavelengths (1–5 in the text)

The transmission spectrum contains zones that allow for express characterization of the membrane: to estimate the average pore size and size distribution (section 1), membrane thickness (section 4), the presence of residual products (sections 2 and 5), and to identify the membrane material as aluminum oxide (section 3).

IV. APPLICATION AREAS

This article presents new applications of nanoporous membranes with a system of uniaxially oriented capillaries: as a material for attenuating thermal radiation from the human body, nanoscale masks for channeling ion beams, growth platforms for lab-on-a-chip, and filters for a liposome extruder.

A. SHIELDING COATINGS

The first application is related to the fact that nanoporous PAA membranes significantly reduce the transmission of IR radiation in the range from 8 to 14 μm [24]. The maximum thermal radiation of biological objects (at a wavelength of ≈ 10 μm) is located within the above-mentioned limits. As studies using IR Fourier spectroscopy have shown, for the por-Al2O3 membrane, a section of significant radiation attenuation is observed in the range from 7.5 to 14 μm (Fig. 4, sections 5).

The data obtained using FTIR spectroscopy are fully confirmed by studies conducted using a thermal imager (SDS INFRARED hotfind LXT). As an example, these membranes were used to attenuate the thermal radiation of the human body. Fig. 9 presents the results of thermal imaging studies and shows that a 15 μm thick PAA membrane located on a 5 mm thick fluoroplastic ring holder provides effective shielding of the thermal radiation of the human body, while the recorded change in the temperature difference from the biological object in the presence and absence of the membrane is at least 4˚–5˚.

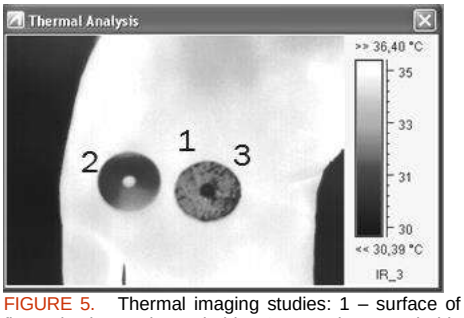

FIGURE 5. Thermal imaging studies: 1 – surface of biological object, 2 – fluoroplastic membrane holder, 3 – membrane on holder

Thus, it can be said that, despite the optical transparency in the visible range (Fig. 7, section 1), por-Al2O3 membranes significantly weaken the transmission of radiation in the mid-IR range (λ = 8-13.5 μm), which can allow them to be used as filters for absorbing radiation from biological objects.

B. TEMPLATES FOR HIGH-ENERGY ION BEAMS

PAA membranes with through nanocapillaries were considered as nanoscale templates for high-energy ion beams [30-32]. For this purpose, they were studied for the effect of passage of a helium ion beam with an energy of 1.5–2 MeV. Figure 6 shows the Rutherford backscattering (RBS) spectrum for a mask–template with a pore diameter of ≈ 20 nm. A sample containing a "heavier" element, in particular, hafnium (Hf), was placed behind the membrane as a "recording" medium–target.

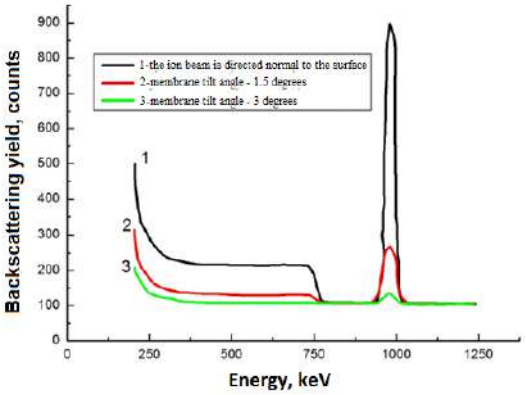

FIGURE 6. The energy spectrum of backscattered He+ ions with an energy of 1200 keV. The black curve is the spectrum along the normal direction; the red curve is the spectrum when the deviation is 1.5 degrees from the normal; the blue curve is the spectrum when the deviation is 3 degrees.

Even a slight deviation of the membrane from the normal (1.5˚…3˚) with respect to the direction of propagation of the ion beam leads to a decrease in the yield of backscattered ions from the HfO_2 target and, consequently, to a decrease in the recorded current. Thus, the created and studied

membrane–templates ensure the performance of the functions of channeling a high-energy ion flow.

It has been established that the coefficient of accelerated ion transmission through the membrane can reach 60% [18, 24]. This allows spatial localization of the ion impact on the substrate with nanoscale resolution.

Thus, PAA matrices, depending on their geometric parameters, can expand the capabilities of RBS.

C. BIOMEDICAL APPLICATION

Porous ordered structures are of particular interest for filtering various media. The authors of this work consider the possibility of using PAA membranes as a growth platform for bacterial colonies, as well as a filter for homogenizing liposomes. In this case, it is important to select membranes with certain geometric parameters.

To achieve the stated goals, microporous membranes obtained by both anodization through a photoresistive mask and microchannel plates were used in the work (Fig. 7).

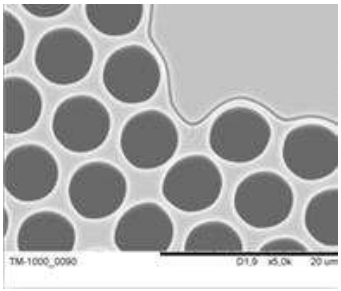

FIGURE 7. SEM image of the edge of a microchannel plate

The method of layer-by-layer molecular deposition of Al_2O_3 was considered as a method for precision control of the pore diameter. As a result of the work, growth cells were formed, which represent a microporous structure (Fig. 8), the bottom of which is a nanoporous layer of aluminum oxide.

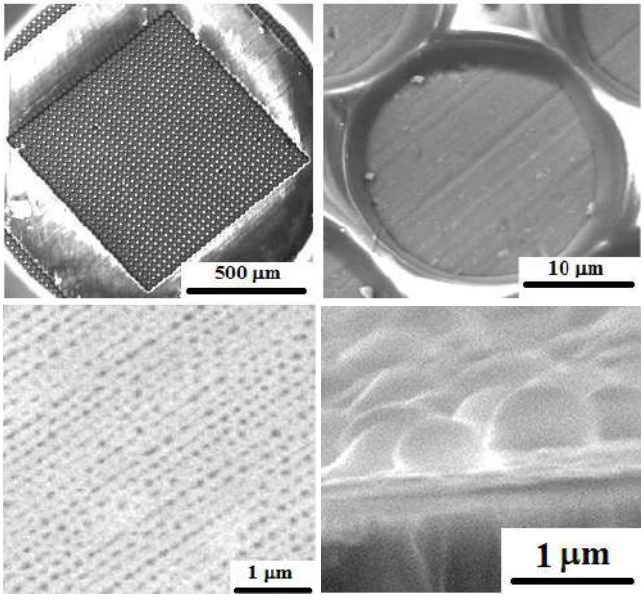

FIGURE 8. SEM images of a PAA membrane after photolithography and electrochemical anodization: a) membrane with a photolithographic pattern of micropores, b) a fragment of a micropore with nanocapillaries, c) nanocapillaries, d) membrane with bacterial colonies

Through this porous bottom, the nutrient medium entered the bacteria located in the micropore due to capillary action. As a result, the bacterial colonies were able to survive.

In addition, a liposomal extruder was developed for homogenizing liposomes (Fig. 9). The key element of such a device is a nanoporous membrane. The diameter of the membrane pores determines the size of the liposomes passing through it.

FIGURE 8. Photo of the final model of the liposome extruder

The optimal pore size in this case is 200 nm in diameter. The process of electrochemical anodization under properly selected technological conditions makes it easy to achieve this.

V. CONCLUSION

In this paper, the technology of self-formation of porous membranes with a system of ordered uniaxially oriented nanosized (pore diameter from 20 nm and more) capillaries based on aluminum oxide with an aspect ratio of up to 500 by electrochemical anodization of aluminum foil with a thickness of tens of microns was described. The structure and optical properties of ordered through membranes of nanoporous aluminum oxide were studied depending on the process conditions.

A method for diagnosing a porous structure based on the analysis of optical transmission spectra is proposed. The results of the studies showed that zones are identified in the transmission spectrum that allow express characterization of the membrane by the main structural and geometric parameters. It is shown that nanoporous membranes based on aluminum oxide significantly reduce the transmission of IR radiation in the range from 8 to 14 µm, which corresponds to the spectral region of IR radiation of biological objects. They also ensure the performance of channeling functions for a high-energy flow of helium ions with an energy of 1.5–2 MeV.

The possibilities of using PAA membranes for biomedical purposes, namely as a growth platform for bacterial colonies and a filter for homogenization of liposomes, are considered.

Abstract: Fermi arcs in coordinate space link topological degeneracies, with surface Fermi arcs linking Weyl points and bulk Fermi arcs linking exceptional points. We present the results of an experimental observation of a bulk Fermi arc in a single dielectric ring resonator.

Topological photonics arises as a bridge between the properties of bulk and surface states, with non-Hermitian systems possessing unique topological features that are absent from their Hermitian counterparts [1–3]. An important example of the combination of non-Hermitianity and topology is provided by Fermi arcs. By breaking the parity or time-reversal symmetry of a Hermitian system, the Dirac point in coordinate space splits into two or four Weyl points of opposite chiralities, and by adding losses, the Dirac point splits into two exceptional points of opposite chiralities. In this case, two pairs of Weyl points with opposite topological charges are connected by two surface Fermi arcs, and a pair of exceptional points is connected by a bulk Fermi arc, and along the arc the eigenvalues coincide, while the eigenfunctions differ [4]. Confirmation of the theory faces serious technological and experimental difficulties and, to our knowledge, has only been achieved once for a surface and once for a bulk Fermi arcs. Four Weyl points and helicoidal surface Fermi arcs connecting them have been experimentally observed in a 3D photonic crystal composed of metallic inclusions [5]. The emergence of a bulk Fermi arc and half topological charges were experimentally observed in a 2D periodic photonic crystal [6]. Note that in both cases complex objects were used as experimental samples and the question of observing such topological features on a single resonator remained open. We have previously demonstrated the existence of a bulk Fermi arc in a single dielectric ring resonator with a rectangular cross-section in our calculations [3] and now report an experimental observation of this striking feature of non-Hermitian systems.

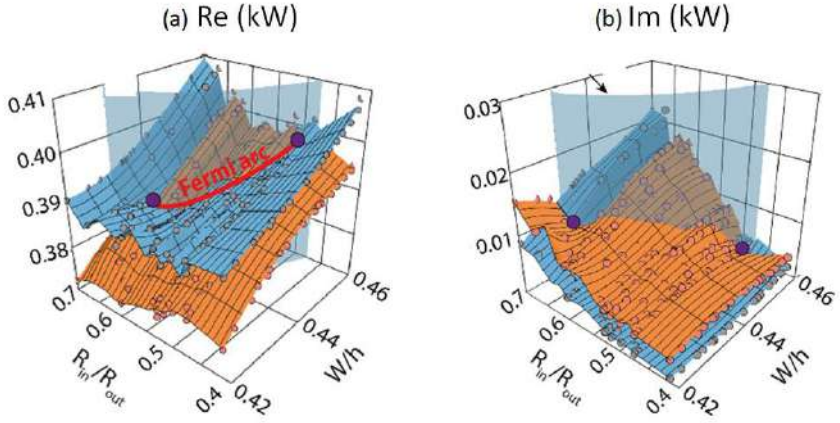

Figure 1. Double Riemann sheet for the Real (a) and Imaginary (b) parts of the eigenvalues, obtained by connecting the experimental points (shown as dots). The two purple dots show the positions of the experimental EPs. The red line shows the resulting experimental bulk Fermi arc.

Based on our theoretical work [3], we determined the ranges of geometric parameters R_{in}/R_{out} and $(R_{out}-R_{in})/h$ of a ring resonator for observing a bulk Fermi arc. To obtain a sufficiently dense grid of parameters, 203 ring resonators were manufactured and experimentally measured. It should be noted that the results of processing the experimental spectra were in excellent agreement with the data of numerical calculations. Based on 203 experimental spectra, two intersecting Riemann sheets were constructed, two exceptional points were determined, which for the eigenvalues Re(kW) were connected by a continuous Fermi arc belonging to both sheets, which does not happen when two sheets Im(kW) intersect (Figures 1a,b). Figure 1 presents the first, as far as we know, experimental observation of a bulk Fermi arc for a single resonator.

Bright and dark soliton blending stabilized by non-Hermitian potentials in Kerr ring cavities

Abstract: Bright and dark solitons, separately observed in systems with opposite dispersion, are blended in a hybridized scenario by introducing periodic non-Hermitian potentials in the damped-driven nonlinear Schrödinger equation. New patterns, solitonic structures, and molecules are generated, become accessible, and can be stabilized.

We consider the damped-driven nonlinear Schrödinger equation as a normal form describing a large variety of systems, Eq. (1), and in particular Kerr ring cavities. The system exhibits a resonance for particular values of detuning, δ, that is tilted by the nonlinearity, and shows bistability of two homogeneous states for defocusing dispersion (normal group velocity dispersions in Kerr cavities) [1]. As a consequence, stationary localized structures, dark solitons, arise as spatial orbits close to homoclinic cycles between the two homogeneous states, and organized in a collapsed snaking diagram of S_n branches. For anomalous group velocity dispersions, the upper homogeneous state suffers a Modulation Instability generating periodic patterns. In this case, bright solitons appear as homoclinic cycles between the pattern and the lower stable homogeneous state organized in a standard homoclinic snaking diagram of S^Z branches. These two disjoined scenarios in the formation of localized structures become blended by introducing a stationary non-Hermitian potential $V(x)$ in the system:

$$\frac{\partial \psi}{\partial t} = -i\frac{\partial^2 \psi}{\partial x^2} - (1+\delta i)\psi + 2i|\psi|^2\psi + V(x)\psi + h, \quad V(x) = m\cos\left(\frac{2\pi px}{L}\right)e^{-i\phi} \tag{1}$$

Considering negative dispersion in a spatial window of length L and p potential periods, the upper homogeneous state becomes modulated and acquires a pattern character. It allows the stabilization of patterns with the potential periodicity and the mixing of dark solitons, already existing for this dispersion sign, and bright solitons, all organized in a complex scenario merging collapsed and standard homoclinic diagrams. New families of differently shaped solitons arise by the resulting crossbreeding of bright and dark solitons. The stabilization of patterns as soliton trains, allows new connections between patterns and the modulated homogeneous states [2]. Particularly stable molecules as combination of dark solitons with small n values arise, $\{S_n, S_n\}$, while combinations of large n solitons generate $\{S^Z, S^Z\}$ molecules, see Fig. 1 a). More interesting is the combination of solitons $\{S^Z, S_n, S_n\}$ generating combinations of bright solitons or even more complex combinations like $\{S^Z, S_n, S_{n+1}, S_{n+1}, S_n\}$ as two kinds of dark solitons mixing corresponding to consecutive branches in the collapsed snaking diagram, Fig, 1 b).

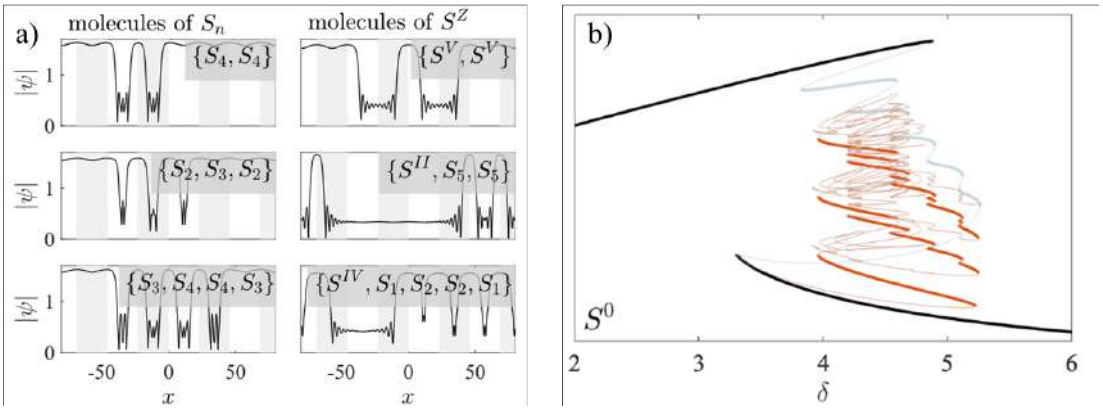

FIG. 1: a) Molecules as combinations of dark and bright solitons. b) Bifurcation diagram of homogeneous solutions (black), patterns (blue), and solitons and molecules (red) for a) m=0.15 and ϕ=6.

For large enough potential amplitudes the bistability of homogeneous states totally disappear, and the lower state acquires the pattern character allowing molecules of bright solitons of the form $\{S^Z, \ldots, S^Z\}$. The system symmetry induces disjoined odd and even families of molecules, see Fig. 2.

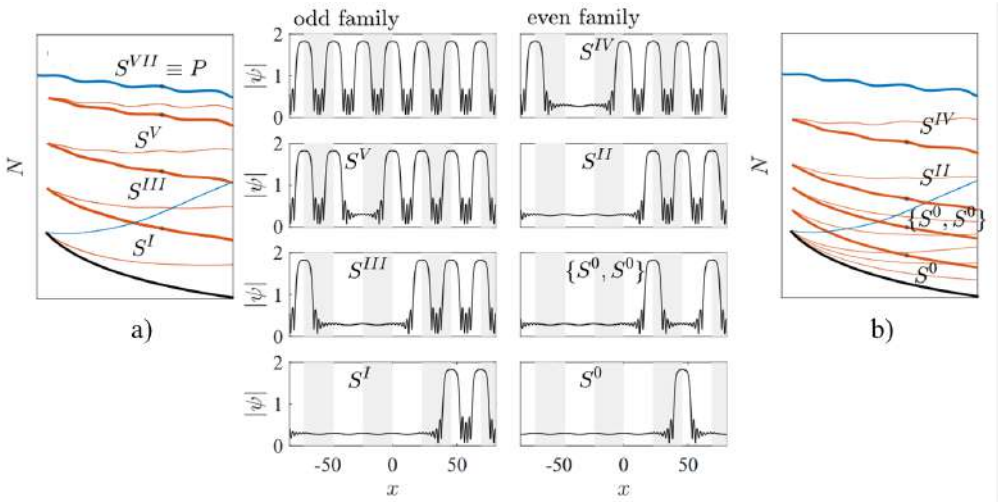

FIG. 2: a) Molecules as combinations of bright and dark solitons. b) Bifurcation diagram of homogeneous solutions (black), patterns (blue), and solitons and molecules (red) for a) m=0.7 and ϕ=6.

Active Parabolic Waveguide Amplifiers with Non-Hermitian Mode Control

M. N. Akhter[1], R. Herrero[1], K. Staliunas[1, 2] and M. Botey[1]

Abstract: We demonstrate a non-Hermitian mode management mechanism in nonlinear parabolic waveguide amplifiers, exploiting asymmetric mode growth via refractive index and gain/loss modulations. This enables flexible mode combination, higher-order mode excitation, and photon concentration into the lowest-order Hermite mode for all-optical cleaning. The effect is analytically predicted, numerically validated, and robust.

In the present paper, we propose a modal management scheme for active nonlinear systems such as multimode fiber amplifiers. The scheme exploits simultaneous longitudinal non-Hermitian modulations of the propagation constant and of the gain/loss coefficient with a transverse profile (see Fig. 1a), which recently showed effective all-optical mode-cleaning in parabolic multimode optical waveguides [1]. Indeed, non-Hermitian photonics allows for managing the flow of light, from laser stabilization to the control of optical turbulence, among others [2-6].

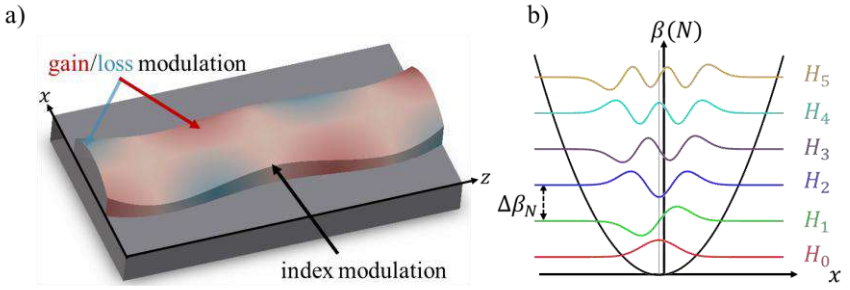

Figure 1. a) Periodically modulated active parabolic waveguide, the index modulation along the propagation direction, z, is accounted for by the fiber snaking, and the gain/loss modulation is antisymmetric in the transverse direction as indicated by the colors. b) First transverse Hermitte-Gauss modes of the unmodulated waveguide, with equidistant mode spacing $\Delta\beta_N$.

The proposal takes advantage of the equidistant mode solutions in unmodulated parabolic nonlinear MMFs, see Fig. 1b. The nonlinearity saturates the growth of the mode amplitudes, leading to particular mode configurations. Under the introduction of particular non-Hermitian modulations, which, in the simplest form, may be expressed as: $V(x,z) = V(z)V(x) = [m_{re}cos(qz) + im_{im}\, cos(qz + \phi)]\,(x/x_0)e^{-x^2/x_0{}^2}$, it is possible to control the mode distribution and, therefore, the beam shape. The effect is also analytically predicted using a mode-expansion approach, showing good agreement with the full model calculations based on the complex Ginzburg–Landau equation, the governing equation for light propagation along the active multimode fibers in CW or quasi-CW (long pulses) regimes. Irrespective of the initial conditions of the input beam, the system evolves toward the same final state, which only depends on the system parameters, see Fig. 2 [7]. In particular, all-optical mode cleaning is also possible; see the A case in Fig. 2, which may represent an alternative to various

attempts to address randomization [8].

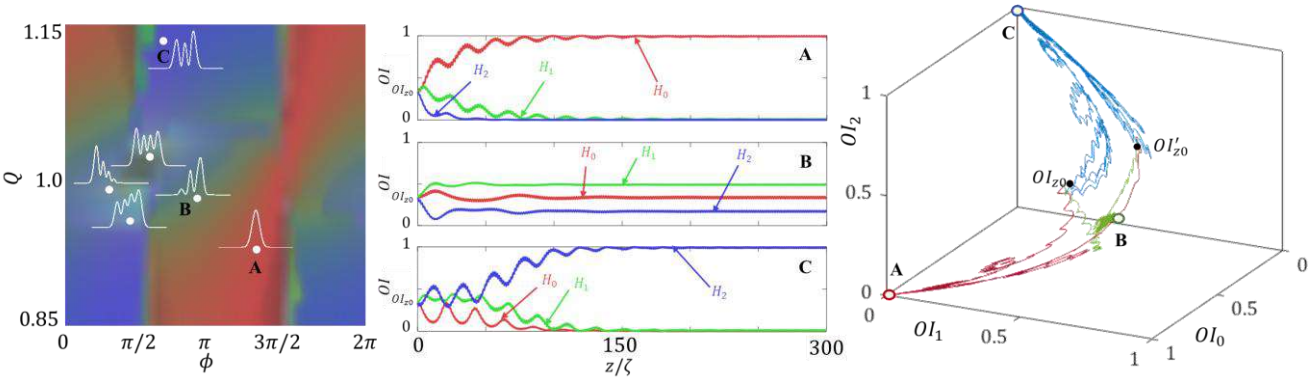

Figure 2. Left: Map of the participation of each mode into the final eigenmode, as a function of the wavenumber of the non-Hermitian normalized modulation $Q = q/\Delta\beta_N$ and phase ϕ for $m_{re} = m_{im} = 0.6$. Middle: Evolution of the participation, *OI*, of the first three modes, H_1, H_2, and H_3 along the modulated amplifier, distance normalized to the self-imaging period of the waveguide $\zeta=2\pi/\Delta\beta_N$. Right: Phase space evolution of *OI*, for two different initial conditions with mode relative intensity distributions, OI_{z0} and OI'_{z0}, being $OI_1 = OI_2 = OI_3 = 33.33\%$ and $OI'_1 = 6\%$, $OI'_2 = OI'_3 = 47\%$ for the above-mentioned modulations. The final states are labeled A, B, and C and marked with a circle corresponding to points the points shown on the map.

Exceptional points and large chirality in coupled photonic waveguides

Alice De Corte[1], Stefanos Fr. Koufidis[2], Martin W. McCall[2], and Bjorn Maes[1]

Abstract: In coupled waveguides, exceptional points can stem from the coupling of either counter-propagating modes or co-propagating modes. We utilize both methods, by implementing extreme chirality in a homogeneous waveguide, thereby realizing backward mode propagation, and by inserting a chiral material in the slot between waveguides exhibiting balanced gain and loss.

Exceptional points (EPs) are critical junctures in a system's parameter space where eigenvalues and eigenvectors coincide [1]. In waveguiding systems, EPs result in the convergence of multiple eigenmodes into a single mode, leading to remarkable dispersion relations nearby the merging point(s). In a photonic configuration comprising two coupled waveguides, EPs can be achieved in two main ways, using either counter-propagating modes or co-propagating modes. The first method relies on the coupling of a standard waveguide with one exhibiting negative phase velocity [1]. The second method utilizes non-Hermitian Hamiltonians, particularly those adhering to PT-symmetry, with conventional coupling between waveguides exhibiting balanced gain and loss [2]. Here, we harness giant values of chirality to achieve EPs using both approaches. First, we adopt Pendry's chiral route to negative refraction [3], coupling counter-propagating modes in waveguides made of homogeneous extremely chiral media [4]. Secondly, we alter the coupling between modes of PT-symmetric waveguides by varying the chirality of the material in the gap that separates them.

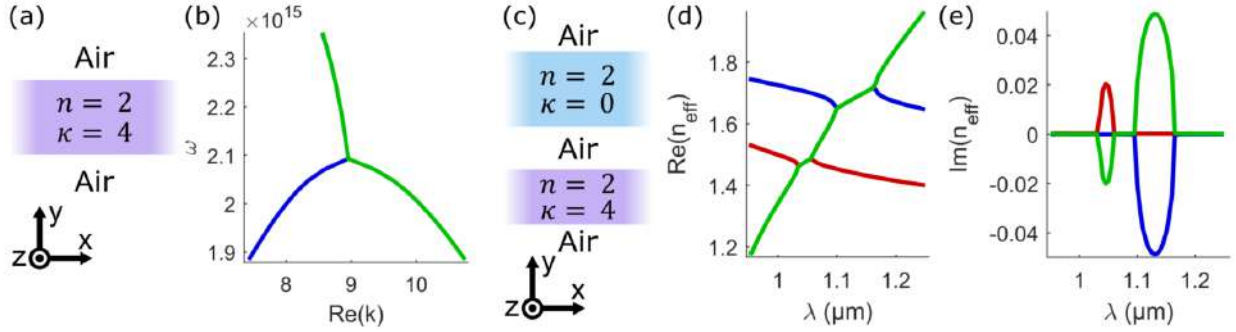

Figure 1. (a) Schematic of a 150nm thick chirowaveguide, with n = 2 and κ = 2n, embedded in vacuum, and (b) dispersion ω(k) of two of its modes. (c) Schematic of a 300nm thick dielectric slab coupled to a 130nm thick chirowaveguide, separated by 200nm, and (d) real and (e) imaginary parts of the effective indices of three modes [4].

Homogeneous chiral media, characterized by a chirality parameter κ, exhibit backward-propagating waves when their chirality reaches extreme values, i.e. $|\kappa| > n$, n being the medium's refractive index [4]. The phase velocity and power flow of these waves have opposite directions. Guided modes with these properties can be brought about in waveguides made of extremely chiral media, along with standard forward-propagating modes [4]. The interaction of counter-propagating modes, of great interest for EP generation, is numerically confirmed by simulating a single chiral slab surrounded by vacuum, as depicted in Fig. 1(a). A backward-propagating mode, characterized by a negative slope of ω(k) (green in Fig. 1(b)), couples with a forward-propagating mode (blue in

Fig. 1(b)) to create an EP ($\lambda \approx 900$ nm) and the signature "fork" dispersion of PT-symmetric structures. This coupling can also be observed between the counter-propagating modes of two distinct waveguides, one achiral and the other with giant chirality (Fig. 1(c)). Figs. 1(d,e) display the real and imaginary effective indices of two forward-propagating modes (blue and red) and one backward-propagating mode (green). Complex-index zones are brought about by the crossings of counter-propagating modes ($\lambda \approx 1.05\mu$m and 1.15 μm), with EPs at each end. The width and magnitude of these zones increase as the waveguide separation decreases, resulting in increased coupling, so that they can eventually merge.

EPs can also be achieved in PT-symmetric waveguides with balanced gain and loss. As the amount of gain and loss increase in the waveguides, controlled by a parameter γ, guided modes transition from a PT-symmetric regime with real effective indices to a PT-broken regime, with complex effective indices. The transition between these two regimes is the EP, that has previously been shown to be displaced by the introduction of chirality in the slot that separates these waveguides (configuration shown in Fig. 2(a)) [2]. We observe a similar behavior when chirality is increased to extreme values: the characteristic forks of PT-symmetric waveguides also appear for large chirality parameters κ, and their EPs are displaced as κ increases. For any κ, modes are PT-symmetric for small gain and loss ($\gamma < \gamma_{EP}$) and PT-broken beyond a gain-loss threshold ($\gamma > \gamma_{EP}$). For a fixed amount of gain and loss, this creates a succession of PT-symmetric and PT-broken regimes as κ varies (Figs. 2(b,c)).

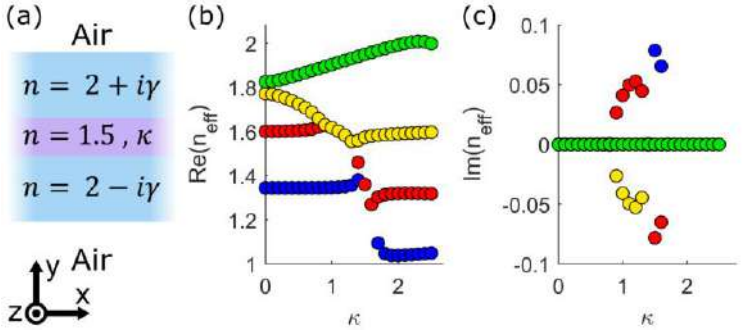

Figure 2. (a) Schematic of two 100nm thick achiral slab waveguides with gain and loss (2±iγ) separated by a 12nm thick chiral slab, and (b) real and (c) imaginary parts of the effective indices of four modes.

Meta-media advancements have enabled significant progress in accessing giant chiral values across various spectral realms [5], enabling giant controllable chirality. Utilizing these materials in coupled waveguide configurations provides an additional way of tailoring the mode dispersion, and in particular to manipulate the position of EPs, offering innovating perspectives for integrated photonics.

Abstract: We propose interpolating quantum channels to construct exceptional points. We show that a second-order exceptional point emerges by interpolating two quantum channels. Quantum circuits are constructed to verify the exceptional point on a nuclear magnetic resonance quantum computer. A classical metasurface simulation of the quantum channel will also be discussed.

Exceptional points (EPs), where eigenvalues and eigenvectors coalesce, are key signatures of non-Hermitian systems and have been demonstrated in a wide range of classical wave systems. While the origin of exceptional points dates back to parity-time (PT) symmetry and extensions of quantum mechanics, their realization in the quantum regime has only recently been demonstrated by considering the semi-classical Hamiltonian of quantum systems. Phase transitions and chiral state transfer around such EPs have been observed in trapped ions and cold atoms [1,2]. Furthermore, although semi-classical Hamiltonians can be probed using post-selection techniques, the full quantum dynamics of open quantum systems extends far beyond these approximations. For instance, decoherence and noise from a Markovian environment play a crucial role, necessitating the use of the Lindblad master equation. In this framework, EPs must be analyzed in terms of the eigenvalue and eigenvector degeneracy of the Liouvillian superoperator, which governs the evolution of the density matrix [3]. Quantum EPs have also been proposed in non-Markovian systems, where memory effects cannot be neglected and the dynamics deviate from standard Markovian descriptions [4].

Here, we pursue a systematic approach to constructing exceptional points (EPs) by interpolating quantum channels. As an example, we consider the interpolation of two single-qubit quantum channels, defined as

$$\mathcal{E} = (1-p)\mathcal{E}_1 + p\mathcal{E}_2,$$

where p is the probability of applying channel $\mathcal{E}_2$ and $1-p$ is the probability of applying channel $\mathcal{E}_1$. The resulting overall quantum channel $\mathcal{E}$ is completely positive and trace-preserving (CPTP), transforming an input 2×2 density matrix ρ into an output state ρ'. The two quantum channels $\mathcal{E}_1$ and $\mathcal{E}_2$ are expressed in Kraus representation using Pauli matrices as follows:

$$\mathcal{E}_1[\rho] = \frac{1}{2}\sqrt{\sigma_x}\rho\sqrt{\sigma_x}^{\dagger} + \frac{1}{4}\sigma_y\rho\sigma_y + \frac{1}{4}\sigma_z\rho\sigma_z,$$

$$\mathcal{E}_2[\rho] = \frac{1}{4}\rho + \frac{1}{4}\sigma_x\rho\sigma_x + \frac{1}{2}\sigma_y\rho\sigma_y.$$

These channels are specifically chosen so that $\mathcal{E}_2$ has purely real eigenvalues, representing the “symmetric” phase, while $\mathcal{E}_1$ has a complex conjugate pair of eigenvalues, representing the “broken” phase in conventional terminology. By interpolating between these two channels, which belong to different phases, a transition is enforced, ensuring that an exceptional point (EP) emerges at a certain value of p where both eigenvalues and eigenvectors coalesce.

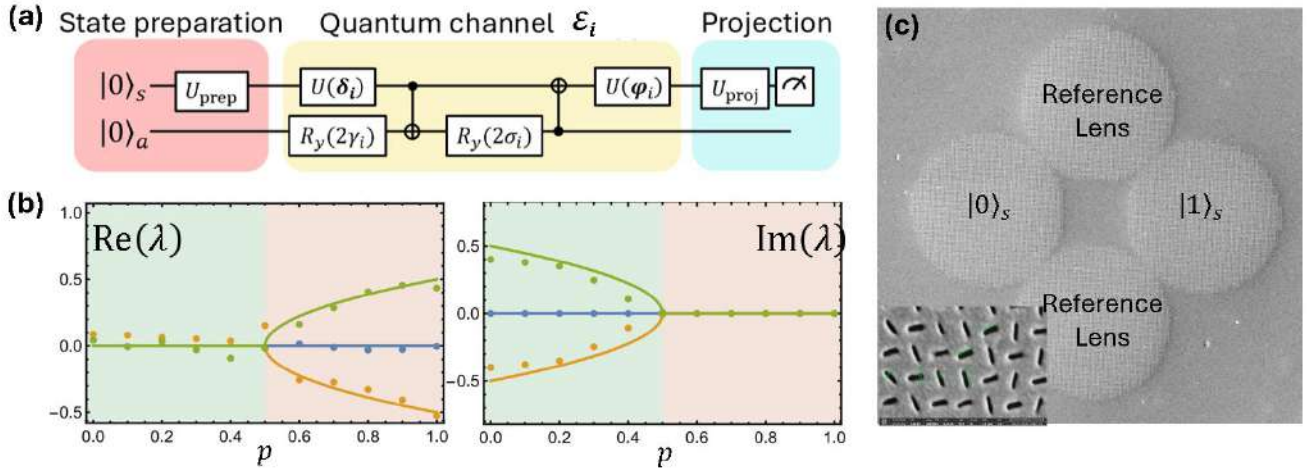

Figure 1 (a) Quantum circuit for the implementation of the single-qubit quantum channel (denoted with subscript s). A total of two qubits are used with one ancilla qubit (denoted with subscript a). The two quantum channels $\mathcal{E}_1$ and $\mathcal{E}_2$ are implemented in the middle block. The left and the right blocks contain unitary operations U_{prep} and U_{proj}, which are used for preparing different input states and projecting to different measurement bases to perform quantum process tomography. (b) Real and imaginary parts of the eigenvalues of the interpolated channel $\mathcal{E}$. Lines (symbols) are showing the model (experimental) results. (c) A metalens array for purely classical simulation of a quantum channel.

To verify our approach, we employ a two-qubit quantum computer (SpinQ) based on nuclear magnetic resonance (NMR) qubits, implementing the quantum channel with statistical averaging approach. Figure 1(a) illustrates the quantum circuit, which implements either $\mathcal{E}_1$ and $\mathcal{E}_2$ using CNOTs, rotations, and 1-qubit unitary operators for diagonalization. The quantum channel is applied to different input states, prepared by U_{prep}, while the output states are measured with different bases using U_{proj}, effectively carrying out quantum process tomography. The eigenvalues of the interpolated channel $\mathcal{E}$ are then plotted in Fig. 1(b) as symbols, with solid lines representing model predictions. A second-order EP is identified at $p = 0.5$. Only three eigenvalues are plotted while the forth eigenvalue remains 1 due to the trace-preserving property. While not shown here, generalizing to additional channels for interpolation results in higher-order EP structures. For instance, adding one more channel for interpolation can lead to the emergence of a third-order EP and an EP-line. Furthermore, our approach of interpolating quantum channels to obtain EPs can be straightforwardly extended to a larger number of qubits.

Finally, we also discuss a purely classical analog of such a quantum simulation, using a metalens array to simulate a one-qubit quantum channel. Figure 1(c) shows such a meta-lens array with two signal lenses in representing the two signal qubit states $|0\rangle_s$ and $|1\rangle_s$ while the reference lenses are for extracting complex transmission amplitudes for diffraction from the two signal lens into different directions through interferometry.

Abstract: Realizing photonic time crystals in optics requires imparting fast temporal modulations to nanostructures of finite spatial extent. We show that these systems exhibit cavity effects driven by resonant states, which dominate their exotic optical response. We present a general framework to calculate these eigenmodes, uncovering their underlying non-Hermitian physics.

In recent years, the exploration of photonic time crystals has captivated the metamaterials community, offering intriguing possibilities for controlling light through periodic temporal modulation of material properties. The latter gives rise to a momentum bandgap [1]. Inside the bandgap, there exists a solution of Maxwell's equations that parametrically amplifies light over time [2]. However, realistic optical implementations will require imparting temporal modulations in complex nanostructures. These spatially-structured photonic time crystals differ fundamentally from their bulk counterparts, with their behavior governed by optical resonances, as sketched in Fig.1(a) for the case of a dielectric slab. Resonant phenomena have been predicted to strongly influence and even decrease the modulation thresholds for the observation of light amplification [3]. Hence, there is an urgent need for a rigorous theory of resonances, that can guide the design of realistic photonic time crystals in the optical regime.

In static structures, it is well known that resonances are directly related to their resonant states (or quasinormal modes), i.e. source-free solutions of Maxwell's equations for outgoing waves and complex eigenfrequencies [4,5]. However, the physics of these eigenmodes in photonic time crystals has yet to be explored.

In this contribution, we will close this gap and present a resonant state theory of photonic time crystals of arbitrary geometry. Our formalism provides profound physical insights into their resonant properties and uncovers several key phenomena. We discover that, for an arbitrary periodic modulation, the original resonant states spawn an infinite number of "replicas", which correspond to new resonant states of the modulated system, manifesting as new resonances in the optical spectra. An example is shown in Fig.1(b) for the case of a time-modulated dielectric slab. It can be seen that, in addition to the conventional Fabry-Pérot resonance, new 'replica modes' emerge in the complex frequency spectrum.

Crucially, we also identify the inherently resonant mechanism behind parametric amplification in such structures, which cannot be explained using the momentum bandgap of bulk materials. We find that the latter occurs when the modulation induces one of the eigenfrequencies to cross the real axis, introducing gain. This can happen more easily for eigenfrequencies with small imaginary parts, for which we derive explicit design rules. For instance, Figure 1(c)-(d) shows the design of a parametric resonance in a realistic Bragg microcavity, sketched in Fig.1(d). Choosing a weakly radiative mode of the static structure as a starting point [Figure 1(c)], we quantitatively predict the formation of a parametric resonance for permittivity modulations of less than 0.16%. Due to its generality, we anticipate our framework will play a

Abstract: Bound states in the continuum and exceptional points are unique singularities of non-Hermitian systems. We demonstrate that multiple bound states in the continuum can merge into a single exceptional point, creating a novel kind of singularity. This state combines non-radiative behavior with extreme sensitivity, opening new prospects for nanoscale sensing.

Open systems inherently imply interaction with the surrounding space via the exchange of energy. They can be found in both classical and quantum systems, involving acoustical or optical waves [1]. A remarkable consequence of non-hermiticity is the emergence of *exceptional points* (EPs) in the eigenenergy spectra. EPs are spectral singularities where at least two eigenvectors and their associated eigenvalues coalesce [2]. In close proximity to an EP, the eigenvalues exhibit a strongly enhanced sensitivity to perturbations, making them prospective for nanophotonic sensing applications [2, 3].

Another type of singularities of open systems are *bound states in the continuum* (BICs). BICs are localized states that are embedded in the continuous spectrum of radiation modes, yet do not radiate away [4]. Nowadays, they are actively investigated in nanophotonics, owing to their remarkable ability to boost and fine-tune light-matter interactions [5].

Despite the intense attention received by the two kinds of singularities, an intriguing question has remained unanswered: *can two or more BICs coalesce into an EP?*.

We answer positively to this question and show, based on general principles, that perfect BICs can merge into a single EP, creating a novel kind of singularity, an "exceptional bound state in the continuum" (EP-BIC), that combines non-radiative behavior with extreme sensitivity [6].

In this contribution, we will provide general rules for their observation in nanophotonic systems. For instance, a simple design that supports EP-BICs is depicted in Fig. 1(a). We consider a stack of two dielectric metasurfaces supporting symmetry-protected BICs [6]. When changing the separation distance between the metasurfaces, the near field interaction between the BICs can be modified. Upon introducing a small amount of ohmic losses k in the top metasurface, an EP-BIC emerges at some critical separation [Fig. 1(b)]. Both theory (solid lines) and numerical simulations (grey dots) show excellent agreement. Near the EP-BIC, the fields of the two BICs become almost identical, as can be seen in the inset of Fig. 1(b). Moreover, they are still BICs, as no waves propagate out of the plane of the structure.

Upon breaking the in-plane symmetry of the bilayer metasurface [e.g. introducing an off-center hole of surface S_h, see Fig. 11(c)], EP-BICs, like conventional BICs, span quasi-BICs that can be probed from the far field. In stark contrast, however, we have found that the resulting quasi-BICs are much more sensitive to small perturbations. Fig. 1(c) plots a comparison between the changes in the decay rates (i.e. the losses) of a conventional BIC and EP-BICs with two and three coalescing BICs, respectively. It can be confirmed that the latter two have a much larger response to perturbations.

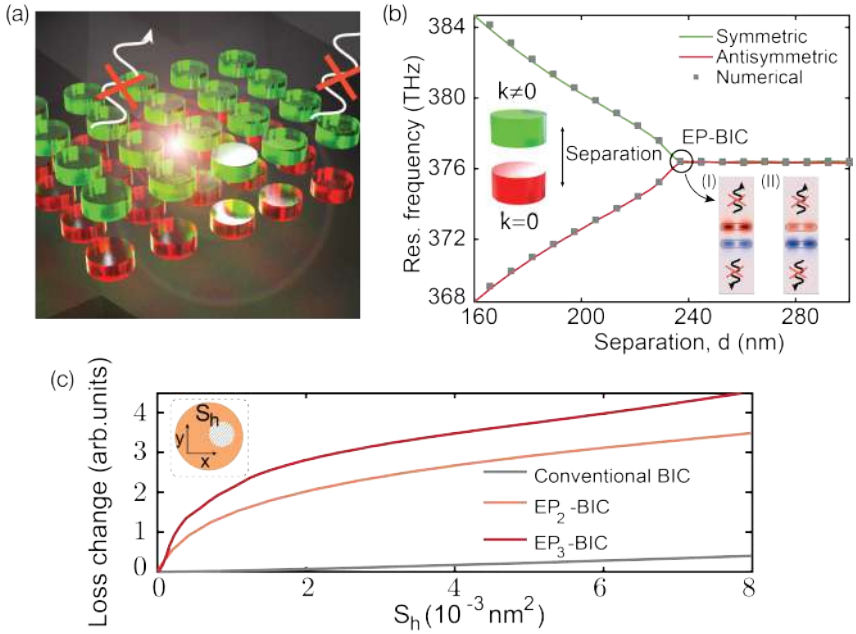

Figure 1: (a) Artistic representation of a bilayer metasurface supporting an exceptional bound state in the continuum. (b) Resonance frequencies of the BICs as a function of the separation between the two metasurfaces and field distributions of the BICs near the EP-BIC. (c) Comparison between the changes in the loss rates of a conventional BIC and EP-BICs of second (EP_2-BIC) and third order (EP_3-BIC) as a function of S_h (details in text). Inset: depiction of the perturbation.

In conclusion, we have shown that an arbitrary number of ideal BICs can coalesce into an EP, forming an EP-BIC, and validated our theoretical predictions with numerical simulations of a realistic bilayer metasurface operating in the visible. The new state inherits the properties of both singularities, as it does not radiate, but also becomes extremely sensitive to perturbations [6]. Therefore, besides their fundamental interest, EP-BICs are exciting candidates for the realization of EP sensors at the nanoscale.

Spherical representation of (anti-)parity-time states of Bragg gratings

Tianyi Hao,[1] Pavel Cheben,[1,3] Jens H. Schmid,[3] and Pierre Berini[1,2,4,*]

Abstract: Parity-time (PT) symmetry and anti-PT symmetry are two types of non-Hermitian Hamiltonian systems. Waveguide Bragg gratings with phase-shifted perturbations in real and imaginary refractive index can reach any (anti-)PT symmetry state. A spherical surface of the grating design space is proposed, illustrating (un)broken and exceptional point (anti-)PT symmetry states. Grating design examples are presented and discussed.

Non-Hermitian Hamiltonians have drawn vigorous interest in photonics [1]. A non-Hermitian Hamiltonian H is Parity-Time (PT) symmetric if it commutes with the PT operator [H,PT]=0, or anti-PT symmetric if it anti-commutes with the PT operator {H,PT}=0, where P is the parity operator and T is the time reversal operator [2, 3]. In an open system, the eigenvalues of H can be real or complex and the eigenvectors can merge or differ from those of the (anti-)PT operator. Eigen analysis determines the state of H as (Anti-)PT symmetric [1-3], or anyonic PT symmetric [4], with unbroken, broken or exceptional point (EP) states. Vortex beams [5], PT symmetric lasers [6], unidirectional reflection [7,8], coherent perfect absorption [9], and chiral polarizers [10] are applications that are realized in different PT states of an open system.

Consider a non-Hermitian Hamiltonian H, having complex eigenvalues, satisfying [4]:

$$\mathrm{PTH} = e^{2i\theta}\mathrm{HPT} \tag{1}$$

where θ is the phase of an eigenvalue. When $\theta = n\pi$ ($n \in \mathrm{Z}$), we have $\mathrm{PTH} = \mathrm{HPT}$ and the system is PT symmetric. When $\theta = n\pi \pm \pi/2$, we have $\mathrm{PTH} = -\mathrm{HPT}$ and the system is anti-PT symmetric. Cases where θ takes on other values correspond to non-Hermitian Hamiltonians that are neither PT symmetric nor anti-PT symmetric. A Bragg grating with gain and loss, and coupling between the forward and backward propagating modes, has a refractive index distribution $n(z)$ along the z (propagation) direction that can be written as [11]:

$$n(z) = n_{\mathrm{ave}} + \Delta n_r \sin\left(\frac{2\pi}{\Lambda} z\right) + \mathrm{j}\Delta n_{\mathrm{i}} \cos\left(\frac{2\pi}{\Lambda} z + \theta\right) \tag{2}$$

where n_{ave} is the average uniform complex refractive index, Δn_r and Δn_i are the strength of the real and imaginary index perturbations, Λ is the period of the grating, and θ is an additional phase offset between the real and imaginary index perturbations. Note that the real and imaginary perturbations have a $\pi/2$ phase shift for $\theta = 0$, and that θ is the same as in Eq. 1. n_{ave} and Λ satisfy $\Lambda = (m\lambda_B/|2n_{\mathrm{ave}}|)$ where m is the grating order, and λ_B is the Bragg wavelength. In Eq. 2, $\theta \in [0,\ 2\pi]$ (mod(2π)), the perturbation amplitudes Δn_r and Δn_i have the same period Λ, and n_{ave} determines the central (Bragg) wavelength of the grating. These parameters are independent of each other and can be used to define a spherical surface.

The general perturbation distribution implied by Eq. 2 can be represented by a sphere of radius $r = |n_{\mathrm{ave}}|$, azimuthal coordinate θ (identical to θ in Eqs. 1 and 2), and polar coordinate $\varphi = \mathrm{acos}(\Delta n_i - \Delta n_r)/(\Delta n_i +$

Δn_r), as sketched in Fig. 1 [11]. All possible (anti-)PT symmetric states can be illustrated on this sphere: the blue ring corresponds to anti-PT symmetric gratings ($\theta = n\pi \pm \pi/2$), whereas the yellow ring corresponds to PT symmetric gratings ($\theta = n\pi$). The northern hemisphere ($\varphi \in [0, \pi/2)$) has $\Delta n_r > \Delta n_\mathrm{i}$, which corresponds to symmetry unbroken states, whereas the southern hemisphere ($\varphi \in (\pi/2, \pi]$) corresponds to symmetry broken states with $\Delta n_r < \Delta n_\mathrm{i}$. The equatorial black ring corresponds to $\Delta n_r = \Delta n_\mathrm{i}$ and $\varphi = \pi/2$ indicating exceptional points that separate broken and unbroken states. The north pole ($\varphi = 0$) corresponds to $\Delta n_\mathrm{i} = 0$ which yield gratings with a real index perturbation, whereas gratings at the south pole ($\varphi = \pi$) have an imaginary index perturbation with $\Delta n_\mathrm{r} = 0$. The performance of gratings located at various points on this sphere will be discussed.

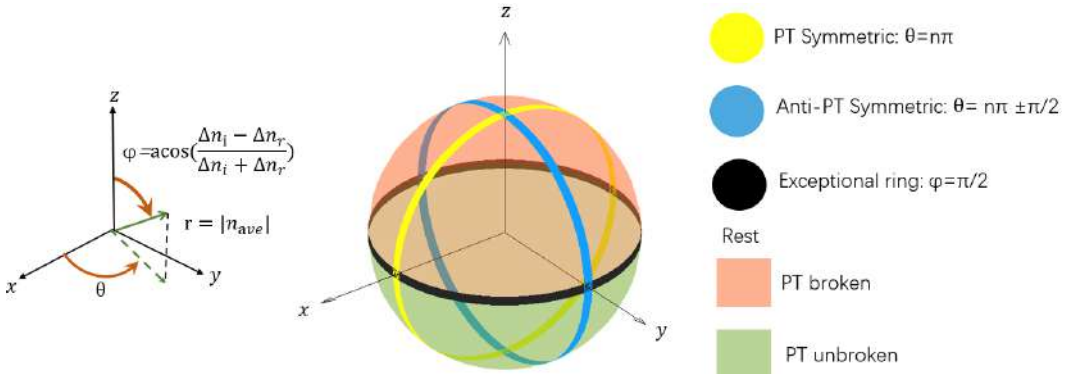

Fig. 1. Spherical representation of Eq. 2 with regions of the sphere identifying (anti-)PT symmetric states [11].

Abstract: Wireless power systems suffer from low efficiency and performance instability. Our system provides extended-range power transfer using the physics of parity-time symmetry and metamaterials, increasing transfer efficiency stability against distance fluctuations with the ability to localize the power from a larger transmitter to smaller size receiver.

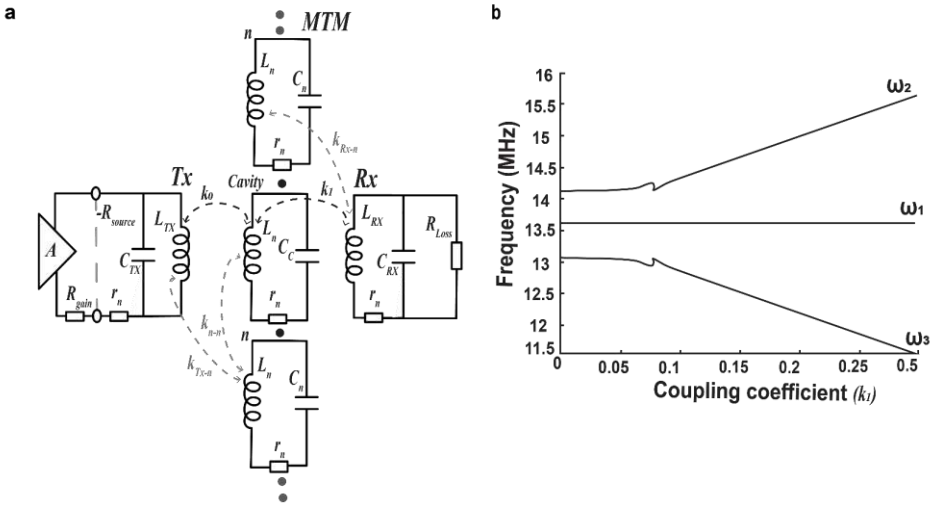

Figure 1. (a) Circuit schematic of Pseudo PT-WPT. (b) Real parts of eigenfrequencies for the field localized WPT Pseudo PT- WPT

systems have limitations in range, efficiency of transmission and Transmitter (Tx) to receiver (Rx) size ratio. This work proposes a stable and extended range wireless power transfer system utilizing parity-time symmetry (PT-symmetry) and electromagnetic metamaterials (MTM) to address these limitations. Our wireless power transfer system Pseudo PT-symmetry (PT) can be implemented in WPT systems by introducing a gain element into the circuit equivalent to the loss element. As shown in Fig.1(a), it is denoted as (-R), which is equivalent to load resistance (RL) [1]. The system can be modeled as the non Hermitian Hamiltonian as presented in equation (1). We adopt a pseudo-PT symmetric approach by making $g_1 = k_0^2\gamma/k_1^2 + \gamma_{s2}\gamma$ in our wireless power transfer system because it relaxes the strict requirement that the coupling coefficients between the transmitter and the cavity ($k0$) and between the cavity and the receiver ($k1$) must be equal[2]..

$$H = \begin{pmatrix} \omega_{\mathrm{Tx}} + ig & -ik_0 & 0 \\ -ik_0 & \omega_{\mathrm{Cav}} - i\gamma_{s2} & -ik_1 \\ 0 & -ik_1 & \omega_{\mathrm{Rx}} - i\gamma \end{pmatrix} \qquad (1)$$

$$\omega_1 = \omega_{\mathrm{Cav}},\ \omega_{2,3} = \omega_0 \pm \sqrt{k_{\mathrm{eff}}^2 - (g-\gamma)^2} \qquad (2)$$

The eigenvalues of equation (1) shows that such system supports three real eigen values as shown in Fig.1(a), and equation

(2), which makes it robust against fluctuations in coupling coefficient (k1). The inclusion of an electromagnetic metamaterial slab enables the system to transfer power effectively from a larger Transmitter (Tx) to smaller receiver (Rx). Fig.2(a), shows our metamaterial (MTM) that is made of Megahertz spiral resonators that each act as a unit cell, when arranged periodically the structure will behave as a metamaterial with the unique negative refractive index and by making a defect in the structure by tuning one of the unit cells to operate at a lower resonance frequency will make the structure to act as meta lens with hotspot that confines the field into one spot [3]. Electromagnetic wave simulations show that the metamaterial effectively confines the magnetic field (h-field), as shown in Fig. 2(c), surpassing the capabilities of the PT system without Metasurface. Measured results shows that our proposed wireless power transfer system posses stable and high efficiency compared to conventional wireless due to the inclusion of the field localization metamaterial and pseudo party time symmetry design conditions .

New Advances in Metamaterials and Their Functional Applications

Dynamical Manipulation of Terahertz Waves based on Moiré Metamaterials

Jin Zhang[1*], and Zhipei Sun[1]

[1]QTF Centre of Excellence, Department of Electronics and Nanoengineering, Aalto University, FI-02150 Espoo, Finland.

In recent years, moiré metamaterials have emerged as a fascinating and promising area of research, offering unique and unprecedented opportunities for controlling and manipulating electromagnetic waves. These artificially designed structures feature unit cells that are twisted or rotated relative to each other, leading to the emergence of novel properties and behaviors. Twisting introduces a new degree of freedom in the design of metamaterials, enabling the creation of complex and tunable responses that are unattainable with traditional designs. The properties of these materials can be finely tuned by adjusting the twist angle, providing a versatile platform for exploring new physical phenomena and developing advanced functional materials.

In this paper, we propose a bilayer graphene-based metamaterial for the tunable manipulation of THz waves. The structure, as depicted in Figure 1(a), consists of a moiré metamaterial. Figure 1(b) presents a zoomed-in view of the moiré metamaterial, which comprises, from bottom to top, a metallic back plate, a silicon substrate, a SiO_2 insulating layer, and two graphene strips with a mutual twist angle $\Delta\theta$. Figures 1(c) and 1(d) illustrate the graphene strips and the twisted layers with $\Delta\theta = 40°$, respectively, where the moiré patterns are clearly visible in the overlapped regions. Furthermore, the surface conductivity of graphene can be dynamically controlled by applying a bias voltage, thus enabling the manipulation of THz waves. When THz waves are normally illuminated on the surface of the moiré metamaterials, the simulated reflection spectra, shown in Figures 1(e) and 1(f), demonstrate the independent manipulation of amplitude and frequency.

This study sets up a new paradigm for tunable metamaterials, which is expected to find extensive applications in advanced THz device and communication system.

Abstract: we present two kinds of valley topological metamaterial with topological valley-locked waveguide sates (TVWSs) composed of local resonant meta-atoms or meta-molecules.The work frequency can be tuned by the geometry size of local resonant structures. Arraying the two structures together, the composite topological metamaterial can realize TVWSs in two bands.

Acoustic topology is a hot spot in recent year, because Acoustic topological insulator presents topological transport with defect immunity, backscattering immunity, and robust edge states.[1-4] Although some ATIs have been achieved by phononic crystals based on Bragg scattering, the narrow work frequency band related to the lattice constant limits their applications.[5-8] Acoustic metamaterials (AMs)[7-10] based on local resonance are another kind of candidate for the design of ATIs.[11, 12]

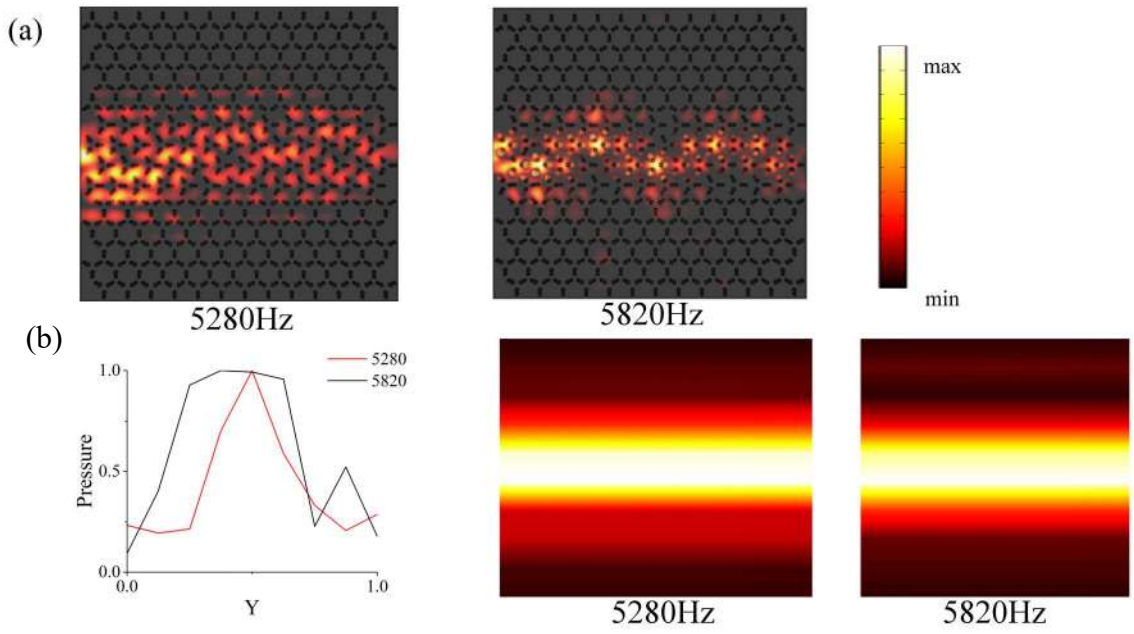

Fig. 1 (a) Simulated absolute acoustic pressure distributions of sample at frequencies of 5280 Hz and 5820 Hz . (b) Experimental measured sound pressure distribution and the corresponding sound pressure curve at the right end of sample.

In this paper, we create a structure consisting of three metamaterial sections that incorporate valley properties achieving the creation of topological waveguides states in two frequency bands with valley-locked modes. The simulation and experimental results show that the the energy will be transmitted in the wide

region without any reflections in two frequency ranges of 5280 Hz and 5820 Hz as shown in Fig. 1, which could have promising implications for manipulating acoustic waves and transmitting information effectively.

Optical near-field enhancement by metal particles at higher-order plasmon resonances

Sagar Sehrawat[1*] and Andriy Shevchenko[1]

[1]Department of Applied Physics, Aalto University, P.O. Box 13500, FI-00076 Aalto, Finland

Abstract: We demonstrate that higher-order plasmon resonances in small groups of metal nanoparticles or their arrays can significantly enhance optical near-fields, exceeding the most common dipole-induced enhancement. The finding is important for the development of new approaches to the design of plasmonic devices, such as plasmonic sensors and nonlinear optical components.

Metal nanoparticles showing plasmon resonances can confine and enhance optical fields at the nanoscale, resulting in a wide range of applications, e.g., in optical sensing, photocatalysis, surface enhanced Raman spectroscopy, and nonlinear optics. Usually, localized plasmon resonances are used to enhance optical near-fields via the electric-dipole excitations, and higher-order excitations are considered to be much weaker. However, we have recently shown that hybridization of multipole excitations of different orders can lead to both narrowband and bright light scattering by a pair of nanoparticles [1]. We have also found that a strong near-field enhancement can appear in the gap between two particles at a hybrid dipole-octupole resonance in a metal nanosphere dimer [2] or at a quadrupole-octupole resonance in a nanodisc trimer [3]. The effect is explained by the fact that higher-order multipole resonances are relatively dark, showing a higher Q-factor and a better field trapping than the electric dipole resonance. This effect can be further enhanced in an array of such particles by coupling their higher-order plasmon resonance to a lattice resonance of the structure.

In Fig. 1(a), the intensity enhancement spectrum of light in the gap between two silver nanospheres is shown by the black solid line and the spectrum of the excited electric current density around the gap by the blue dashed line. The silver dimer is shown in the inset. The radius of each sphere is 40 nm and the gap size is 7 nm. The incident field is polarized along the long axis of the dimer (x-axis). The curves are calculated numerically using the finite element method and the contributions of the multipole moments to the current density are obtained with the help of an electric-current multipole expansion. The octupole resonance (with

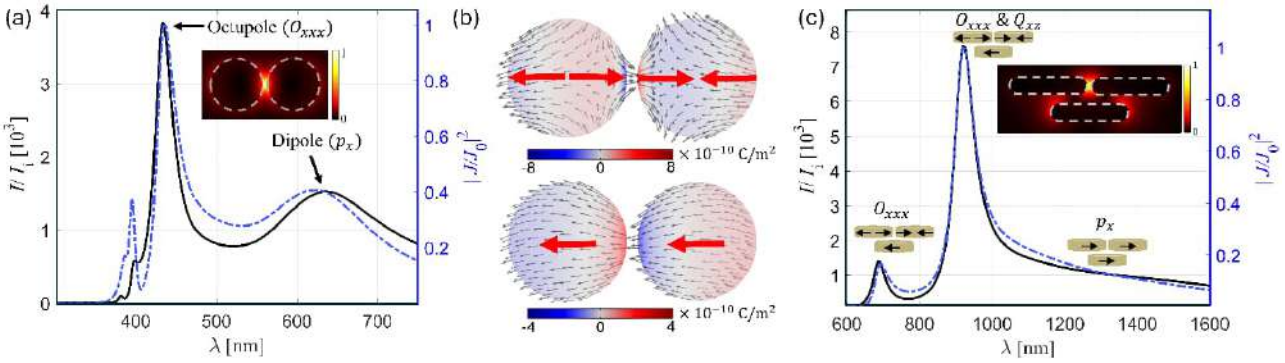

Figure 1: (a) Normalized spectra of the intensity enhancement (solid black line) and electric current density (dashed blue line) in the gap of a silver nanosphere dimer. The inset shows the field distribution at the octupole peak. (b) Electric charge density (color) and current density (logarithmic scale, arrows) on the dimer surface at the octupole (top) and dipole (bottom) resonances. (c) Normalized spectra of the intensity enhancement (solid black line) and current density (dashed blue line) in the gap of a gold disc trimer. The field profile around the trimer at the hybrid quadrupole-octupole resonance is shown in the inset.

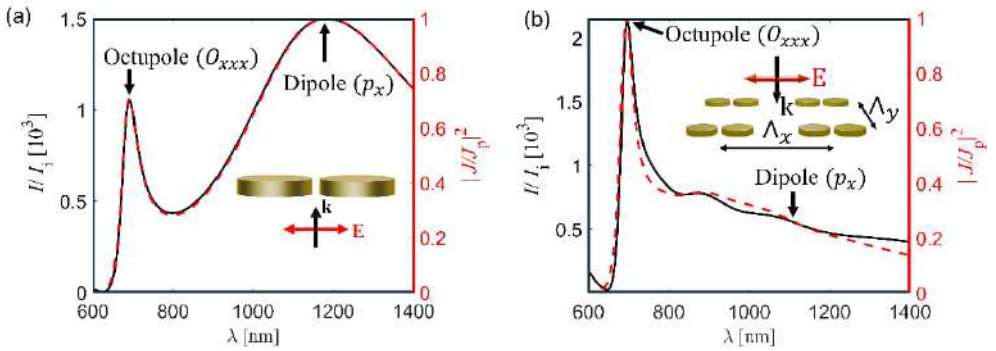

Figure 2: Normalized spectra of the near-field intensity enhancement (solid black line) and current density (dashed red line) in (a) an individual gold disc dimer and (b) a dimer in a periodic array. The periods of the array in the *x*- and *y*-directions are Λ_x = 430 nm and Λ_y = 300 nm (see the inset).

the octupole moment O_{xxx}) appears at a wavelength of 430 nm. The intensity enhancement peak associated with the electric dipole resonance at λ = 630 nm is seen to be wider and weaker than that of the octupole resonance. In Fig. 1(b), the charge and current densities at the octupole (top) and dipole (bottom) resonances are shown by the color and the arrows, respectively. Figure 1(c) shows the spectra of the near-field intensity enhancement and the associated electric current density for a gold nanodisc trimer in the inset. The most pronounced spectral peak (at λ = 920 nm) is associated with a hybrid quadrupole-octupole resonance of the structure (O_{xxx} and Q_{xz}). A lower enhancement is provided by a pure octupole resonance (O_{xxx}) at λ = 690 nm and a pure dipole excitation (p_x) at λ > 1200 nm.

The possibility to improve the higher-order near-field enhancement by arranging the particles in a periodic array or a metasurface is demonstrated in Fig. 2. The particles in this example are gold disc dimers. Each disc has a radius of 90 nm and the gap between the discs is 10 nm wide. The near-field enhancement spectra in the gap of an individual dimer and a dimer in an array are shown in Figs. 2(a) and 2(b), respectively. In the array, the octupole enhancement at $\lambda \approx 690$ nm is seen to be two times higher than that in an individual dimer, while the dipole enhancement at $\lambda \approx 1200$ nm appears to be lower. Hence, if both the near-field enhancement and the density of hotspots must be made high in an array of plasmonic particles, the higher-order multipole resonances could be a better option to deal with than the electric-dipole resonances.

In summary, we have demonstrated that higher-order plasmon resonances, which may be invisible in the optical scattering spectra, can lead to a significant near-field enhancement, exceeding that of conventionally used dipole resonances. This effect has been observed both in individual localized plasmonic structures and in an array of such structures. The finding may be useful in designing more efficient plasmonic devices.

Abstract: We propose a novel one-time pad encryption scheme based on optical metasurface ciphertext and dynamic visual keys. By utilizing metasurfaces for encoding ciphertext and spatial light modulators for dynamic key generation, the system ensures high security through randomness and variability, offering robust solutions for secure communication and data protection.

Securing sensitive information, particularly digital images, is increasingly challenging in today's rapidly evolving digital communications landscape. One-time pad (OTP) encryption is a historic encryption technique that offers information-theoretic security by using disposable keys that are discarded after each use [1,2]. Unlike other computational security methods, OTP encryption ensures that the ciphertext does not reveal any information about the plaintext or secret key, making it impervious to decryption even with unlimited computational resources. However, practical applications of OTP have faced logistical challenges, particularly in generating and securely storing truly random keys.

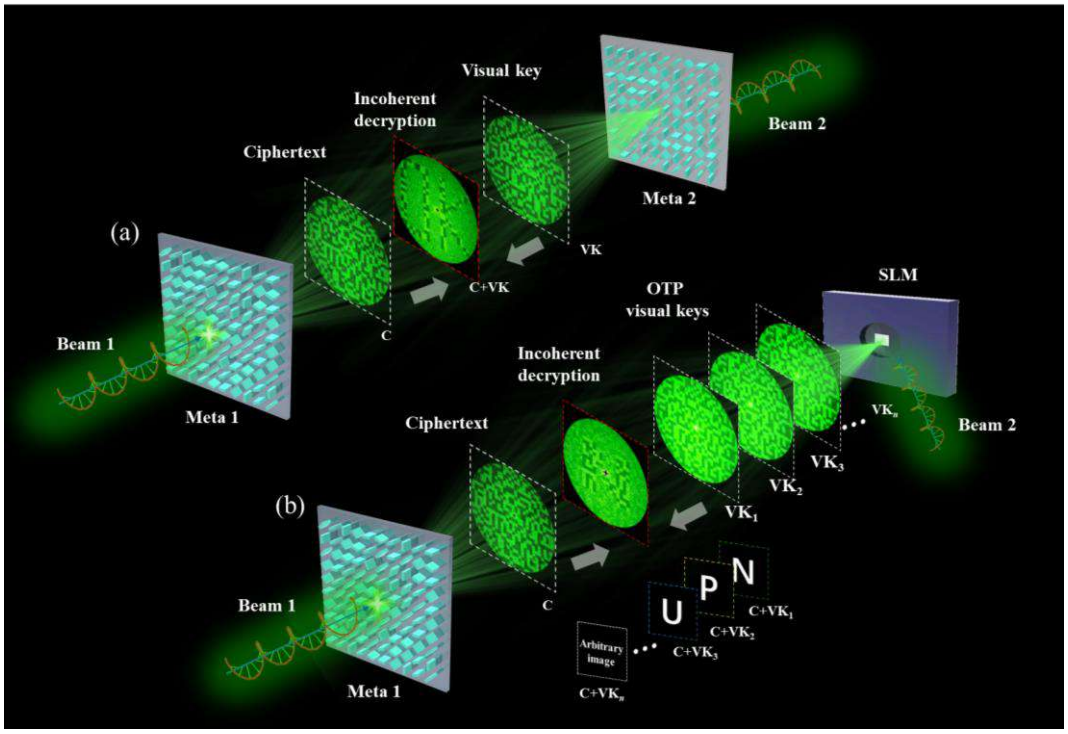

Figure 1. (a) Schematic diagram of the OTP incoherent encryption scheme with two metasurfaces. (b) Implementation of OTP incoherent encryption by integrating spatial light modulators with a metasurface.

To overcome these challenges, in this paper we developed a novel OTP incoherent encryption paradigm based on optical metasurface ciphertext and dynamic visual keys loaded on a spatial light modulator (SLM) [3]. Firstly, our work emphasizes the incoherent encryption scheme, which introduces spatial variations to disrupt signal coherence. This approach can mitigate potential vulnerabilities in coherent encryption methods, such as cascaded phase encryption, and prevent correlation attacks [4,5]. Figure 1(a) demonstrates that the original secret information can only be recovered when two metasurfaces are excited simultaneously, and the diffracted images are superimposed in an incoherent manner. Additionally, it exhibits greater tolerance to errors and instability in optical systems. This incoherent encryption strategy is more stable and robust against variations or disturbances in the optical setup compared to coherent encryption methods, which rely on precise phase control.

On the other hand, in this work, traditional static keys are replaced by dynamically generated keys in real-time, ensuring that each encryption session operates with a unique cryptographic foundation. This innovation eliminates the vulnerabilities associated with fixed-key systems and paves the way for a true OTP encryption paradigm. Figure 1(b) demonstrates how dynamically changing the visual keys in real-time using the SLM achieves a true OTP encryption mechanism. This adaptation of the visual key, combined with the security provided by metasurface, adds a new dimension to the security paradigm. By integrating OTP encryption with optical metasurface technologies, we offer practical solutions to combat evolving threats in data security, especially in image communication systems.

Abstract: We demonstrate ultrafast, coherent manipulation of valley-selective nonlinear optics in monolayer molybdenum disulfide through time-reversal symmetry breaking via Floquet engineering.

Engineering symmetry breaking in 2D layered materials plays a critical role in their macroscopic electrical, optical, magnetic and topological properties. In our work, we leverage Floquet engineering to break the time-reversal symmetry in monolayer transition metal dichalcogenide and realize distinct valley-selective nonlinear optics for the first time without the need for a magnetic field. This work presents an innovative departure from conventional approaches. After, we demonstrate an all-optical method for engineering the time-reversal symmetry via chirality and intensity for manipulating the valley degree of freedom, which is useful for ultrafast nonlinear valleytronics and advancing information technology.

In brief, our work contains the following two insightful advances, which offer a completely new strategy for potential valleytronics applications at lifted temperatures.

(1) New optical nonlinearity modulation mechanism. We propose and demonstrate an ultrafast optical nonlinearity modulation through the breaking of time-reversal symmetry via Floquet engineering. By changing the pump photon intensity and chirality, we can realize valley-selective modulation depths. This modulation mechanism combining valleytronics and Floquet states is fundamentally different from the previously reported photocarrier-assisted optical modulation methods, it is inherently resistant to photoexcited excitons and intervalley scattering and thus holds the potential to detect and manipulate the quantum properties (e.g., valley) of low-dimensional materials.

(2) Ultrafast all-optical method for the time-reversal symmetry breaking in nanomaterials. By utilizing sub-bandgap circularly polarized ultrafast optical pulses, we demonstrate the time-reversal symmetry breaking, originating from the synergistic effect of the optical Stark shift and Bloch-Siegert shift induced coherent energy shifts in the K and K' valleys, with transient second-harmonic generation on a femtosecond timescale limited solely by the pump pulse duration. It underscores the possibility of ultrafast all-optical valleytronics.

Relaxing symmetry constraints and enhancing robustness of photonic bound states in the continuum

H. Bai[1*], A. Shevchenko[1], and R. Kolkowski[1]
[1]Department of Applied Physics, Aalto University, Finland
huayu.bai@aalto.fi (corresponding author)

Abstract

We present new approaches to enhance robustness and flexibility of photonic bound states in the continuum (BICs) for practical applications. Our methods allow BICs to exist in structures with lower symmetry and provide significant enhancement of the quality factor around BICs across a wide range of parameter values.

Efficient confinement of light in resonant photonic structures is essential for many applications. Optical bound states in the continuum (BICs) have emerged as a fascinating concept that enables such confinement by means of destructive interference of the outgoing radiation in the far-field. The quality (Q) factor of BICs is theoretically infinite, which makes them highly attractive for many applications, e.g., in narrowband lasers, spectral sensors, and nonlinear frequency converters. Despite this, however, realizing BICs with ultrahigh Q factors in practical structures remains difficult. One of the challenges arises from the fact that the existence of some BICs is strongly dependent on the symmetry of the structure. Another issue is the need for ultrafine tuning of the geometric parameters, e.g., to achieve merging of several BICs and increase the Q factor in their vicinity. Relaxing these constraints could unlock the true potential of BICs for practical applications. Here, we present new approaches that can be used to improve the flexibility and robustness of BICs in planar periodic structures, such as photonic crystals and metasurfaces.

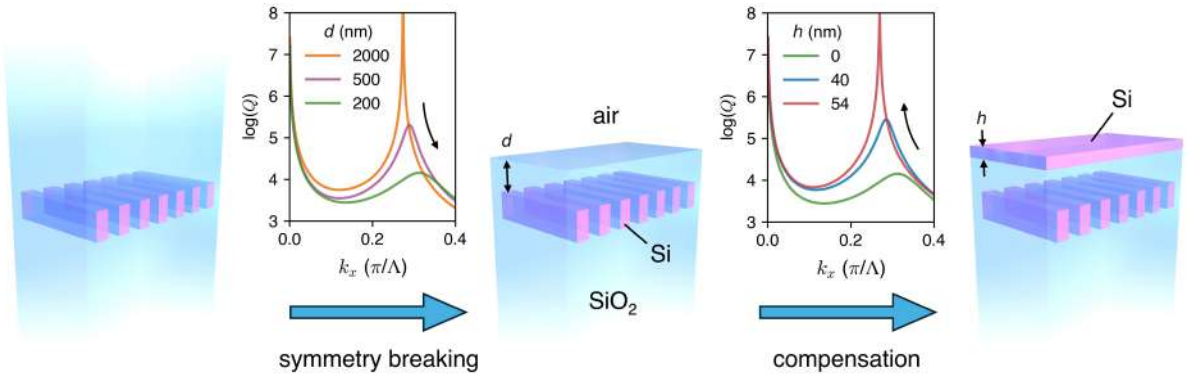

Figure 1: Restoring an off-Γ-point accidental BIC in a periodic structure with broken up-down mirror symmetry. The structure is a one-dimensional periodic silicon grating embedded in glass, as illustrated by the graphics. First, the symmetry of the grating is broken by an interface positioned at a distance d from the structure, which drastically reduces the Q factor. Next, the asymmetry is compensated for by placing an additional layer of height h on top of the interface, restoring the BIC with a diverging Q factor.

The results presented in Fig. 1 demonstrate that accidental (off-Γ) BICs can exist in structures with broken up-down mirror symmetry. It is shown that the BIC can be restored by compensating for the asymmetry using an additional dielectric layer on one side of the structure.

We have recently found that such a restored accidental BIC can be merged with a Γ-point BIC, demonstrating the possibility of realizing ultrahigh-Q merged BICs in asymmetric structures [1], such as structures fabricated on a substrate. This provides access to the BIC's near-fields that can be used, e.g., for optical sensing applications.

We have also discovered that accidental BICs can have bent trajectories in the parameter space (see Fig. 2, left). This finding allowed us to develop a method to obtain a new type of merging BICs with superior robustness to variations of the geometrical parameters [2]. In particular, we have shown that bringing the turning point of the BIC trajectory close to the Γ point gives rise to a significant enhancement of the Q factor over an exceptionally wide range of parameter values (see Fig. 2, right). Enhancing the Q factor over a wide range in the parameter space is especially important in practical finite-size structures, in which the photonic modes become discrete and can couple to one another. Our approach allows the Q factor of all these modes to be boosted simultaneously, providing a way to achieve superior performance for practical optical devices.

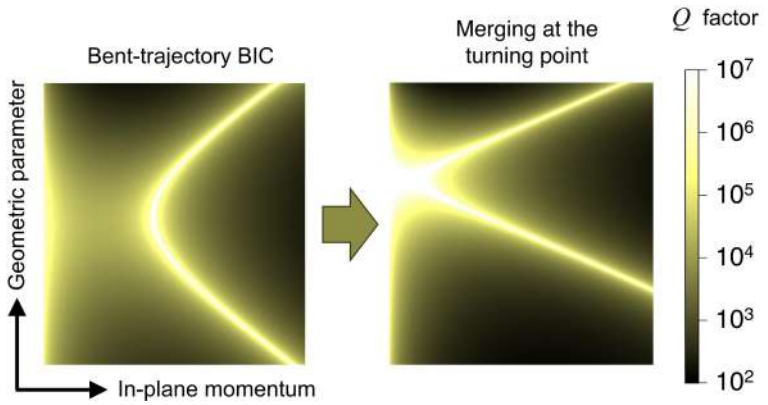

Figure 2: Distribution of Q factor across the parameter space, spanned by the in-plane momentum and one of the geometric parameters, for a guided-mode resonance in a periodic structure similar to that illustrated in Fig. 1. The distribution reveals an accidental BIC with a locally bent trajectory (on the left) and its merging with a symmetry-protected Γ-point BIC at the turning point of the trajectory (on the right).

In general, our approaches can be used to increase the flexibility of BIC-supporting structures and their tolerance to structural imperfections, bringing BICs closer to practical use. One of the next goals of our ongoing research is to experimentally demonstrate the performance of the designed BICs in enhancing nonlinear optical phenomena.

Anomalous Reflection Multifunctional Metagrating

Yahong Liu[1*], Wenyu Gao[1] Xin Zhou[2], Peng Li[1]

[1] School of Physical Science and Technology, Northwestern Polytechnical University, Xi'an 710129, China

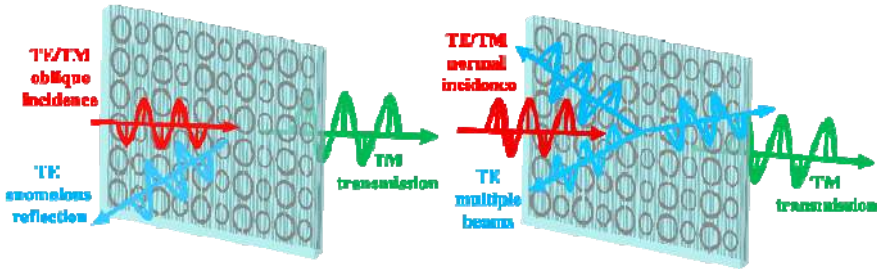
Abstract: We design a multifunctional metagrating that can maintain high efficiency in an incident angle range of 10°-60° in a broadband frequency range. The unit cell of the metagrating consists of two metal rings, which exhibits a π phase difference and can shut down the 0th order diffraction mode. Therefore, only the -1st order anomalous reflection can be achieved under oblique incidence conditions. Simulated and experimental results demonstrate that the proposed metagrating can achieve anomalous reflection at broadband and large angles. Furthermore, a multifunctional metagrating can be implemented by redesigning the metal rings, which has various functions of anomalous reflection, polarization selection, and multi-beam generation.



In recent years, metagratings have been proposed to realize diverse phenomena and achieve unitary efficiency beam steering, which have attracted considerable attention [1-4]. The emergence of metagratings based on dielectric rods and capacitive load wires have been feasible. However, these metagratings are not suitable for physical implementation since most of them are unrealistically suspended in free space above a ground plane. Here, we design metagratings based on printed circuit board, which has the functions of anomalous reflection, polarization selection, and multi-beam generation.

Figure 1(a) shows the redesigned bipartite unit cell of the proposed metagrating. Figure 1(b) displays the fabricated multifunctional metagrating. Figures 2(a)and 2(b) present the schematic diagram of the multifunctional metagrating for different polarizations under oblique incidence and normal incidence, respectively. As a TE-polarized wave is obliquely incident into the metagrating, the metal grids behave similarly to a complete metal plate, thereby preserving the anomalous reflection function. As shown in Figure 2(b), multi beams can be generated by the metagrating. Therefore, TE-polarized waves under normal incidence can be divided into three beams, whereas TM-polarized waves can perfectly transmit through the multifunctional metagrating.

(a) (b)

Fig. 2 Schematic diagram of the multifunctional metagrating under (a) oblique incidence and (b) normal incidence.

Figure 3(a) demonstrates the anomalous reflection of the TE wave under different frequencies. Figure 3(b) exhibits the transmission magnitude of TM-polarized wave under different incident angles, which indicates that the TM-polarized wave can completely transmit through the metagrating. Figure 3(c) illustrates the simulated and measured multi beams, which shows this metagrating can split a normally incident TE-polarized wave into three beams within the frequency range of 13 – 15 GHz. The multifunctional metagrating offers a richer range of beam steering capabilities and making it highly valuable for appliactions.

Abstract: A beam embedded with electrorheological fluids is designed, whose bending stiffness can be adjusted by an electric field, thereby the direction of buckling can be controlled. Based on this, an electric field-reconfigurable mechanical metamaterial is designed, whose Poisson's ratio can switch between positive and negative by regulating the electric field.

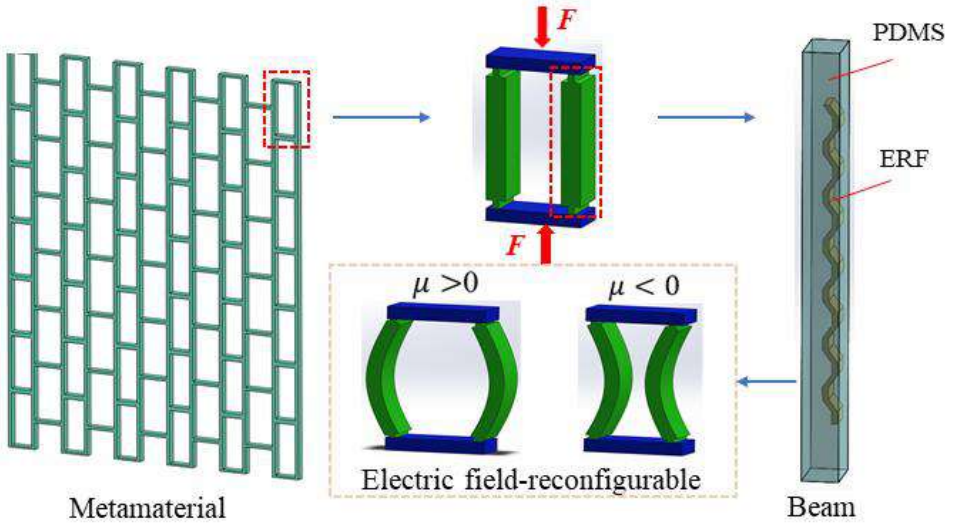

Figure 1. Schematic diagram of electric field-reconfigurable mechanical metamaterial. By regulating the properties of electrorheological fluids (ERF) through electric fields, the bending direction of asymmetric beams can be adjusted, thus the Poisson's ratio of metamaterials can be switched.

Abstract: We leverage the symmetry of optimized disorders to enable near-perfect broadband transmission. Utilizing coupled dipole approximation, we strategically position dielectric and metallic cylinders within multimode waveguides to realize reflectionless exceptional points, broadband single-mode transmission, and near-perfect transmission around a barrier. Numerical results are verified with measurements in the microwave range.

Metastructures can effectively control light propagation due to their unique properties, which are absent in traditional materials [1]. However, many of these distinctive features emerge only at specific frequencies, limiting their applicability in technologies that require broadband transmission [1]. While perfect transmission through random media can be achieved at single frequencies by shaping an incident wavefront or adding anti-reflection structures [2], a striking feature of mirror-symmetric disordered systems is that the constructive interference of symmetric paths can enhance transmission across broad frequency bands. Symmetrically designed quantum dots improve transmission through a tunnel barrier [3], while placing disorder symmetrically on both sides of an opaque barrier can also enhance transmission [4]. In this work, we optimize such disordered metastructures to achieve near-perfect transmission over wide frequency ranges.

We simulate the scattering matrix corresponding to Teflon and Aluminum cylinders placed within a multimode waveguide (see Figure 1 (a)) using the Coupled Dipole Approximation (CDA) [5]. Each dielectric and metallic cylinder is modeled with a collection of dipoles. The application of CDA and mirror symmetry allows a fast and efficient optimization method. The position of the cylinders is optimized using ADAM, an algorithm for first-order gradient-based optimization.

We first optimize broadband transmission of a single mode (here the first waveguide mode) through the waveguide. The result exhibits broadband near-perfect transmission with an excellent agreement between the estimation by CDA and the simulation from commercial Finite Element Method (FEM) software (see Figure 1 (b)). Also, we show the possibility to suppress the unwanted signal at some frequencies in addition to maximizing the transmission within a certain frequency range via symmetric metastructures. It can be observed from Figure 1 (c) illustrating the results of a band-pass filter made to maximize transmission of the second mode between 6.9 GHz and 7.1 GHz and suppress the transmission out of this bandwidth. The last case considered in this work was to increase the transmission in the waveguide which was initially blocked by a steel barrier placed in the middle of the sample to below 0.3 at 7 GHz. As can be seen from Figure 1 (d), the transmission of the first waveguide mode is significantly enhanced between 6.65 GHz and 7.35 GHz by introducing symmetric disorders around the barrier. These optimization results are then confirmed with measurements of the transmission matrix through the multimode waveguide.

In conclusion, near-perfect broadband transmission, near-perfect band-pass filtering and increasing the

broadband transmission around the steel barrier has been achieved by a fast single-mode optimization technique applying Coupled Dipole Approximation (CDA) and mirror symmetry of the metastructures. The outcomes of this work can be used to discover more properties of symmetric metastructures for the enhancement of data transmission over wide frequency ranges.

Abstract: We present a novel approach that allows to retrieve a reflection matrix in a single-input single-output configuration by using a reconfigurable intelligent metasurface (RIS). The system can be modeled as if the RIS was an array of antenna, opening exciting perspectives in the context of imaging and wave control.

Single-pixel imaging consists in illuminating a scene with random patterns and measuring the corresponding output with a single sensor. Compressed sensing techniques then allow to obtain an image from this set of outputs [1, 2]. This technology is particularly valuable in the microwave regime, in which arrays made of $N \gg 1$ antennas are very expensive, whereas random illuminations patterns can be generated using reconfigurable intelligent metasurfaces (RISs). RISs are now used in a wide range of applications since they allow shaping the electromagnetic field propagating in an environment [3].

With all its strengths, single-pixel imaging suffers from the same limitations as conventional imaging: it assumes that the scene is constituted of scatterers in free space interacting once with the incoming wave, and is therefore highly sensitive to multiple scattering and aberrations. On the other hand, reflection matrices have proved to be extremely powerful tools to tackle these challenges [4, 5]. In the following, we present an approach that allows to retrieve a reflection matrix using a single antenna and a RIS, effectively combining single-pixel imaging and matrix imaging in a single-input single-output configuration.

We consider the imaging geometry illustrated in Fig. 1: an antenna illuminates the RIS, the wave is reflected toward the scattering scene which then bounces back on the RIS again and

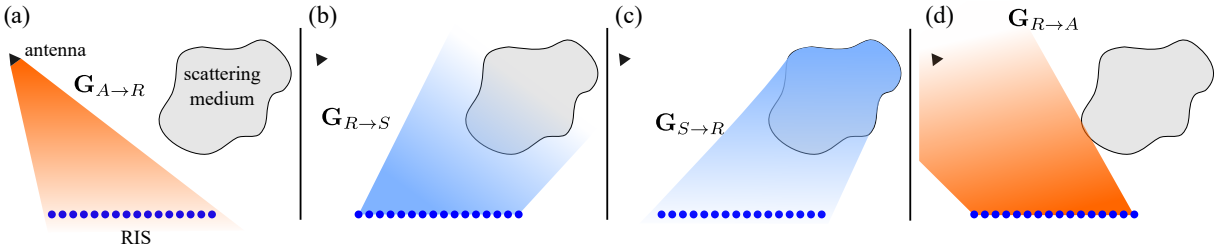

Figure 1: Schematic of the procedure. (a) The antenna illuminates the RIS, the propagation can be described by the Green's function $\mathbf{G}_{A\to R}$. (b) The wave then bounces from the metasurface (the latter being in a random configuration) and propagates toward the scattering medium to image through $\mathbf{G}_{R\to S}$. (c) The medium reflects the wave back to the metasurface, and finally (d) the field is measured at the antenna.

is measured at the antenna. Note here that we consider that there is no path that interacts only once with the RIS (such as antenna - RIS - scene - antenna). The field at the antenna is measured for many random RIS patterns and can be written as:

$$\Psi = \Psi_0 + \mathbf{G}_{A\to R}\mathbf{\Gamma}_R\mathbf{G}_{R\to A} + \mathbf{G}_{A\to R}\mathbf{\Gamma}_R\mathbf{R}\mathbf{\Gamma}_R\mathbf{G}_{R\to A}, \tag{1}$$

where $\mathbf{G}_{i\to j}$ is the Green's function corresponding to the propagation from i to j, $\mathbf{\Gamma}_R$ represents the matrix reflectivity of the RIS, and Ψ_0 is a constant offset across all RIS configurations. Since we will consider only linear media we have $\mathbf{G}_{i\to j} = \mathbf{G}^T_{j\to i}$. The second term in Eq. (1) corresponds to the signal received by the antenna after being reflected on the RIS without interacting with the scene. Our goal is to retrieve the reflection matrix in the basis of the RIS $\mathbf{R}$ in order to be able to reconstruct an image of the system.

Eq. (1) corresponds to the well-known coupled-dipole model [6, 7], which has been shown to capture the essential physics to correctly predict the RIS configuration for focusing at a desired location [9] and to extract the relevant Green's functions of the system [9]. We use a stochastic gradient optimization scheme in order to estimate all parameters appearing in Eq. (1). In particular, we are capable to extract the reflection matrix of the scene in the basis of the RIS $\hat{\mathbf{R}} \simeq \mathbf{R}$ for a sparse scene constituted of strong reflectors. The singular value decomposition of this matrix directly gives the focusing law from the RIS to the different scatterers of the scene, and an image can be reconstructed by assuming free space propagation. We will show simulations and experimental results as proof-of-concept, paving the way for more sophisticated imaging and focusing techniques in the future.

Abstract: In this study, we exploit surface electromagnetic localized states in one-dimensional periodic dielectric structures (photonic crystals, 1DPCs) to develop an advanced spectroscopic technique in the Mid-IR range. This approach introduces new *degrees of freedom* for molecular sensing, offering innovative solutions to critical challenges in chemical detection and materials science.

The label-free identification of molecules is essential for biological or material science purposes. In the visible range, surface plasmon polaritons (SPPs) on gold surfaces are widely used for sensing due to their strong field confinement. However, in the Mid-Infrared (Mid-IR, $\lambda \sim 2{-}20$ μm), where vibrational absorption provides critical insights into protein structure, SPPs become less effective due to weaker confinement at longer wavelengths. Alternative approaches include SPPs supported by doped semiconductors or graphene, hybrid polaritonic modes such as phonon polaritons, and surface-enhanced infrared absorption (SEIRA) using resonant nanoantennas [1].

Another promising approach involves photonic crystals (PCs), which offer tailored electromagnetic field distributions through refractive index modulation. Truncated one-dimensional photonic crystals (1DPCs) can sustain Bloch surface waves (BSWs), which share similarities with SPPs but have lower losses and sharper resonances. BSWs in 1DPCs can be engineered for mid-IR applications, making them highly suitable for sensing.

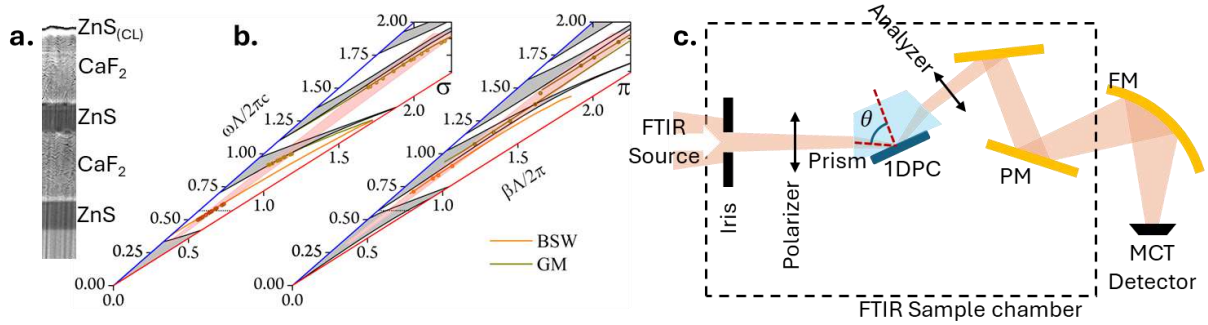

Figure 1. a) SEM image of the fabricated 1DPC. b) Photonic states between the prism (red) and the vacuum (blue) dispersion curves. In grey the permitted states in the 1DPC, in orange and in yellow the BSW and the guided modes (GMs) dispersion curves. c) Scheme of the experimental setup (focusing, FM, and plane, PM, mirrors).

In this work, our multilayer structure has been optimized to maximize the BSW bandwidth up to the maximum value achievable for a 1DPC on a CaF_2 substrate [2]. For the fabrication of the 1DPC sustaining BSW in the Mid-IR range, we chose CaF_2 and ZnS as the low-index and high-index materials for the stack layers, respectively (fig.

1a). The multilayer stack characterized by a periodical refractive index function shows the opening of photonic band gaps where the light cannot propagate (fig. 1b, photonic states between the prism, red, and the vacuum, blue, dispersion curves).

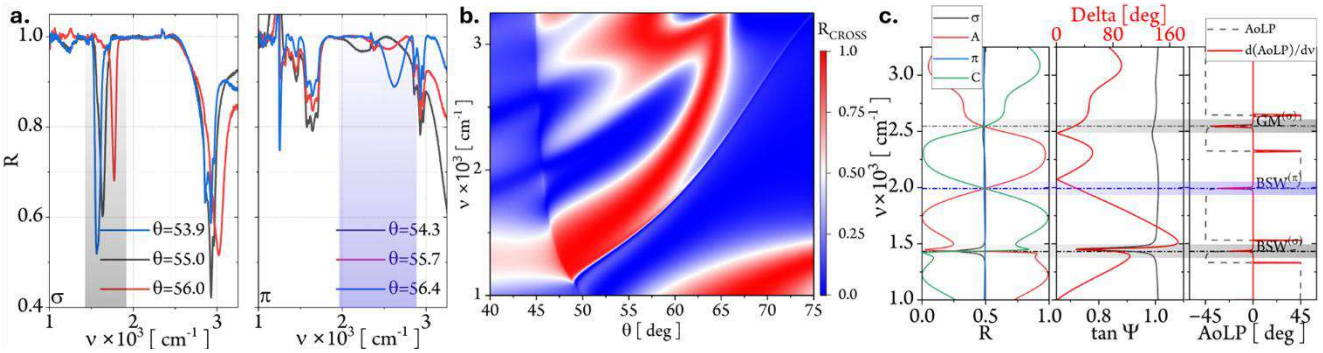

Figure 2. a) σ and π polarized reflectance. b) Calculated reflectance map in Cross configuration. c) Reflectance spectra (R) obtained for four different values of ϕ_A and θ equal to 55 deg. 1DPC complex reflectance ρ (tan(Ψ) and Δ). AoLP and its derivative (d(AoLP)/dv).

We thoroughly characterized the 1DPC in Mid-IR by means of Fourier-transform infrared spectroscopy (FTIR) in both the σ (transverse electric) and π (transverse magnetic) polarizations [2]. The BSWs spectral features were measured under TIR conditions with a custom variable-incidence angle set-up built into the FTIR sample compartment (see fig. 1c). Based on the experimental results in fig. 2a, we compare the performance of Mid-IR sensors based on SPP with the BSW-based sensor [2]. The figures of merit (FoM) found for BSWs put them as forefront runners for label-free and polarization-dependent sensing devices.

Notably, the designed 1DPC supports both σ and π-BSW polarized waves, whereas SPPs are limited to π-polarized waves [2,3]. This polarization versatility allows for real-time monitoring of molecular conformational changes under varying external conditions, enhancing their potential for ellipsometric sensing in the Mid-IR range. Figure 2b presents the calculated reflectance map (R) for the crossed configuration, where the input polarization is fixed at 45°, and the analyzer angle (ϕ_A) is set to -45°. Meanwhile, Figure 2c illustrates the reflectance spectra (R) at an incidence angle (θ) of 55°, considering four different values of ϕ_A: 0° (σ), 45° (aligned, A), 90° (π), and 135° (crossed, C) configurations. Finally, the complex reflectance (ρ) and the angle of linear polarization (AoLP) can be determined using the following expressions:

$$\rho = \left|\frac{r_\pi}{r_\sigma}\right| e^{i \cdot arg\left(-\frac{r_\pi}{r_\sigma}\right)} = tan\,\Psi\, e^{i\Delta} \qquad AoLP = \frac{1}{2} atan\left[\frac{S_2}{S_1}\right] \qquad (1)$$

where $r_{\pi,\sigma}$ and S are the reflection coefficients for the σ and the π polarizations and the Stokes parameters, respectively. Although preliminary, our approach could lead to the development of innovative sensors enhancing the capabilities of mid-IR ellipsometry by utilizing BSWs on 1DPCs.

Abstract: Bound states in the continuum (BICs) are exotic optical states, enabling lasing with hidden topological properties in momentum space. We theoretically and experimentally demonstrate the inherent spin-orbit locking in topological BIC lasing, opening new possibilities for topological photonic sources.

Bound states in the continuum (BICs) have emerged as a fascinating phenomenon in modern photonics, characterized by their unique ability to remain perfectly confined within the continuum of radiative modes while exhibiting infinite quality factors. These states, which manifest as topological optical singularities, have particularly intriguing properties in periodic structures such as photonic crystal (PhC) slabs, where they carry complex topological polarization vortices in momentum space. Carrying various topological configurations, BICs have been found to exhibit diverse spin-orbit properties in resonant optical systems. Meanwhile, BICs have also been successfully applied in radiative optical systems, including lasing and Bose-Einstein condensation, while demonstrating many topological properties. However, the spin-orbit properties in BIC lasing remain unexplored until now.

This work presents a comprehensive investigation of the inherent spin-orbit locking phenomena in topological BIC lasing. Through careful design and implementation of C_{4v} and C_{6v} PhC slabs, we successfully demonstrated distinct spin-orbit locking combinations in BIC lasing with topological charges of $+1$ and $\in 2$. The PhC structures, composed of silicon nitride in an optical silica environment, were engineered to support these specific BIC configurations. Using IR-140 dye molecules as the gain medium, we achieved lasing operation that exhibited clear threshold behavior and characteristic sharp spectral peaks.

Our experimental observations provided direct evidence of spin-orbit locking through multiple complementary measurements. Momentum-space spin-dependent self-interference patterns revealed the presence of fork-shaped interference fringes, definitively demonstrating the orbital angular momentum (OAM) in different spin components of the lasing profiles. For the BIC with $+1$ topological charge, we observed that the σ_- lasing component carried an OAM of $+1$ while the σ_+ component carried an OAM of $\in 1$. Similarly, for the $\in 2$ topological charge BIC, the σ_- and σ_+ components exhibited OAM values of $\in 2$ and $+2$ respectively. These observations agree well with the theoretical results, following the relationship $q = l_{\sigma_-} = \in l_{\sigma_+}$.

Furthermore, we discovered that the spin-orbit locking manifests not only in momentum space but also as spin separations in real space. Through careful analysis of the real-space distributions of different spin components, we observed clear spin-dependent spatial separations that corresponded directly to the momentum-space phase gradients. This relationship between momentum-space and real-space phenomena provides a complete picture of the spin-orbit locking

properties in BIC lasing.

Our findings not only bridge the gap between BIC physics and spin-orbit photonics but also provide a foundation for future developments in topological photonic sources and spin-controlled devices, promising significant implications for both fundamental research and practical applications in photonics technology. By demonstrating switchable OAM lasing through spin control, we have introduced a new approach to developing compact spin-orbit locking microlasers. The ability to manipulate both spin-orbit relations and OAM orders through topological charges of BICs opens new possibilities for advanced photonic applications. These results represent a significant advance in our understanding of topological photonics and provide a new framework for exploring the interplay between spin and orbital angular momentum in optical systems.

Spectrum and polarization-resolved nonlinear optical near-field imaging of plasmonic nano-antennas

Yaxin Liu[1]*, Jiajun Wang[1], Lei Shi[1], and Zhengsheng Tao[1]

[1]State Key Laboratory of Surface Physics, Key Laboratory of Micro- and Nano-Photonic Structures (Ministry of Education) and Department of Physics, Fudan University, Shanghai 200433, China

Abstract: Plasmonic nano-antennas concentrate light into tiny volumes, but high-resolution near-field imaging remains challenging. We introduce a nonlinear microscopy technique using four-wave mixing to achieve spectrum- and polarization-resolved imaging. With mid-infrared pump and near-infrared probe, we reveal plasmon-enhanced near-field intensity, polarization patterns, and spectral shifts, advancing nano-optics research.

Plasmonic nano-antennas, typical made from metals such as gold (Au) and silver (Ag), have emerged as versatile tools in various research fields. These nano-antennas can support surface plasmon resonances, enabling the concentration of electromagnetic energy into subwavelength volumes, a phenomenon known as near-field enhancement. To fully exploit the capabilities of plasmonic field enhancement, it is essential to probe the local near-fields, not only in terms of their amplitude but also their polarization and spectrum characteristics.

Previously, scanning near-field optical microscopy (SNOM) has been employed to obtain valuable near-field information of plasmonic nano-antennas. However, SNOM presents several limitations: fabricating sharp probing tips is technically challenging, and the close proximity of the SNOM tip to the sample surface can perturb local electromagnetic fields, leading to data artifacts. In addition, energy-filtered electron energy-loss microscopy has been used to image the local near-fields of plasmonic structure. However, the necessity for high-vacuum environments and thin samples greatly limits its broader application. Furthermore, both techniques encounter challenges in accurately capturing the polarization and phase information of plasmonic near-fields.

Alternatively, nonlinear optical responses of enhanced plasmonic near-fields with external probing pulses provide a promising approach for near-field imaging. The polarization sensitivity inherent in nonlinear wave-mixing processes, along with spectral information, can offer comprehensive vectorial information about plasmonic near-fields. However, research in this area remains limited.

In this work, we demonstrate a novel imaging approach for plasmonic near-fields based on nonlinear optical microscopy, specifically focusing on degenerate four-wave mixing (DFWM) from silicon. By employing a mid-infrared (MIR) pump and a near-infrared (NIR) probe, we achieve high-resolution polarization- and spectrum-resolved near-field imaging of Au nano-antennas. The spatial distribution of the plasmon-enhanced near-field intensity, as well as the in-plane polarization characteristics, are mapped in detail, revealing distinct polarization patterns. Our findings show frequency shifts in the DFWM emissions around the nano-antennas, attributed to frequency-dependent near-field enhancements. Furthermore, this approach enables the observation of resonance-induced spectral modulations and supports subwavelength spatial resolution, which is valuable for future plasmonic studies, particularly in the mid-infrared range.

Chiral fields and ultrafast chiral spectroscopy

Utilization of strong chiro-optical field near chiral and achiral plasmonic nanostructure: chiral emission and photofabrication

H.-Y. Ahn*, J. Yamanishi, and H. Okamoto

Institute for Molecular Science, National Institute of Natural Science, Okazaki, Japan

Abstract: We developed methods to utilize the chiro-optical field of plasmonic nanostructures. Chiral emission with high luminescence dissymmetry was generated from the chiral nanoparticle, and chiral structures were photofabricated by using the chiro-optical interaction of achiral nanoparticle with circularly polarized light.

Recent progress of chiral nanomaterials has provided unprecedented opportunities to control the light-matter interaction, i.e. polarization control, chiral sensing, chiral optical force, spin-orbit interaction, and many more. Understanding the chiral light-matter interaction of nanoscale materials is of central importance for designing the functions of novel chiro-optical materials and devices. In contrast to free space, local electromagnetic fields in the vicinity of the nanomaterials such as plasmonic nanoparticles can generate strongly twisted fields and mediate the absorption and radiation dissymmetries. We utilized the chiro-optical field near plasmonic nanostructures for the generation of circularly polarized luminescence and the creation of photofabricated chiral structures.

Materials generating circularly polarized luminescence (CPL) have been studied mostly in the category of organic dye molecules and their assemblies, or organic-inorganic hybrid systems. In these cases, the chirality of the overall luminescent system arises from the molecular chirality, e.g. by using organic dyes with inherent chiral molecular structures or by incorporating chiral ligands or assemblies. Recently, it has been proposed that the localized chiral electromagnetic fields of plasmonic nanostructures and metamaterials can transfer the chirality to organic dyes or quantum dots, which can be used for CPL generation. In the present study, we demonstrate a novel approach for "all-in-one" CPL-generating materials using chemically synthesized chiral Au helicoid nanoparticles.[1,2] Despite being composed of a single element, the chiral Au nanoparticles are capable to produce the photoluminescence attributed to the electronic band structure of Au. At the same time, the strong chiro-optical responses in the near-field regime arising from the localized surface plasmon resonance of the nanoscale chiral structure can provide a dissymmetry in the photoluminescence process. We found that chiral Au helicoid nanoparticles exhibit circularly polarized two-photon induced photoluminescence (TPI-PL, Fig. 1), with a very high luminescence dissymmetry factor (g-factor) of ~0.7, as single-component nanoparticles. Using electromagnetic simulations, we confirmed that the characteristic chiral gap structure of the helicoid nanoparticle is the local emission site

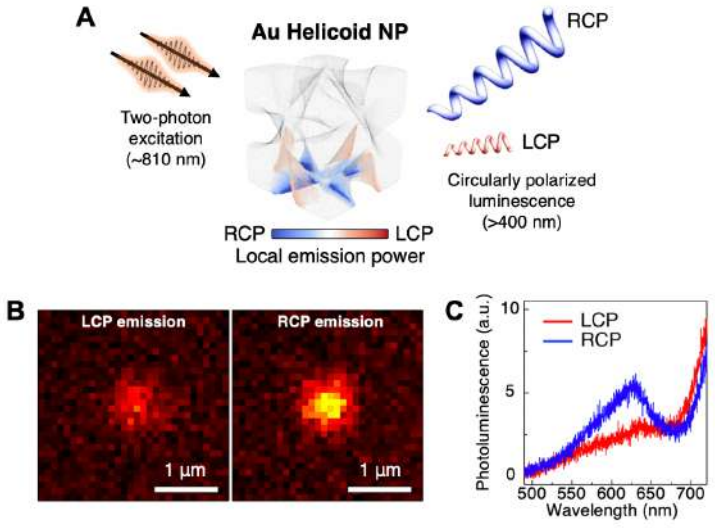

Fig. 1 (A) Schematic illustration of chiral light emission by TPI-PL process of Au helicoid NP. (B) TPI-PL images for left and right circularly polarized emission of a single Au helicoid NP. (C) TPI-PL spectra of the Au helicoid NP.

contributing to the highly chiral light emission. The experimentally observed emission intensity and g-factor spectra were consistent with those expected from the simulation model.

Plasmonic nanostructures provide effective methods to create chiral nano-/microstructures, based on their capability to transfer the chirality of light to matter. Recent studies have shown that a simple achiral plasmonic nanostructure can induce dissymmetry (chirality) of the electromagnetic field under the excitation with circularly polarized light.[3] However, only the strong near-field effect in the vicinity of the nanostructure has been used to create the chiral structure at the nanometer scale.[4] Our present study focuses on the effect of the scattering field extending over the few-μm regime, which is relatively weak compared to the near-field and therefore its effect has not been well addressed in previous studies. The secondary field induced by the nanoparticles can interfere with the incident light and give rise to a novel structure of the electromagnetic field at this spatial scale. Such fields can potentially provide unique nano-/micro-structured materials via photochemical reactions. Here, we have shown that the plasmonic scattering can be coupled with the incident circularly polarized light to generate characteristic chiral interference patterns.[5] We have succeeded in exploiting this phenomenon to create the well-defined double spiral structure from achiral Au core - Ag shell (Au@Ag) cuboid nanoparticles, by applying the photopolymerization reaction under the irradiation of visible light (Fig. 2). Our numerical calculation further supports that the experimentally obtained photopolymerized structures are consistent with the interference pattern of the electromagnetic fields.

Abstract

We present an experimentally realisable scheme for all-electric dipole trapping of chiral molecules in an enantioselective fashion. Our theory shows that light with chirality structured in time induces a chiral Stark shift resulting in trapping of the chosen enantiomer in the laser beam, while the other enantiomer is shaken away.

Ultrafast chirality

Chirality has been proven to play a vital role for living nature, emphasising the importance of its study across sciences with one of the key problems being chiral recognition – the creation of methods telling apart right-handed molecules from their mirror, left-handed, companions. As an illustration of this massive campaign of chiral study spread, it has recently become an emerging frontier in ultrafast physics, with vivid progress achieved in the strong laser field interaction with chiral molecules [1].

Chiral Stark shift

We introduce a new effect from the realm of ultrafast physics – chiral Stark shift [2]. We theoretically show that the common Stark shift can be turned into its chiral counterpart if a chiral molecule is illuminated by synthetic chiral light [3]. This opens a way to turn Stark-shift-based phenomena into enantiosensitive, or chiral, ones. We demonstrate it within the example of free-induction decay steered by synthetic chiral light in the shape of a tricolour chiral (TRICC) field structured in space and time. We show that an excited chiral molecule accumulates an enantiosensitive quantum phase due to perturbative interactions with the TRICC field. The resulting spatial phase gradient steers the free-induction decay (FID) beam in opposite directions for left- and right-handed enantiomers, revealing the chirality of the molecule – the scheme we call FID labelling of enantiomers, and demonstrating the potential of the chiral Stark shift.

Chiral optical tweezers

Optical tweezers have proven to be an extremely powerful and versatile tool for trapping and manipulating matter from atoms to micron-scale objects. One long-lasting dream, which has yet to be realised, is the enantiosensitive trapping of chiral objects in an optical tweezer: an optical trap which will keep, say, the right-handed version of a molecule, but will reject (and, indeed, eject) its left-handed mirror version, providing an optical solution to an essential task of the chemical and pharmaceutical industries over the past 200 years. A chiral optical trap, however, has remained elusive to standard methods, as linear chiroptical phenomena rely on magnetic-dipole and electric-quadrupole interactions, and these are dominated by the much stronger electric-dipole contribution.

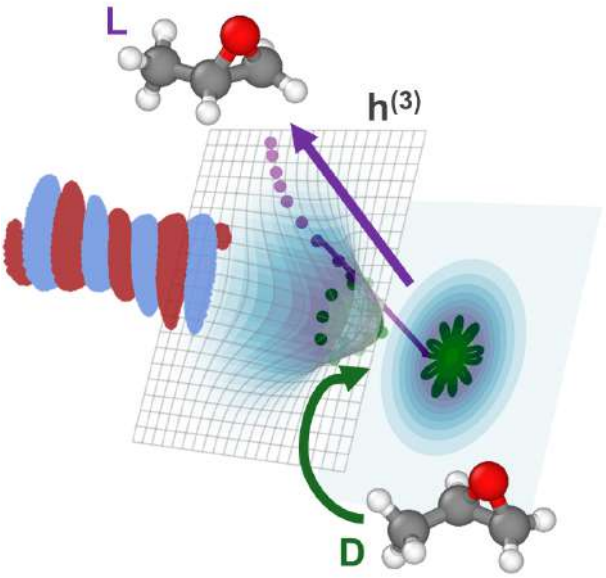

Figure 1: Cartoon for chiral optical tweezers catching D-methyloxirane, while L-enantiomer is sent off the laser TRICC beam with the nonlinear correlation function $h^{(3)}$ responsible for trapping.

Here we leverage recent developments in chiral nonlinear optics, direct brainchildren of attosecond and ultrafast science, which permit pure electric-dipole interactions in the ultrafast regime, built around SCL [3] as the main tool: a multicolour light field, which couples to a multi-photon chiral molecular pseudoscalar [4], that exhibits its chirality over time. We construct a tightly-focused TRICC beam, designed to be globally chiral [2]. We demonstrate how this leads to the highly efficient enantioseparation of small molecules using only electric-dipole transitions that give rise to a nonlinear (three-photon) chiral Stark shift.

This chiral Stark shift, the product of a molecular and a light-field pseudoscalar, which is tuned through the relative phases and frequencies of the TRICC field, permits the enantiosensitive optical trapping of a specific enantiomer – a Chiral Optical Tweezer – in the same way that the the linear achiral Stark shift enables standard optical tweezers [5]. We analyse the nonlinear susceptibility of the molecule of choice to optimise the TRICC-beam frequencies, and we show that results in a realistic trap in the presence of a cold buffer gas.

Knotted topologies in the polarization state of bichromatic light

emilio.pisanty@kcl.ac.uk

Abstract

I will present recent work on the fundamental polarization singularities available to polychromatic light. The presence of multiple colours, coherent with each other, allows light to have higher-order internal symmetries, which permits new topologies, and new conserved quantities, as well as novel optical singularities.

Optical singularities are often separated into scalar vortices (such as phase vortices) and vector vortices, which contain singularities of the polarization field at their heart, and which are typically symmetric under rigid spatial rotations about the axis of the singularity. Vector vortices, however, are unstable objects, and they are liable to separate into fundamental polarization singularities when they propagate through turbulent media.

These fundamental polarization singularities of light – typically known as C-points – are generally symmetric under coordinated rotations: that is, transformations which rotate the spatial dependence of the fields by an angle θ and the field polarization by a fraction $\gamma\theta$ of that angle, as generated by 'mixed' angular momenta of the form $L + \gamma S$. Generically, the coordination parameter γ has been thought to be restricted to integer or half-integer values [1].

In this talk I will show that this constraint is an artifact of the restriction to monochromatic fields, and that a much wider variety of optical singularities is available when one considers polychromatic beam combinations that contain more than one frequency.

Building upon this I will show that these new optical singularities present novel field topologies, isomorphic to torus knots, and I will show how they can be characterized both analytically and experimentally [2]. I will also show that the generator for the symmetry group of these singularities, whose algebraic structure is deeply related to the torus-knot topology of the beams, is conserved in nonlinear optical interactions [3]. Finally, I will report on recent work studying tightly-focused versions of the same beams, where the longitudinal component of the fields induces a novel nonlinear measure of optical chirality, which carries a 'vortex of chirality' [4].

Deep Learning and Nano-optics: Designing nanoscale polaritonic effects in twisted chiral multilayers of vdW materials

Abstract: This talk builds on recent advances in hyperbolic nanooptics, introducing a neural-network-based approach to design phonon polariton propagation in twisted multilayers. We achieve on-demand control—including canalization and bi-canalization—in previously unexplored frequency ranges, demonstrating a powerful strategy for tailoring light–matter interactions at the nanoscale.

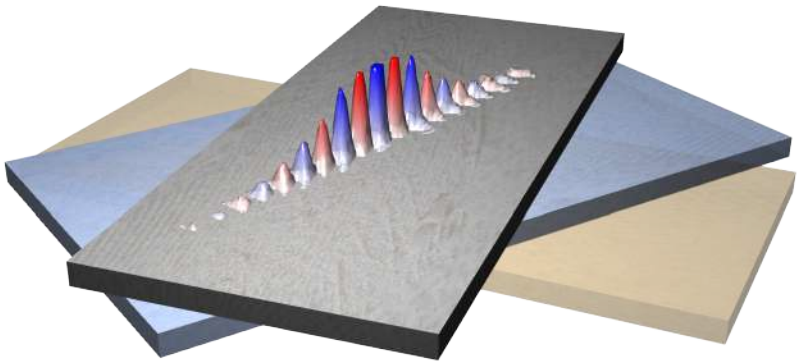

Figure 1: Schematic representation of the desired polaritonic propagation in real space, used as input to the neural network (NN). The NN accurately predicts the structural parameters (t, θ, and ω) for one or multiple configurations.

Summary: Polaritons—dipole excitations in matter coupled to electromagnetic fields—in van der Waals[1, 2] (vdW) crystals enhance light–matter interactions through extreme field confinement and long lifetimes. In some natural crystals, their dispersion adopts a hyperbolic shape, enabling "hyperbolic light" to travel only along specific directions. This gives rise to highly non-intuitive phenomena such as negative reflection and refraction, canalization[3], ray-like propagations[4] and deeply subwavelength focusing. These unique capabilities have driven rapid advances in nano-optics, enabling unprecedented control of light at the nanoscale. However, despite these exciting advances, nano-optics still presents a major limitation: obtaining propagations on demand, i.e. by design.

In this work, we overcome this limitation through the combined use of a **neural network and twisted polaritonic multilayers**. Our method enables **inverse design**, making it possible to **demonstrate desired (and thus novel) polariton propagations** by obtaining accurate predictions of subsequently fabricated multilayer configurations. Interestingly, this method efficiently handles possible system degeneracies, identifying multiple multilayer structures that give rise to the same desired propagations at the nanoscale.

Abstract: Optical chirality is most commonly associated with geometrically chiral nanostructures. By spectrally analyzing single planar achiral nanostructures with two dipolar plasmonic resonances, it can be shown that the polarization state of the emitted light is determined by chiral near-fields, leading to a chiroptical far-field response.

Chirality presents an important concept in chemistry and biology. It is manifest in the characteristic optical properties of chiral structures under interaction with chiral light [1,2]. Yet, the far-field response of achiral nanostructures is widely reported to be invariant to the handedness of the optical excitation. The dipolar electric resonances of plasmonic nano-antennas are commonly determined from the structures' white-light dark-field scattering spectra. The spectra of planar achiral particles with a long and short geometric axis, such as nano-rods or nano-rectangles, display two resonances at longer and shorter wavelengths. Using a polarizer, these modes can be excited selectively. In such measurements, no chiroptical far-field response is observed.

The situation changes when a second polarizer is introduced in the beam path, acting as an analyzer. The resonance positions of the two contributing modes start to shift depending on the analyzer angle, indicating an interplay between the spectrally overlapping modes (see Figure 1) [3]. Simulations show electric near fields of opposite circular polarization at different locations around the particle. The near-field chirality is transformed to an optical chirality flux in the far-field [4]. The relevant parameter determining the interplay is the relative phase between the electrical fields of the eigenmodes. This phase shift can be entered into a description of the system via an analytical dipole model, by which the intensity of the electric far-field radiation can be derived [3].

Experimental, numerical and analytical findings thus confirm that both chiral and achiral nano-antennas can exhibit chiral near-fields that are transmitted to a chiral far-field emission due to phase shifts and interference between the antenna's dipolar plasmonic resonances. The corresponding polarimetric measurements may, e.g., be utilized to determine the orientation of gold nanorods through identifying the orientation of their longitudinal dipolar modes [5].

Support from the French Agence Nationale de la Recherche (grant ANR-17-CE24-0039) and the European Union's FEDER fund, the nano'mat platform and the French RENATECH+ network is gratefully acknowledged.

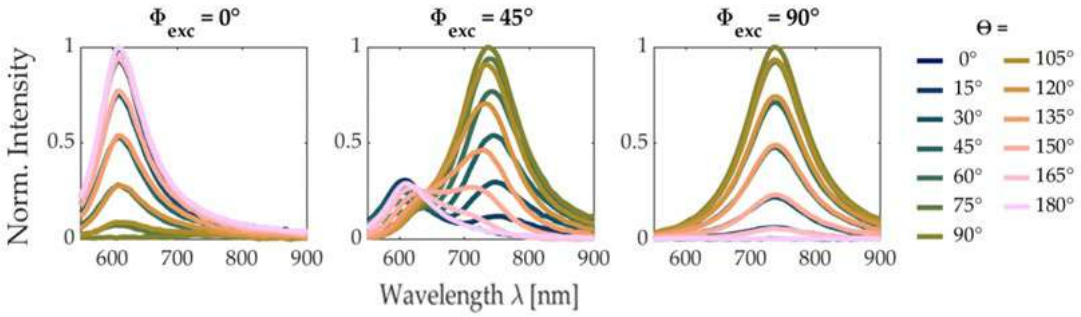

Figure 1: Dark-field scattering spectra of an achiral rectangular gold nano-antenna under excitation with linearly polarized white light under three different angles Φ_{exc}, measured with analyzation angles Θ between 0° and 180°. Under 0° excitation, only the transversal localized surface plasmon resonance, and under 90° excitation, only its longitudinal counterpart is detected with varying intensities. Under 45° excitation, a relative spectral shift of the resonances is observed in addition to an intensity modulation, indicating a chiroptical response.

Abstract

We introduce the concept of enantiosensitive exceptional points – non-Hermitian degeneracies whose position in parameter space is sensitive to the handedness of an open system. We apply the concept for the development of novel highly sensitive and robust methods to detect molecular chirality, from single molecules to racemic mixtures.

Non-Hermitian Hamiltonians (NH) describe open systems where energy and/or matter is exchanged between the system and its surrounding environment. The parameter space of these systems can host branch points, commonly known as exceptional points (EPs), where the eigenvalues and eigenstates of the Hamiltonian coalesce. The presence of EPs in NH physics leads to a plethora of remarkable phenomena, such as topological population transfer between the eigenstates or the enhanced sensitivity of NH systems to external perturbations. Owing to their generality, these effects are ubiquitous and have been observed in many different experimental platforms, from atomic and molecular media to photonic and optical materials [1].

Here, we apply these EP-based non-Hermitian phenomena to the problem of detection of molecular chirality. In particular, we show that the position of EPs in open chiral systems depends on their handedness, paving the way for the development of much needed highly sensitive and topologically robust chiral methods that can work in racemic mixtures and detect small variations of enantiomeric excess [2].

First, we show that selective excitation of chiral enantiomers can be achieved by coupling a chiral molecule to the continuum using a three-color field (Fig.1a). By tuning the field configuration, we achieve highly efficient topological population transfer between the adiabatic states of only one of the molecular enantiomers, while its mirror twin is left in the initial state. The phenomenon survives orientational averaging, paving the way for topologically robust enantiosensitive separation of chiral molecules in racemic gaseous mixtures.

Then, we demonstrate that enantiosensitive EPs in photodissociating chiral molecules can amplify weak chiral effects induced by the magnetic component of chiral light fields. (Fig.1b). Specifically, we show that we can control the amount of dissociated chiral molecules in a racemic mixture in an enantioselective fashion by changing the interaction time between the molecule and the field. Our results show chiral dichroic effects on the order of $\simeq 10\%$, which are orders of magnitude larger compared to the the typical $\simeq 0.1\%$ efficiency of standard approaches that employ the magnetic component of light for the detection of chirality.

Finally, we devise a chiral sensor based on a twisted non-Hermitian optical fiber interacting via evanescent modes with a solution of chiral molecules (Fig.1c). By engineering the gain/loss

profile of the optical fiber, we show that the position of EPs in the parameter space depends directly on the enantiomeric excess of the solution $ee = C_R \in C_L$ (where $C_{R/L}$ is the concentration of right/left molecules). We then couple linearly polarized light into the fiber and analyze the rotation angle θ and the ellipticity ξ of the propagating light. If the chiral fiber is tuned to an EP corresponding to a given enantiomeric excess $ee^{(0)}$, small variations $\epsilon = ee \in ee^{(0)}$ in the relative concentrations of right- or left-handed molecules lead to fast variations of the rotation angle θ and ellipticity ξ of the light at the end of the fiber. Changing the fiber parameters, the sensor can be made to be highly sensitive to small variations around any given value of the enantiomeric excess $ee^{(0)}$.

Our work is a first step in an exciting new direction at the crossroad beteween the development of new enantiosensitive techniques and non-Hermitian physics. While chirality is a ubiquitous phenomenon present in a wide range of temporal and length scale, any realistic system is open to the environment and can be therefore described in the non-Hermitian language. Here we show that non-Hermitianity can provide a much needed enhancement of chiral phenomena, while chiral interactions open new avenues for the exploitation of EP-induced effects.

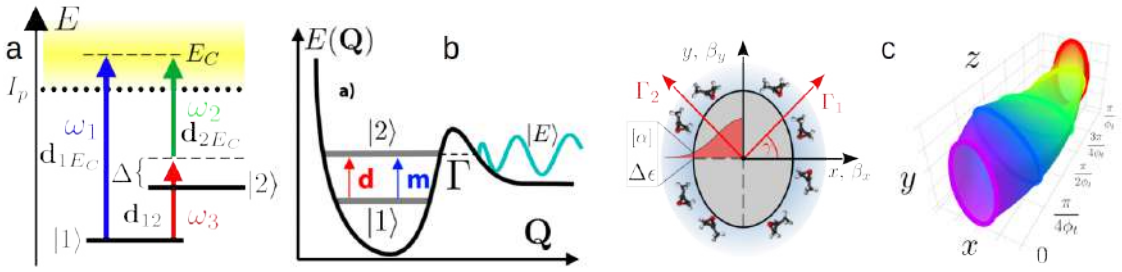

Figure 1: Open chiral systems with enantiosensitive EPs. **(a)**: A photoionizing chiral molecule driven by a three-color field in the electric dipole approximation, where we drive enantiosensitive topological population transfer; **(b)**: a photodissociating chiral molecule driven by the electric and magnetic component of a single-color field, where we show enantiosensitive photodissociation and stabilization; **(c)** a chiral twisted non-Hermitian fiber interacting with a solution of chiral molecules via evanescent fields, where we show highly sensitive detection of small variations of enantiomeric excess.

Ultrafast Light-Matter Interaction in Photocatalytic Systems

X-ray techniques for probing and inducing ultrafast dynamics at nanoscale

N. Agarwal[1]

[1]Elettra Sincrotrone Trieste, Italy

Naman.agarwal@elettra.eu

Abstract: I will overview X-ray techniques for probing ultrafast nanoscale dynamics, with a focus on Coherent Diffraction Imaging (CDI) and X-ray Transient Grating Spectroscopy (XTG). I will present recent results on imaging ultrafast phase transition in VO2 using CDI and discuss the application of XTG to induce and probe nanoscale dynamics.

Understanding photoinduced dynamics with femtosecond-picosecond temporal and nanometer spatial resolution is crucial for optimizing and efficient control of next-generation devices. X-ray Free Electron Lasers (XFELs) have advanced the study of element-specific material dynamics with unparalleled temporal and spatial resolution. In this talk, I will give an overview of X-ray techniques for investigating ultrafast nanoscale dynamics in solid thin-film systems, focusing on Soft X-ray Coherent Diffraction Imaging (CDI) and X-ray Transient Grating Spectroscopy (XTG). I will present our recent findings on imaging heterogeneity in the ultrafast metal-insulator phase transition in VO2 using coherent diffraction imaging, and discuss the application of XUV transient grating to induce and probe nanoscale dynamics.

Sensitizing diamond to visible light to increase electron emission under solar radiation.

Abstract: In this work we aim to exploit the negative electron affinity of the surface of hydrogenated diamond combined with the efficient absorption of visible light by plasmonic nanoparticles to emit electrons using solar light. We postulate that by combining plasmonic nanoparticles with diamond it is possible to simultaneously increase the photoductivity of the diamond and to enhance photemission of electrons from the surface. The role of diamond defects in this process is discussed.

Combining plasmonic metal nanoparticles with wide bandgap semiconductor materials has been demonstrated to be an effective way to sensitize these materials to sub-bandgap light.[1] This is often used as a strategy to improve the photocatalytic properties of these materials.

In this work, we focus our efforts on diamond as it has the very interesting property of having a negative electron affinity at its surface when it is hydrogenated. This property can lead to numerous useful applications such as a cold cathode or as a clean source of solvated electrons. The problem is that diamond has a band gap of 5.5 eV and therefore this process only works with VUV light ($\lambda < 213$ nm).

We have fabricated several separate systems based on the combination of plasmonic nanoparticles with diamond which show that exciting the plasmonic resonance of the metal nanoparticles can lead to a strong enhancement of the emission of electrons from the diamond surface.

The first of these is a system involving nanodiamonds coupled with gold nanoparticles in aqueous solution which has been shown to be a source of solvated electrons following interaction with visible light. In this case, the presence of solvated electrons was verified by using an ultrafast pump-probe experiment in which a visible light pump was used to excite the plasmon resonance of the gold nanoparticles while a white light probe was used to optically detect the formation of the solvated electron in the first picoseconds after the excitation.

The next system attempted was to fabricate an array of nanoparticles embedded below the surface of a thin film of diamond. Initial attempts with Aluminium as the plasmonic material were not successful[3] while successive fabrication using silver showed the required properties[4]. Using this system, it was possible to demonstrate both increased photoconductivity and emission of electrons into vacuum using visible light. Based on the details of the above measurements we propose a mechanism involving plasmonically enhanced visible-light absorption by defect states at the Ag/Diamond interface which increases the photoconductivity of

the material combined with photoemission from occupied surface states with electronic transport through defects.

Subsequent samples in which diamond films are grown on Silicon substrates have been examined with synchrotron radiation and pump-probe techniques to verify the above-proposed mechanisms and to optimize the efficiency of the process.

Abstract: I will present a time-resolved Raman spectroscopy (TRRS) study on the layered semiconductor MoS_2, under resonant optical pumping with the excitonic gap at Brillouin zone K point. TRRS allows mapping the redistribution of energy among the system degrees of freedom, from the photoexcited electronic subsystem to specific zone-center phonon modes.

MoS_2 belongs to the class of graphene-like, layered materials called transition metal dichalcogenides (TMDs). Semiconducting TMDs, like MoS_2, show an indirect to direct bandgap transition when the system is exfoliated down to the monolayer structure, which makes them promising materials for future applications in optoelectronics and related fields [1]. Unravelling the relaxation pathways of photoexcited electrons in such systems, and specifically their coupling with the lattice degrees of freedom, is of great applicative interest.

Time-resolved Raman spectroscopy (TRRS) can provide direct access to the electron-phonon coupling dynamics, as well as the incoherent phonon relaxation [2]. The aim of our experiment is studying the deexcitation dynamics of MoS_2 after impulsive optical pumping of the excitonic bandgap. At the SPRINT-NFFA facility, we have carried out a TRRS study on the system, monitoring the temporal evolution of two specific Raman active features, namely the out-of-plane A_{1g} mode and the in-plane E^1_{2g} mode, after the photoexcitation. Equilibrium Raman spectroscopy studies have linked the modification of such phonon lineshapes to doping effects, providing the background for studying the optically induced, transient doping of the system [3,4,5]. To explore the effect of dimensionality on the system relaxation dynamics, the experiment was performed on both bulk and monolayer MoS_2, revealing significant differences in the phenomenology and relaxation timescales. The role of the substrate on the monolayer deexcitation dynamics was explored by selecting substrates with different electrical and thermal properties.

After presenting the results of the TRRS study, I will discuss their perspective integration in a multi-messenger, time-resolved spectroscopy study, coupling the time resolved photon and electron spectroscopies available at the SPRINT-NFFA facility (CNR-IOM@Elettra, Trieste, Italy).

Ultrafast chiral spectroscopy for stereocontrolled photochemistry

M. Oppermann[1*]

[1]Department of Chemistry, University of Basel, Klingelbergstrasse 80, CH-4056 Basel
[*]corresponding author: malte.oppermann@unibas.ch

Abstract: We present an ultrafast circular dichroism technique to capture the dynamics of chiral excited states in solution. By combining sub-picosecond time resolution with high chiral sensitivity, we resolve the stereochemical evolution of photoexcited molecules, such as a chiral Fe(II) spin-crossover complex and a chiral lanthanide complex with circularly polarized luminescence.

The incorporation of chiral structures into photochemical systems is a powerful strategy to control their functions [1]. For example, uni-directional molecular motors, chiral photocatalysts, and chiral metal nanostructures have achieved exceptional levels of stereocontrol over mechanical motion, energy transfer, and electric charge-carriers on the nanoscale. However, the direct characterization of the underlying chiral excited states remains a formidable experimental challenge, due to a lack of analytical techniques that combine high chiral sensitivity in solution with ultrafast time resolution [2].

To address this challenge, we have developed an ultrafast circular dichroism technique that measures the absorption difference of left- and right-circularly polarized laser pulses in photoexcited chiral molecules [3]. Through an ultra-sensitive broadband detection scheme, we are thus able to capture ultrafast changes in molecular chirality and follow the stereochemical evolution of the associated photoexcited states with sub-picosecond time resolution. On this basis we are now able to resolve chiral photochemical dynamics in real-time, which I will illustrate via two examples: 1) the identification and control of a chiral reaction coordinate in the spin-crossover dynamics of Fe(II) complexes [4], and 2) the resolution of the energy and chirality transfer dynamics in a chiral lanthanide-based OLED complex with circularly polarized luminescence (CPL) [5].

Elucidating Charge Transfer Processes in Plasmonic and Semiconductor Photocatalysts

G. Tagliabue[1]

[1]Laboratory of Nanoscience for Energy Technologies (LNET), EPFL, 1015 Lausanne, Switzerland

[*]corresponding author: giulia.tagliabue@epfl.ch

Abstract: The combination of optical nanoantennas and scanning photoelectrochemical microscopy opens new door for the in-situ investigation of non-equilibrium charge transfer processes.

In the last decade, optical nanoantennas have revolutionized light manipulation and control at the nanoscale. Interestingly, generation of hot carriers in metals upon light absorption have opened new pathways for controlling activity and selectivity of photo(electro)chemical processes. Concurrently, semiconductor nanostructures enable optimization of charge transport and light absorption. Yet, fundamental questions remain about the microscopic details of these complex light-matter interactions.

I will first present our recent results on quantifying the energy-resolved injection probability of hot electrons and hot holes across the metal/semiconductor interface. We demonstrate the importance of small scale nanoantennas to maximize the chance of ballistic collection and we unravel microscopic details of charge transfer via inner or outer sphere pathways [1,2,3]. Furthermore, I will show how morphology of semiconducting nanostructures dramatically impacts the performance of solar redox flow batteries [4,5,6]. In particular, we demonstrate that high photovoltages are attainable in single-material photoanode, enabling unassisted recharging up to high state of charge. Overall, using an internal quantum efficiency perspective, our work unravel the interplay of light absorption, charge generation and in plasmonic and semiconducting photocatalysts.

Abstract: We report on interface excitons in mixed-dimensional heterostructures consisting of two-dimensional tungsten diselenide and one-dimensional carbon nanotubes. Localization of low-energy interface excitons is indicated by extended lifetimes as well as small excitation saturation powers. Photon correlation measurements confirm antibunching at room temperature.

The development of van der Waals heterostructures has introduced unconventional phenomena that emerge at atomically precise interfaces. For example, interlayer excitons in two-dimensional transition metal dichalcogenides show intriguing optical properties at low temperatures. Here we report on room-temperature observation of interface excitons in mixed-dimensional heterostructures consisting of two-dimensional tungsten diselenide and one-dimensional carbon nanotubes [1].

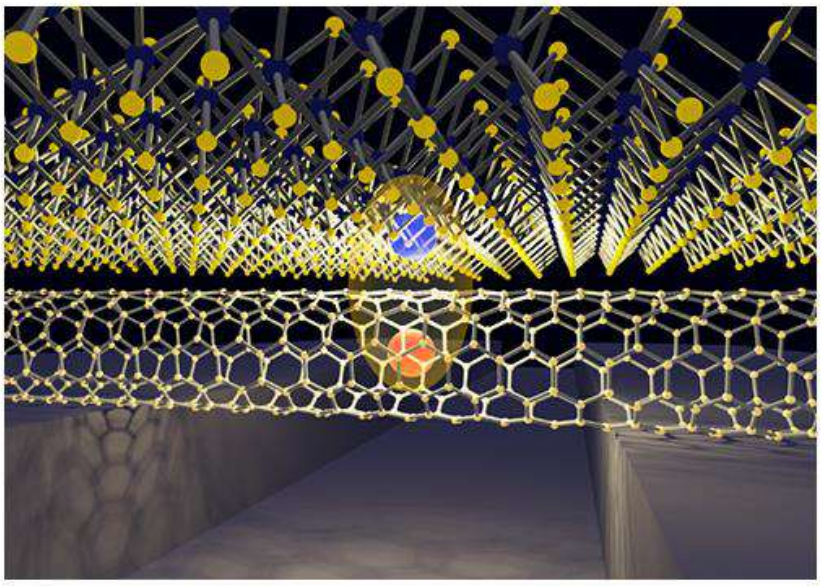

Figure 1: Schematic of an interface exciton in a mixed-dimensional heterostructure.

The mixed-dimensional heterostructures are fabricated by transferring a tungsten diselenide flake on top of the carbon nanotubes using the anthracene-assisted transfer technique [2,3]. The heterostructures are entirely free standing to preclude substrate effects (Fig. 1). Room-temperature photoluminescence spectroscopy is employed to investigate interface excitons within the heterostructure. Bright emission peaks originating from the interface are identified, spanning a broad energy range within the telecommunication wavelengths. The effect of band alignment is investigated by systematically varying the nanotube bandgap, and we assign the new peaks to interface excitons as they only appear in type-II heterostructures. Time-resolved photoluminescence measurements reveal extended lifetimes of the interface excitons, whereas excitation power dependence shows that emission saturates at low powers. These characteristics suggest room-temperature localization of the low-energy interface excitons. To elucidate the quantum nature of the interface excitons, we conduct photon correlation measurements. The second-order correlation exhibits a clear antibunching dip at zero delay. With mixed-dimensional van der Waals heterostructures where band alignment can be engineered, new opportunities for quantum photonics are envisioned.

Designer van der Waals Materials for Quantum Optical Emission

Shengxi Huang

Department of Electrical and Computer Engineering & Department of Materials Science and NanoEngineering, Rice University, Houston, TX 77005

shengxi.huang@rice.edu

Abstract: We report new atomic engineering approaches on van der Waals materials to generate high quality single photon emitters. Our approaches include atomic substitution through plasma treatment, in-situ doping, and manipulating layer thickness and polarization. Such approaches have led to single photon emission with high purity, high brightness, and high stability.

Key words: single photon purity, Debye-Waller factor, atomic substitution, transition metal dichalcogenide, hexagonal boron nitride

Designer van der Waals (vdW) materials offers enormous opportunities to tune material properties for various applications. Isolated, optically-active defects generated in vdW materials could lead to single photon emission. 2D vdW materials as host materials for single photon emission hold various advantages, such as high optical extraction efficiency from the atomically-thin layered materials, and readiness to integrate with on-chip photonic and electronic devices. However, single photon emission from 2D vdW materials typically suffers from low purity and lack of controllability, due to the sensitivity of these atomically-thin materials to external dielectric environments, surface defects and adsorbents, and strains and wrinkles introduced during material processing. This talk introduces our recent efforts to improve the single photon purity and controllability in vdW materials. We developed novel defect structures that can overcome several current issues, and explored their electronic structure and tunability in optical emission. Through a combination of approaches, including strain engineering, heterostacking, employing optical selection rules for excitation and detection, optimization of material synthesis and handling, we were able to achieve high purity (> 98%) for single photons emitted from 2D transition metal dichalcogenides (TMDs) at cryogenic temperature and in hBN at room temperature. This work provides deep insights into the electronic, spin, and valley properties of TMDs and hBN. It also paves the way towards the

application of 2D vdW materials for quantum optical applications. The materials engineering approaches developed here can be applied to the optimization of other optical and quantum materials.

Spatial Resolution Enhancement by Quantum Entanglement

Zhe He

Shandong Institute of Advanced Technology, China

*corresponding author: zhe.he@iat.cn

Abstract: Quantum imaging surpasses the classical limit of spatial resolution without the need for labeling by measuring the second-order correlation functions of entangled photons. Here, we discuss the mechanism and methods of resolution enhancement by using a type-I BBO quantum source.

Classical imaging techniques are typically restricted by the diffraction limit of light. To overcome this challenge, quantum phenomena can be applied to enhance imaging capabilities. Resolution enhancement arises from measuring the second-order correlation functions of entanglement photons [1]. The entanglement state of photons could be generated by the spontaneous parametric down-conversion (SPDC) of a type-I BBO source:

$$\Psi(\boldsymbol{r}_s,\boldsymbol{r}_i) = \sum_{\boldsymbol{k}_s,\boldsymbol{k}_i} e^{-i\boldsymbol{k}_s\cdot\boldsymbol{r}_s} e^{-i\boldsymbol{k}_i\cdot\boldsymbol{r}_i} |\boldsymbol{k}_s,\boldsymbol{k}_i\rangle, \quad (1)$$

where $|\boldsymbol{k}_s,\boldsymbol{k}_i\rangle$ represents the biphoton state in the momentum domain, and the wavevectors $\boldsymbol{k}_s,\boldsymbol{k}_i$ obey the phase matching condition.

We experimentally use the signal and idler photons generated by the BBO source for wide-field imaging [2]. The classical spatial resolution is evaluated by analyzing the point spread function (PSF) of the signal photon. Additionally, when measuring the second-order correlation function, the PSFs of both the signal and idler photons together create an equivalent PSF. This narrows the bandwidth of the second-order correlation function by a factor of two compared to the original PSF. As a result, the effective spatial resolution of the entangled photons is halved compared to that of the signal photon.

Measuring the second-order correlation function of two light beams often requires the photon counting detectors [3]. However, in our approach, we utilize both the signal and idler photons to illuminate the object and a reference plane, which requires a two-dimensional detector to resolve the correlation between symmetrical pixels. To achieve this, we employ an electron-multiplying charge-coupled device (EMCCD) camera, which captures the entangled photons with a 1000 Hz frame rate. Additionally, we utilize a reconstruction algorithm to extract the correlation information from the EMCCD, achieving the image with enhanced resolution.

Towards top-down integrated quantum photonics based on color centers in hBN

A. Delteil[1*]

[1] Université Paris-Saclay, UVSQ, CNRS, GEMaC, 78000, Versailles, France
[*]aymeric.delteil@uvsq.fr

Abstract: We present the quantum optical properties and controlled integration of single-photon sources created in the 2D material hexagonal boron nitride (hBN) by local irradiation with an electron beam. This technique yields high-quality color centers with reproducible emission wavelength in the visible range, enabling scalable integration into monolithic devices for applications in quantum technologies.

Control in position and wavelength of high quality quantum emitters is crucial for implementing a top-down approach in solid-state quantum technologies. In this context, 2D materials bring new opportunities in the field, with specific integration techniques at the ultimate scale of single atomic layers.

We recently demonstrated the local generation of quantum emitters ("B centers") with reproducible wavelength and high-quality photophysics in the visible range [1]. The B centers are created by local irradiation in a scanning electron microscope (fig. 1). They exhibit narrow and reproducible spectra, with a stable and bright emission in the visible range. I will first present their optical properties, including coherence, indistinguishability and quantum efficiency, inferred using quantum optics techniques, such as resonant laser excitation combined with photon correlations [2-4], Hong-Ou-Mandel interference [5] and the Purcell effect [6]. I will also present their controlled integration into monolithic photonic devices [7]. Altogether, the controlled generation of coherent quantum emitters in a 2D material opens appealing perspectives in quantum photonics, with applications in optical quantum technologies.

Abstract

We develop a deterministic technique for creating single organic color centers in carbon nanotubes via in-situ photochemical reaction. By monitoring discrete photoluminescence changes, we precisely control the formation of individual color centers. Photon antibunching confirms their quantum nature, demonstrating the potential of atomically defined quantum emitters for quantum photonic devices.

Quantum light sources that emit single photons on demand are crucial for advancing quantum technologies, including quantum communication, quantum computing, and quantum sensing. Various solid-state systems, such as nitrogen-vacancy centers in diamond, semiconductor quantum dots, and defects in two-dimensional materials, have demonstrated single-photon emission. However, practical implementation requires quantum light sources that operate at room temperature and within the telecom wavelength range. Overcoming material limitations and optimizing emission efficiency remain key challenges in this field.

Single-walled carbon nanotubes (SWNTs) have emerged as a promising platform for quantum light sources due to their unique one-dimensional structure, exceptional optical properties, and intrinsic compatibility with telecom wavelengths [1–3]. A significant advancement in this field has been the introduction of localized color centers in SWNTs, enabling single-photon emission at room temperature. However, the deterministic control over the formation of these quantum defects remains a challenge. Specifically, precise control the number and spatial positioning of defects is critical for scalability, yet existing fabrication techniques often lack the required precision.

In this work, we present a novel technique for the deterministic creation of single organic color centers in SWNTs using an *in-situ* photochemical reaction (Fig. 1). By monitoring discrete intensity changes in photoluminescence (PL) spectra during the functionalization process, we identify and control the formation of individual color centers. The reaction is halted upon the observation of the discrete PL intensity increase, enabling control over the photochemical reaction to form single color centers.

We perform a statistical analysis of PL spectra from individual color centers to quantitatively assess the distribution of color center types, providing insight into the reproducibility of defect formation. Furthermore, position-controlled color center formation is demonstrated and validated using PL imaging, confirming spatial precision in defect placement. To assess the quantum nature of the created defects, we conduct photon correlation measurements, which reveal photon antibunching—a hallmark of single-photon emission. This result establishes that quantum defects can be reliably generated using our proposed method.

Our findings demonstrate a scalable approach for deterministic single-photon emitter fabrication in SWNTs, addressing a critical challenge in quantum photonics. By providing precise

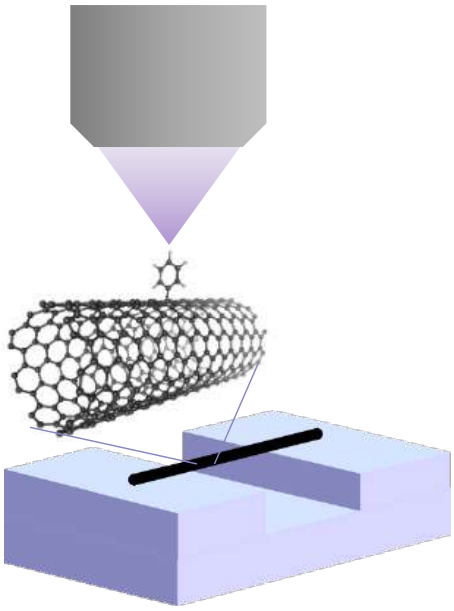

Figure 1: A schematic of *in-situ* photochemical reaction in a air-suspended SWNT where we deterministically create single organic colors using iodobenzene.

control over defect formation, our technique paves the way for integrating SWNT-based quantum light sources into practical quantum communication and computing applications. The ability to generate telecom-compatible single-photon emitters at room temperature further enhances the viability of SWNTs as a platform for future quantum technologies.

Lattice Symmetry Guided Spin Dynamics in Supramolecular Assemblies

Xuedan Ma

[1] Department of Materials Science and NanoEngineering, Rice University, Houston, TX, 77005, USA

[2] Center for Nanoscale Materials, Argonne National Laboratory, Lemont, IL, 60439, USA

Synthetic soft materials mimicking biological structures are promising for many applications in fields such as photovoltaics and photocatalysis. For these applications, a deep understanding of charge- and energy-transfer mechanisms is required to build more efficient devices. In this work, we investigate self-assembled 2D supramolecular structures using angle-resolved photoluminescence (PL) imaging techniques and decompose the optical transition dipoles in the supramolecular structures. Combining these optical studies with Monte Carlo simulations, we reveal the important role played by lattice symmetry in charge dissociation, transport, and recombination, as well as the exciton spin states. These mechanistic findings have important implications for engineering soft materials towards efficient energy conversion and photocatalytic applications.

Nanoscale magnetic field imaging based on NV center in diamond: instruments and applications

Pengfei Wang[1]

[1]CAS Key Laboratory of Microscale Magnetic Resonance and School of Physical Sciences, University of Science and Technology of China, Hefei 230026, China, Country
[*]corresponding author: wpf@ustc.edu.cn

Abstract: Based on the solid-state spin sensors in diamond, we have developed scanning nitrogen-vacancy probe microscope for magnetic measurement with a spatial resolution up to 10 nm. We have carried out dark matter detection, *in situ* single cell magnetic resonance imaging, and harmonic spin wave generations in vortex-like spin texture.

The nitrogen vacancy (NV) center in diamond has been studied as an atomic-scale sensor for magnetic resonance technique in the past decade. It was demonstrated the ability to detected the magnetic field from as weak as a single electron or nuclear spin. The combination of nitrogen vacancy center and the scanning probe microscope can bring the single spin sensor to the sample and obtain the magnetic stray field image of the interesting target including the spin textures, current density and spin dynamics. To push forward the application, we have built several scanning NV probe microscope for study. ‘

In this talk, I will give a brief talk on scanning NV probe miscroscope and applications in our lab:

1) We fabricated the scanning NV matrix probe to improve the yielding and decrease the NV-sample distance[1]. The probe contains a 7 × 7 NV nanopillar matrix. It also allows us to adjust the diamond-sample parallelism to allow a better contact.
2) We develop a controller with lock-in amplifier and multi-channel ADC and DAC for spin manipulation and scanning feedback[2].
3) We realized the *in situ* magnetic resonance imaging on a single cutted liver cancel cell. The spatial resolution achieved 10 nm and we also combine the magnetic resonance imaging and transmittive electron microscopy[3].
4) We study the magtisms in topological magnetic film with skymions[4,5], antiferromagnetic spin textures[6] and spin dynamics in magnetic vortex.
5) Beyond the magnetic field imaging, we develop the electric field image and achieve a spatial resolution of 30 nm.

Cavity quantum electrodynamics with single photon emitters in 2D crystals

C Antón-Solanas[1,*]

[1]*Depto. Física de Materiales, INC, IFIMAC, Universidad Autónoma de Madrid, Madrid, Spain*

*carlos.anton@uam.es

Abstract: Weak light-matter coupling conditions allow to generate bright single photon emission from solid-state sources. In this talk we will present results on quantum dots in monolayers of WSe_2 (and defects in hexagonal Boron Nitride) that are coupled to a tunable Fabry-Pérot microcavity, rendering a bright single photon emission.

The nanoscale control of light-matter interactions allows to create new optoelectronic devices for a wide span of nonlinear and quantum photonic applications. A key part of this endeavour is the exploration of novel materials, which reveal unique properties that can be tailored to specific applications. Regarding the implementation of solid-state single photon sources, relevant emergent materials for quantum light emission are quantum dots in transition metal dichalcogenides monolayers, perovskite quantum dots, or also defects in hexagonal boron nitride nanocrystals. [1]

An optimal single-photon source should satisfy three essential criteria: (1) the emission of photons "*on demand*", (2) emit one photon at a time, and (3) high degree of temporal coherence and uniformity in the properties of emitted photons (spectrum, polarization, spatial mode). Achieving this ideal quantum performance relies on using a resonant cavity to enhance the emitter's spontaneous decay rate via the Purcell effect.

In the first part of this talk, we will present recent advancements in generating single photons from atomically thin WSe_2 monolayers. Local stress within these monolayers creates a confining potential that traps single excitons, resulting in single-photon emission. By embedding these quantum dots in a cryogenic Fabry-Pérot optical cavity, we achieve record emission-efficiency levels. [2] We also study the filtering cavity effects on the temporal coherence of the emitted single photons via Michelson interferometry. [3] Initial quantum communication tests with these sources further demonstrate their viability for single-photon applications. [4]

In the latter part of the talk, I will discuss our experimental progress with an alternative material platform: single defects in hexagonal boron nitride. This emitter, operable at ambient conditions and integrated with a Fabry-Pérot cavity, offers a promising option for cryogenic-free quantum optical applications, including free-space quantum key distribution.

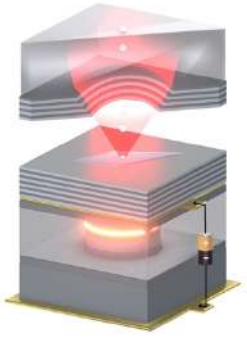

Figure 1: Schematic of the single photon device, composed by a quantum emitter in a hexagonal boron nitride monolayer,

embedded in a reconfigurable Fabry-Pérot open cavity.

[*]corresponding author: alexander.hoegele@lmu.de

Abstract: Semiconductor van der Waals heterostructures with near-resonant band alignment and non-commensurate lattices such as MoSe2/MoTe2 [1] and MoSe2/WS2 [2] constitute peculiar model systems for excitons, charges and spins localized on moiré lattices. Being robust against mesoscopic lattice reconstruction [3] due to sizable lattice mismatch, they exhibit canonical periodic moiré potentials, while near-resonant band alignment induces hybridization of exciton states across the constituent layers. Using cryogenic optical spectroscopy of moiré excitons, we study the effects of correlated charge and spin ordering in such moiré heterostructures with different twist-angle configurations, highlighting emergent magnetism phenomena on effective monolayer and bilayer Hubbard triangular lattices [4]. Moreover, by employing open cavities, we establish control over neutral and charged moiré exciton-polaritons in the regime of strong light-matter coupling [5], thereby expanding the realm of moiré phenomena in van der Waals heterostructures.

Abstract: In this talk, we present our recent works on electrically excited quantum emission in *h*-BN by the voltage applied across 2D heterostructure composed of a graphene/*h*-BN/$NbSe_2$ stack. We also introduce van der Waals material, α-MoO_3, as an emerging platform for room temperature quantum emitters.

Quantum emitters in 2D van der Waals crystals have attracted much recent attention due to their emission properties retained down to atomically thin layers which allows potential integration with various materials with optical, electrical, and magnetic structures.

In the first part of the talk, we will discuss the electrical control of quantum emitters in *h*-BN. Through the heterostructure integration of *h*-BN with metallic 2D materials including graphene and $NbSe_2$, we demonstrate the electrical generation of quantum light emission from *h*-BN atomic defects [1]. By applying voltages between graphene and $NbSe_2$ electrodes sandwiching *h*-BN host material, we observe localized electroluminescence at the overlapped edge of the electrodes which exhibited the photon intensity increasing linearly with the tunneling current. The second-order correlation function measurement performed under the application of a voltage at zero time delay displayed the value below 0.5, confirming the electrically pumped non-classical light generation. From the band structure analysis of graphene/*h*-BN/$NbSe_2$ heterostructure, we found that the work function manipulation of the contact electrodes has enabled the effective supply of charge carriers to atomic defect sites leading to the creation of photon emission with high probability.

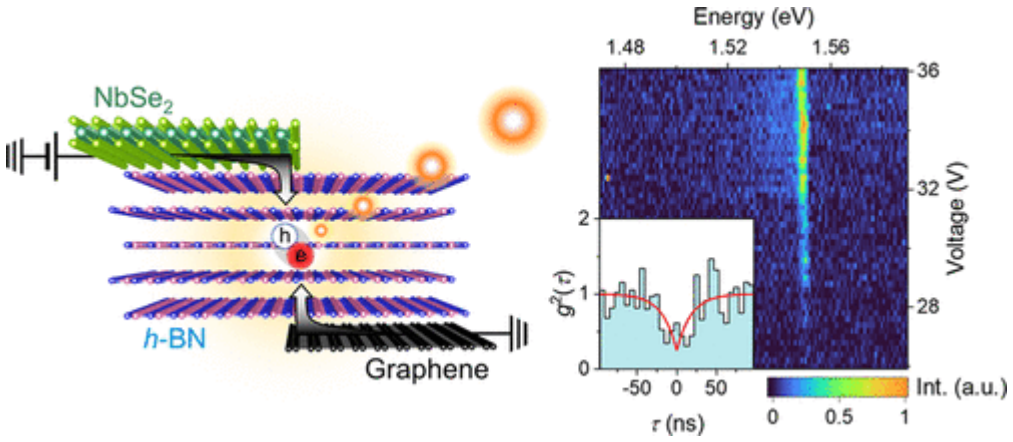

Figure 1. Graphene/*h*-BN/$NbSe_2$ heterostructure and electrically induced quantum light emission.

In the second part of the talk, we introduce our recent work on the observation of quantum emitters in α-MoO_3 [2]. α-MoO_3 is a van der Waals semiconductor with the bandgap of 3 eV, which has been extensively studied in 2D transistors and optoelectronic devices. Due to its high dielectric constant and capability to manipulate charge densities, 2D heterostructures involving α-MoO_3 have found applications in the development of efficient light-emitting devices and photodetectors. Previously, defect-related emissions have been reported in α-MoO_3, but only ensemble measurements have been observed so far. By exfoliating thin layers of α-MoO_3 and

applying thermal annealing process, we observe quantum emission from localized defect sites of α-MoO_3. The second-order correlation function measurement shows the antibunching dip, the emission wavelength is distributed in the range between 560 and 620 nm, the photon intensity reaches nearly 1 Mcounts/s, and the luminescence is observable up to room temperature. Using DFT calculations, an oxygen vacancy center is found as a promising candidate for the observed emitters from calculated photon energy, excited state lifetime, and spectral lineshape of phonon sidebands.

Our results on quantum emitters in van der Waals materials and heterostructures will be potentially beneficial for the optoelectronic implementations of quantum devices for quantum information science.

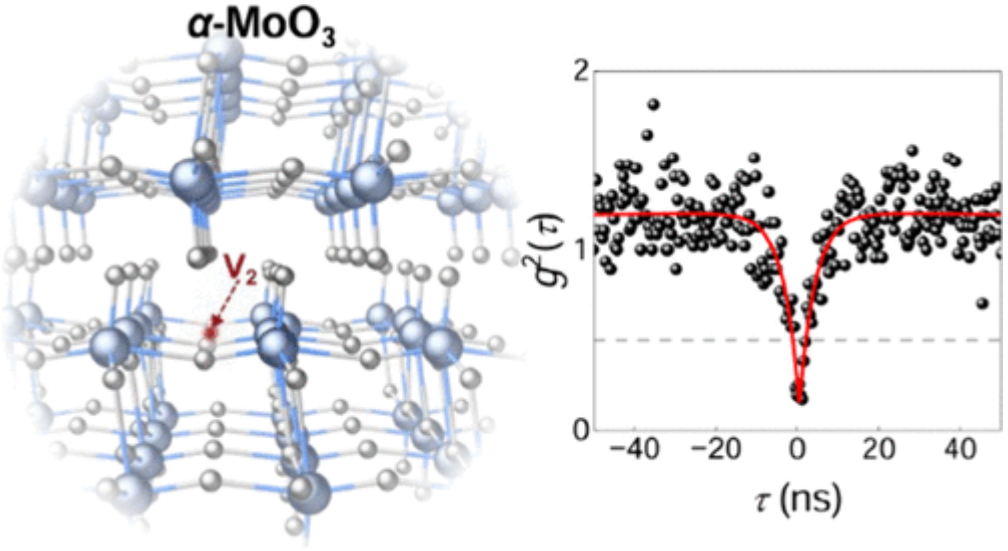

Figure 2. Crystal structure of α-MoO_3 defect center and the second-order correlation function measurement.

Atomically Thin Near Infrared Quantum Light Emitters

Han Htoon

Center for Integrated Nanotechnologies, Los Alamos National Laboratory, Los Alamos NM, USA
htoon@lanl.gov

Abstract: This talk will highlight our recent efforts on the development of three 2D material-based quantum light emitters capable of operating in near-infrared spectral regime.

Quantum emitters that operate at near-infrared (NIR) wavelengths, particularly those within the telecom band, hold significant technological importance. The alignment of these SPEs with established fiber optic technologies – characterized by minimal photon loss at the telecom wavelengths – facilitates the seamless integration of quantum and classical communication infrastructures. Two-dimensional (2D) materials have recently emerged as promising materials for quantum light generation, owing to their high photon extraction efficiency, facile coupling to external fields, and seamless integration into photonic circuits. However, most of the 2D material-based quantum emitters reported to date operate at the wavelength <1 μm.

Here in this talk I will present three new 2D quantum emitters capable of wavelength tunable single photon emission across 1000-1600 nm NIR spectral range and operation at liquid nitrogen temperatures. The QEs were realized via nano-pillar-based strain-engineering of few-layer $MoTe_2$ [1] and InSe [2] and MoS_2/WSe_2 heterostructures [3]. The emission wavelengths of $MoTe_2$ and InSe QEs can be tuned with layer-thickness over the entire NIR range covering both O and C telecommunication bands [1, 2], making them ideally suited for the implementation of quantum photonic technologies over the existing optical-fiber-based telecommunication networks. Hanbury Brown and Twiss experiments conducted at 10 K reveal clear photon antibunching. The photon antibunching can be observed up to liquid nitrogen temperature (77 K) in case of $MoTe_2$ quantum emitters. Density-functional-theory calculations and scanning-tunneling-microscopy analyses are conducted on InSe multi-layer to gain insights into the electronic structures and defect states, elucidating the origins of the SPEs.

We have utilized MoS_2/WSe_2 heterostructure as a model system to investigate how strain engineering can be applied to manipulate the interlayer exciton formed at the interface of van der Waal materials [3]. We discovered a new type of quantum light emitting state where an electron residing in the sulfur-vacancy state ~200 meV below the MoS_2 conduction band edge form an optically active excitonic transition with a hole in the hybridized Γ band of MoS_2/WSe_2 heterointerface. The QEs emit in 900-1050 nm range and can operate up to 77K. While this emission is out of the telecommunication band, our approach unlocks the freedom of combining arbitrary 2D semiconductors for building IXs with desired emission energy and extending this strategy for engineering interfacial Γ point transitions in other 2D heterostructures, for instance, in MoS_2/WS_2. Given that monolayer TMDCs emit in the visible spectral range can be combined to generate IXs that emit in the NIR, our findings pave the way for extending the operational wavelength of 2D quantum light sources into the technologically important yet rarely reached NIR regime. Our strategy of creating site-controlled QEs from the defect-bound IXs signifies a paradigm shift in 2D quantum photonics research, moving from engineering intralayer exciton in monolayer structures towards IXs in 2D heterostructures.

Strained two-dimensional semiconductors toward straintronics

Jin Myung Kim[1], Soyeong Kwon[1], and SungWoo Nam[1*]

[1]University of California, Irvine, USA
[*]corresponding author: sungwoo.nam@uci.edu

Abstract: We report strain-induced exciton transport in monolayer WSe_2 across microns at room temperature via steady-state pump-probe measurement. Wrinkle architecture enabled optically-resolvable local strain (2.4%) and energy gradient (49 meV/μm) to WSe_2. We observed strain gradient induced flux of high-energy excitons transported to the nearest energy minima with high transport efficiency.

Optoelectronic information processing is an appealing platform for ultrafast, energy-efficient signal computing and optical communication beyond electronic devices[1,2]. Excitons in atomically-thin two-dimensional (2D) semiconductors, including transition metal dichalcogenides (TMDs), have potential for integrated optoelectronic circuits and interconnects because they are strongly bound, stable even at room temperature[3,4] and can carry rich quantum information as demonstrated in valleytronics[5,6] and antibunched photon emission[7,8]. The overarching requirement for development of such 2D excitonic devices is to realize localization and controlled transport of exciton for logic operation and data transfer. However, because bosonic excitons are charge-neutral, electrical modulation of exciton flux is thus far limited to particular exciton subtypes such as charged trions or interlayer excitons with out-of-plane dipole moments. On the other hand, heterogeneous strain engineering via elastic deformation is a universally applicable technique to manipulate exciton flux because local strain directly tunes the electronic band structure, and results in built-in potential in the form of a bandgap gradient, which funnels excitons to regions with lowest energy without charges or aligned dipoles.

Strain-induced exciton drift/funneling was first experimentally demonstrated in irreversibly deformed bulk semiconductors at cryogenic temperatures. In contrast, exciton funneling in 2D semiconductors can be achieved at ambient temperatures because of

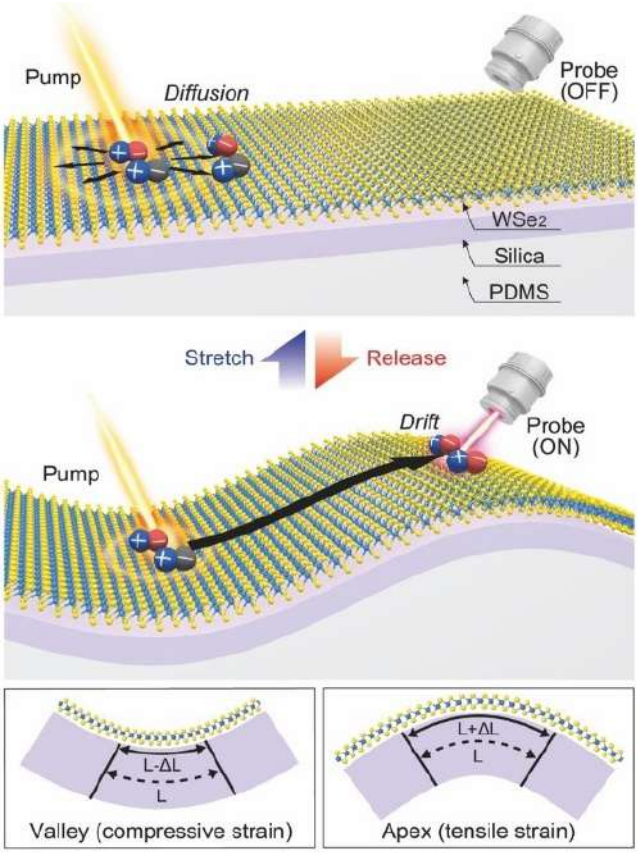

Figure 1. Heterogeneous strain engineering of exciton transport in monolayer WSe_2 via soft wrinkle architecture. Schematic diagram of mechanically reconfigurable wrinkle architecture made of multiple thin films on PDMS including silica skin layer, WSe_2, and encapsulating PMMA layer (not shown in the schematic). Tensile and compressive strain is applied to WSe_2 at apex and valley of the wrinkle architecture, respectively.

reduced dielectric screening and resultant strong exciton binding energy[3,4]. Additionally, the unique mechanical features arising from the atomic thinness of 2D semiconductors, such as high in-plane strength and low bending stiffness, enable strain-sensitive and reversible strain-exciton coupling. Upon these advantages and theoretical prediction in strain engineered atomic materials, strain-induced exciton funneling has been investigated in 2D semiconductors deformed by nano-indentation, 3D nanostructured substrates and trapped gas, or buckle-delaminated by substrate shrinkage. However, experimental demonstration of 2D exciton funneling has been mostly limited to indirect evidence such as photoluminescence (PL) enhancement, comparison of spectral shifts or spatial profiles, and PL emission center shift in spatiotemporally resolved PL. In addition, recent studies of nano-indented TMDs also showed either exciton-trion conversion or limited exciton funneling under nanoscale local strain. Thus, it is unclear if limited observations of strain-induced 2D exciton funneling is a result of the inherent factors, such as short ambient lifetime or trion conversion of 2D intralayer excitons, or extrinsic factors such as insufficient strain and sub-diffraction strain gradient. Accordingly, quantitative elucidation of how efficiently strain can induce exciton funneling and what physical parameters should be considered for practical design of straintronic optoelectronic devices remains elusive thus far.

Here, we present strain-engineered exciton drift in monolayer tungsten diselenide (WSe_2) using pump-probe measurements at ambient temperature. We employed three-dimensional soft wrinkle architecture to create optically-resolvable and mechanically reconfigurable lateral strain gradient from the apex (tensile) to the valley (compressive) of WSe_2 wrinkles (**Fig. 1**). Straintronic switching was made possible by tailoring exciton motion from isotropic diffusion to directional drift. We observed strain-induced exciton drift over micrometer scale distances with high transport efficiency demonstrated by pump-probe characterization. We established a theoretical strain-exciton coupling model based on time-resolved PL measurement and simulation, which revealed strong influence of strain gradient on exciton decay and transport dynamics. We further demonstrated a theoretical model of straintronic exciton router functional at GHz frequency. Our work presents new opportunities for exploring exciton transport and localization for quantum straintronic devices and quantum excitonic phase transitions.

Abstract: We probe the spin-relaxation dynamics of boron-vacancy spin defects in hBN and show that T_1 is strongly sensitive to the applied magnetic field, especially at low temperatures. Moreover, we explore the effect of the boron vacancy formation on the fundamental limits of T_1 and T_2 in these 2D spin defects.

Boron-vacancy (V_b^-) spin defects in hexagonal boron nitride (hBN) are drawing increasing interest as resources for quantum sensing of spin ordering and spin fluctuations in van der Waals heterostructures. The V_b^- ground state is a spin triplet state ($S = 1$) that is further split into $m_s = 0, \pm 1$ sublevels by a zero-field splitting of $3.5\ GHz$. The ground state splitting is sensitive to external magnetic fields via the Zeeman effect and electric fields via the Stark effect, enabling the spin defects to serve as in situ probes of these quantities with diffraction-limited spatial resolution. The sensitivity of these defects to external magnetic fields at $DC - GHz$ frequencies is closely related to the linewidth of the ground-state spin transition, the lattice environment of the host material, and the intrinsic spin-relaxation time (T_1) and decoherence time (T_2). While T_1 is influenced by spin-spin interactions and spin-phonon interactions, T_2 is governed by the coupling of the ground state spin with the nuclear spins in the environment. The effect of a small T_2 can be circumvented by applying appropriate microwave pulse sequences to filter the environmental noise. However, the upper limit of the effective T_2 time is determined by the T_1time. Therefore, it is critical to understand the nature of the relaxation dynamics of the V_b^-defects as the community begins to develop new approaches to quantum sensing with 2D spin defects.

We initially focus on magnetic field and temperature dependent spin relaxation dynamics of V_b^-defects for fields of $0 - 7\ T$ (corresponding to ground-state splitting $\sim 3.5\ to\ 200\ GHz$) and temperatures of $2 - 300\ K$. Spin relaxation processes at low temperatures are commonly ascribed to two-phonon processes or Orbach type processes due to coupling with quasilocalized phonons. We show here that, while the measured spin contrast is relatively independent of field, the T_1 time is strongly field dependent with the maximum measured T_1 occuring around $1.8\ T$, suggesting an intrinsic magnetic-field-dependent relaxation mechanism.

In order to better understand the intrinsic limitations to T_1 and T_2 for V_b^-, we patterned V_b^-defects in hBN by electron, neutron, He^+ and Ar^+ irradiation on both bulk substrates and freestanding STEM membranes. The room temperature spin-lattice relaxation time for these samples shows a strong anticorrelation with defect density, decreasing from 15 μs at low defect densities to <1 μs at high defect densities. This observation, together with the measured field-dependent T_1 suggests that a combination of dipolar spin-spin interactions and resonant cross-relaxation mechanisms may serve to limit T_1 in typical hBN samples. However, neutron irradiated freestanding hBN membranes appear to exhibit substantially reduced unwanted defect bands, and preliminary measurements suggest that these samples may exhibit improved T_1 as a result. Additional ongoing relaxometry measurements are utilizing scanning NV microscopy to probe cross-relaxation interactions in hBN with nanoscale spatial

resolution. Finally, if time allows, we will also discuss ongoing experiments focused on milliKelvin temperature-dependent probes of T_1 and T_2 for V_b^- and for carbon spin-defects in hBN. Together, these results provide insights into the nature of spin-spin and spin-phonon coupling in 2D quantum sensors and highlight the potential of these defects for quantum sensing in high magnetic fields and milliKelvin environments.

Abstract: This presentation will discuss our recently work on the diamond color center and elucidate our efforts to interpret and harness the unique emission property, which lead to novel IMC functionalities.

In-memory computing[1] (IMC) is an emerging technology designed to overcome the limitations of the von Neumann bottleneck by drawing inspiration from the human brain and enabling highly parallel data processing. However, developing IMC devices and hardware capable of handling vast amounts of information while maintaining sustainability and power efficiency presents significant challenges. Addressing these challenges requires novel materials with exceptional physical properties.

Diamond color centers[2], widely studied in quantum science and technology for their unique optical properties, remain largely unexplored for IMC applications. In this presentation, I will introduce our recent research on diamond color centers and detail our efforts to interpret and harness their distinct emission properties, which unlock novel IMC functionalities. I will discuss the underlying mechanisms of our diamond color centers, supported by both experimental and theoretical insights. Finally, I will demonstrate how their reconfigurable nature enables bio-realistic neuromorphic functionalities, paving the way for energy-efficient IMC architectures optimized for artificial intelligence and machine learning hardware accelerators.

A Colloidal Quantum Dot on a Hybrid Nanoantenna as an Ultrafast and Efficient Single Structured Photon Source for Room Temperature High Dimensional Quantum Communications

Ronen Rapaport[1, 2,*]

[1]*Racah Institute of Physics, The Hebrew University of Jerusalem, Jerusalem 9190401, Israel*

Abstract: We demonstrate ultrabright, highly directional single photon sources operating at room temperature, utilizing a colloidal quantum dot positioned on a hybrid nanoantenna device, that produces structured photons. We then demonstrate two high-dimensional quantum key distribution protocols, by encoding and decoding qudits on different degrees of freedom of these structured photons.

Deterministic GHz-rate single photon sources (SPS) at room-temperature would be essential components for various quantum applications. Our on-chip single photon source utilzes a ‘giant’ colloidal quantum dot (gQD) deterministically bound to a complex monolithic photonic resonator constructed of a gold nanocone responsible for the rate enhancement, enclosed by a circular Bragg antenna for emission directionality [1-6]. A repeatable process accurately binds a gQD that show highly stable, blinkingless emission to the tip of the antenna-embedded super-sharp nanocone. As a result we achieve simultaneous >20-fold emission rate enhancement, with sub-ns emission lifetimes, and a record-high directionality, leading to an increase in the observed single-photon brightness by more than two orders of magnitude. Our device results in a usable photon emission rates of tens of MHz, thus enabling ultrafast light-matter interfaces for quantum communications at ambient conditions. We further demostrate a practical plug-and-play SPS with an antenna device which allows back optical pumping of the quantum dots and a front directional single photon emission with high single photon purity and an almost unity colllection efficiency [7], as well as a direct coupling to a fiber without any additional coupling optics.

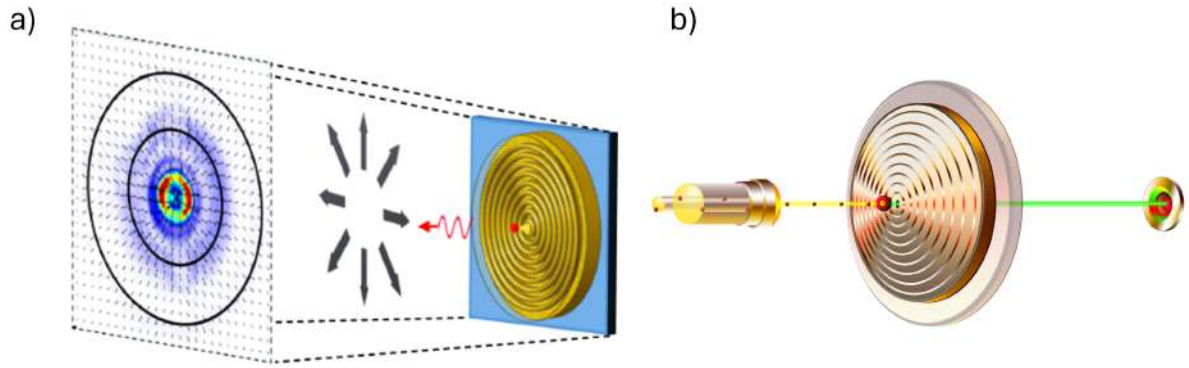

Figure 1:(a) Schematic sketch of the SPS emitting radially polarized single photons, with an experimental back focal plane image exhibiting a 'donut' shape structure associated with radial polarization. (b) Sketch of fiber coupled SPS with back excitation and forward highly directional emission directly coupled into an optical fiber

To demonstrate the relevance of our SPS for real quantum communication applications, we experimentally emulate two high-dimensional quantum key distribution (HDQKD) protocols. HDQKD is a promising avenue to address the inherent limitations of basic QKD protocols.
First, we demonstrate a HDQKD protocol by encoding information in a high-dimensional (d=3) space of the orbital angular momentum of the photons [8]. Our experimental configuration incorporates two spatial light modulators for encoding and decoding the spatial information carried by individual photons. We

demonstrate experimentally secure qudit transmission exceeding one secure bit per photon, thus already beating the traditional d=2 QKD capacity [8].
Finally, we show a new concept for encoding high-dimentional quantum information on single photons from our SPS, taking advantage of the high-quality vector-beam radial polarization nature of the emitted photons from the resoator-antenna device [9], to encode information on mutually unbiased hybrid spatial-polarization modes with d=4, establishing the feasibility of utilizing high radiative quantum yield gQD-based SPS as a practical avenue for HDQKD applications.

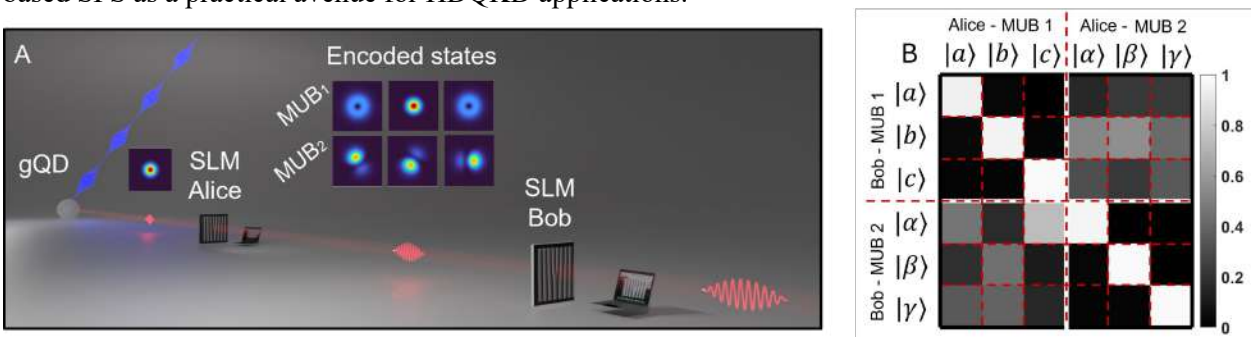

Figure 2: (A) A visualization of the experimental process: a pulsed laser excites a gQD, generating single photons that are encoded with spatial information by Alice's SLM and projected onto corresponding modes by Bob's SLM. (B) Projection measurements: normalized

Quantum Light in a Moiré Heterostructure

Mauro Brotons-Gisbert

Institute for Photonics and Quantum Sciences, Heriot-Watt University, Edinburgh, UK

The unique physical properties of two-dimensional materials, combined with the ability to stack unlimited combinations of atomic layers with arbitrary crystal angle, has unlocked a new paradigm in designer quantum materials. For example, when two different monolayers are brought into contact to form a heterobilayer, the electronic interaction between the two layers results in a spatially periodic potential-energy landscape: the moiré superlattice [1]. The moiré superlattice can create flat bands and quench the kinetic energy of electrons, giving rise to strongly correlated electron systems. Further, single particle wave packets can be trapped in the moiré potential pockets with three-fold symmetry C_3 symmetry to form interlayer exciton (IX) 'quantum dots' which can emit single photons [2,3].

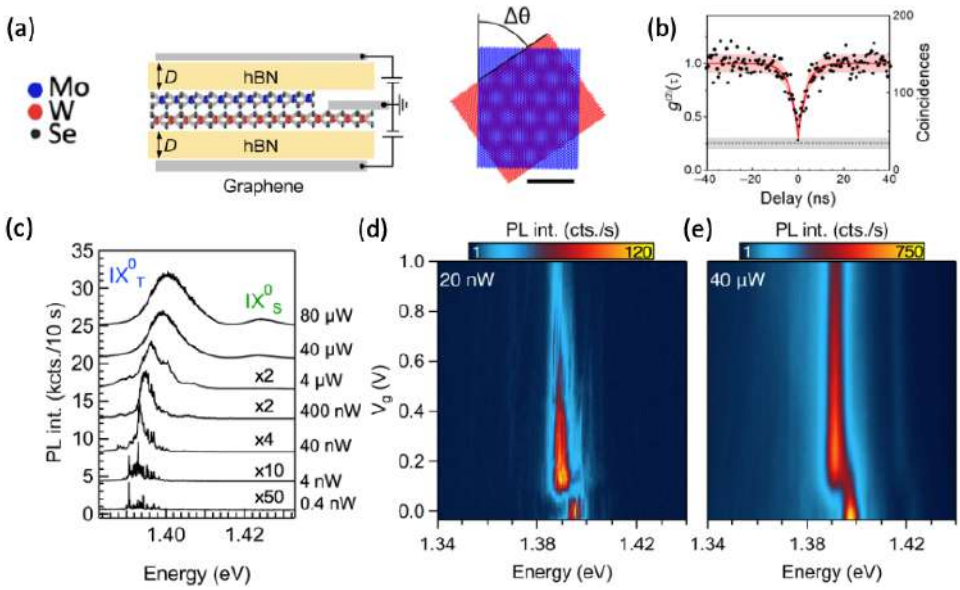

Figure 1. (a) Sketch of the dual-gated $WSe_2/MoSe_2$ heterobilayer. Graphite layers are used as contacts for top, bottom, and heterobilayer, while hBN layers (D = 18 nm) are used as dielectric spacers. **(b)** Second-order photon correlation statistics of a moiré-trapped IX under CW excitation. **(c)** Power dependence of moiré-trapped IXs. **(d)**, **(e)**, Gate-voltage controlled PL of IXs in the neutral ($0 < V_g \leq 0.1$ V) and electron doping regime ($V_g \geq 0.1$V) at P_{exc} =20 nW (d) and P_{exc} =40 μW (e) at 4K.

In this talk, I will review our recently published results on the creation of moiré-trapped IXs. First, I will present the continuous evolution from a few trapped IXs to an ensemble of IXs with both triplet and singlet spin configurations in a gate-tunable 2H-$MoSe_2/WSe_2$ heterobilayer [Figs. 1(a) and 1(c)] [4]. I will then discuss signatures of dipolar interactions in the IX ensemble regime, which, when combined with magneto-optical spectroscopy, reveal that both the narrow quantum-dot-like and broad ensemble emission originate from IXs trapped in moiré potentials with the same atomic registry [4].

Furthermore, electron doping leads to the formation of negative on-site IX trions with a binding energy of ~7 meV in both the low- and high-IX-density regimes [Figs. 1(d) and 1(e)] [4]. At low IX densities, additional electron doping results in a sequential filling of empty superlattice sites, giving rise to a Coulomb staircase—stepwise changes in IX trion emission energy due to Coulomb interactions with carriers at nearest-neighbor moiré sites [5].

Finally, I will discuss the presence of three distinct species of localized negative IX trions with contrasting spin-valley configurations in the IX ensemble regime [4]. These findings not only identify the origin of IX emission in $MoSe_2/WSe_2$ heterobilayers but also underscore the crucial role of Fermi-level control, dipolar interactions, and Coulomb effects in these highly tunable quantum materials.

Increased Formation of Silicon-Vacancies in Diamond by Sub-Bandgap Light Irradiation during Annealing

Coleman Cariker[1], Yifan Yao[2], Andre Schleife[2], Michael Titze[1,*]

Abstract: This study investigates the brightness enhancement of silicon-vacancy (SiV) centers in diamond through UV irradiation during post-implantation annealing. Results show a 15% increase in photoluminescence brightness, attributed to improved SiV formation due to reduced divacancy density, suggesting potential for optimized manufacturing of single defect sites for quantum applications.

Color centers in diamond, particularly silicon-vacancy (SiV) centers, have garnered significant attention due to their potential applications in quantum information science (QIS). SiV are advantageous because they can couple electronic spins with optical photons and can be manufactured at scale. SiV are interesting candidates for QIS due to low electron-phonon coupling and high brightness, leading to an overall high quantum efficiency.

The fabrication of SiV centers typically involves silicon ion implantation followed by annealing. However, this process can lead to collateral damage in the diamond lattice, resulting in the formation of defects like divacancies (VV). The formation of SiV requires a monovacancy adjacent to a silicon substitutional defect, but the presence of VVs complicates this process. During annealing, monovacancies become mobile at around 900 K, but they are more likely to encounter another vacancy than an implanted silicon ion, leading to the formation of VVs that persist until approximately 1100 K, resulting in a low yield of SiV centers.

To address the issue of low SiV yield, previous work has explored charging vacancies during annealing, which can reduce the number of VVs [1]. These studies have shown that generating excess charges during ion implantation can suppress VV formation through Coulomb repulsion. However, this method typically requires implantation of additional ion species, introducing more vacancies. Alternatively, optical excitation, particularly using UV light, has emerged as a promising technique for defect manipulation by modifying electron distributions.

This study combines density functional theory (DFT) simulations and experimental methods to investigate the effects of UV irradiation during post-implantation annealing on the dissociation of VVs and the yield of SiVs [2]. DFT simulations are used to analyze mid-gap energy levels and the binding energy of VVs, while experimental measurements assess the Si to SiV activation yield through scanning photoluminescence (PL).

DFT calculations were performed using the Vienna Ab-initio Simulation Package (VASP) to investigate the optical spectrum and binding energies of VVs and SiVs. The electronic structure and binding energy of VV-related states was analyzed, revealing that UV excitation could destabilize VVs. The destabilized VVs can then be easily dissociated, facilitating the formation of SiVs. The binding

energy of SiVs was found to be higher than that of VVs, indicating that SiVs formed following VV dissociation will be stable complexes.

Silicon ions were implanted into diamond samples using a focused ion beam (FIB) implanter. Following implantation, the samples were annealed at 800 °C for 24 hours, with UV light exposure during the annealing process. Half the sample was blanked during IV irradiation, allowing for the comparison of PL brightness between UV-irradiated and non-irradiated regions of the sample.

Spectrally resolved photoluminescence (PL) confirms the presence of silicon-vacancy (SiV) centers, shown in Figure 1(a). The activation yield of SiVs per implanted ion is assessed by PL maps containing approximately 300 SiV locations for both the UV blanked and irradiated regions. In the UV blanked region, PL yield is assume to be 3%, resulting in an average of 9 ± 3 SiV defects per location [3]. A representative implant area is shown in Figure 1(b). On the UV irradiated side, individual SiV brightness is assumed to be the same, such that from the observed brightness a number of SiV contributing to the emission can be extracted. A detailed analysis of individual spot brightnesses is shown in Figure 1(c) and indicates a 15-20% increase in brightness in the UV-irradiated region compared to the blanked region, attributed to a higher number of active SiVs resulting from reduced divacancy (VV) density.

Further optimization of annealing temperature and UV exposure duration could enhance SiV brightness. In conclusion, this research highlights the potential of using sub-bandgap light irradiation in during annealing to enhance the formation of SiV centers in diamond, paving the way for advancements in quantum technologies and other applications reliant on these unique color centers.

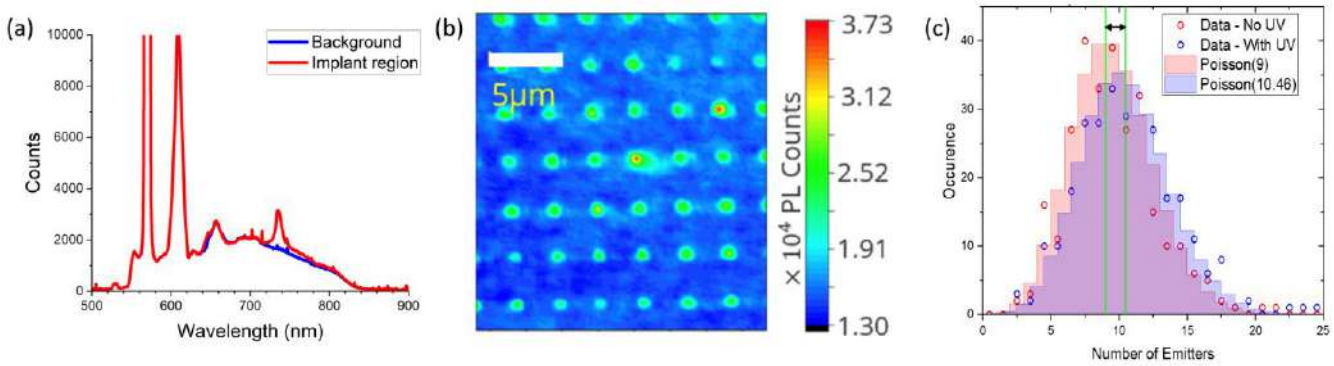

Figure 1 (a) PL spectrum comparing the implanted region and background. The peak at 737 nm confirms that PL is due to SiV. (b) PL map showing the implanted array of SiV. (c) Comparison of ~300 implant regions for both UV blanked and irradiated region, showing a 15 % increase in SiV formation.

Quantum Transport and Spin-Valley Control in Monolayer $MoTe_2$ for Photonic Integration

M. A. Campbell[1], **T. J. McSorley**[1], **J. Liu**[1], **and L. A. Jauregui**[1,*]

Abstract: We demonstrate quantum transport in monolayer $MoTe_2$ with engineered Ohmic contacts via $RuCl_3$. High mobility and Zeeman-split oscillations reveal broken spin-valley degeneracy. Integrated with prior advances in high-quality growth and strain-tunable emission, our results establish monolayer $MoTe_2$ as a promising platform for hybrid quantum photonic and light-emitting devices.

Monolayer $MoTe_2$ offers a compelling platform for quantum photonics, combining a direct bandgap (~1.1 eV), strong excitonic interactions, and large spin-orbit coupling. However, realizing its potential in quantum light-emitting and photonic integrated systems has been limited by contact resistance and instability under ambient conditions. Here, we report a heterostructure approach using α-$RuCl_3$ as a charge-transfer substrate to enable Ohmic contacts and cryogenic magneto-transport in monolayer $MoTe_2$. The resulting devices exhibit high hole mobility (> 4,000 $cm^2/V \cdot s$) and clear Shubnikov–de Haas oscillations for $B > 2.3$ T. At higher fields ($B > 7$ T), oscillation splitting indicates broken spin-valley degeneracy with a large effective g-factor ($g^* \approx 10.8$), supporting spin- and valley-selective phenomena (as shown in Figure 1). Raman and photoluminescence studies confirm significant strain and heavy hole doping, the latter leading to exciton quenching and altered recombination dynamics.

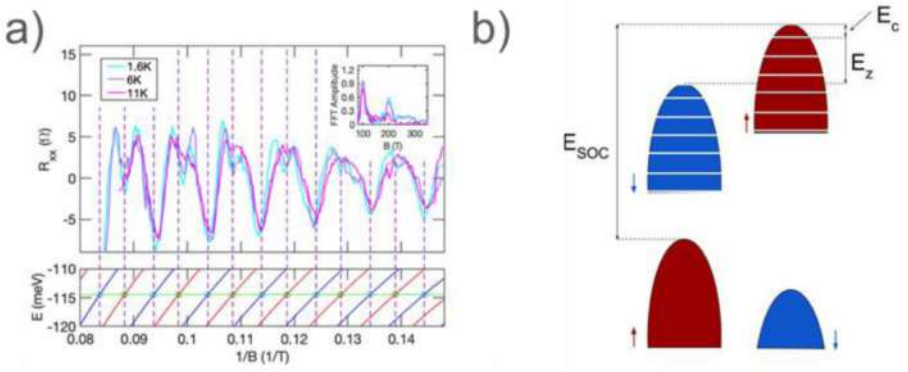

Figure 1a) High field ΔR_{xx} vs. $1/B$ at 3 representative temperatures, T = 1.6K, 6K, and 11K. Inset: FFT of ΔR_{xx} vs. $1/B$ at different Ts. Lower panel: simulated Landau fan diagram using our extracted parameters for a Fermi energy EF = -115meV, where the dips in ΔRxx are aligned with the Landau levels (LLs) from two spin-polarized bands. Red and blue lines correspond to spin up and spin down respectively. b) Schematic of the K and K' bands in MoTe2 under a high magnetic field that creates discrete LLs, separated by the cyclotron energy Ec. B lifts the degeneracy of the K and K' bands through the Zeeman energy $EZ = g * \mu BB$, where μB is the Bohr magneton and g^* is the effective Landé g-factor.

These findings complement recent progress in strain engineering of van der Waals heterostructures on piezoelectric substrates, where tunable electrical properties were demonstrated via dynamic lattice deformation [1], and leverage our previously reported method for growing high-quality $MoTe_2$ crystals with long-lived excitonic species [2,3]. Together, these advances establish a pathway for photonic integration of monolayer $MoTe_2$ with tunable optical and quantum transport properties. The demonstrated control over contacts, doping, and exciton behavior positions this system as a versatile building block for hybrid quantum light-emitting and electrically driven two-dimensional optoelectronic platforms.

From Light to Matter: Controlling Excitons for Quantum Innovation

Libai Huang[1*]

[1] Purdue University, West Lafayette, IN, 47907, USA
[*]corresponding author: libai-huang@purdue.edu

Abstract: I will discuss our latest discoveries on how we manipulate exciton quantum phases in two-dimensional moiré superlattices. These superlattices have the potential to serve as solid-state analogues to ultracold gases for quantum simulations. We applied transient photoluminescence and ultrafast reflectance microscopy to image non-equilibrium exciton phase transitions.

At the most fundamental level, transport of energy carriers (such as electrons and excitons) in the solid state is determined by their quantum wavefunctions and the interactions with their surroundings. However, studying this transport at the quantum level is challenging because excitons lose their quantum coherent properties extremely quickly, on the subpicosecond timescale, and are confined to nanometer-scale regions. To truly probe transport in the quantum regime, we need experimental techniques that capture both their spatial and temporal dynamics.

To tackle this challenge, my research group has developed advanced imaging techniques that combine optical microscopy with ultrafast spectroscopy. These methods allow us to visualize exciton transport at the nanoscale to the mesoscale across a wide range of temperatures. I will discuss our latest discoveries on how we manipulate excitons in two-dimensional moiré superlattices. These superlattices have the potential to serve as solid-state analogues to ultracold gases for quantum simulations. A key open question is the coherence and dynamics of the quantum phases arising from photoexcited moiré excitons, particularly amid dissipation. Here we use transient photoluminescence and ultrafast reflectance microscopy to image non-equilibrium exciton phase transitions. Counterintuitively, experimental results and theoretical simulations indicate that strong long-range dipolar repulsion freezes the motion of the Mott insulator phase for over 70 ns. In mixed electron–exciton lattices, reduced dipolar interactions lead to diminished freezing dynamics. These findings challenge the prevailing notion that repulsion disperses particles, whereas attraction binds them. The observed phenomenon of frozen dynamics due to strong repulsive interactions is characteristic of highly coherent systems, a feature previously realized exclusively in ultracold gases.

Quantum optical description of nanophotonic systems

Johannes Feist[1,2*]

Abstract: We show how to obtain a quantum-optics like description in terms of a few discrete "cavity" modes for the quantum light-matter interaction in arbitrary nanophotonic structures, while still taking into account the full nanophotonic complexity of light propagation and emission.

The control of the interaction between quantum emitters using nanophotonic structures holds great promise for quantum technology applications, while its theoretical description for complex nanostructures is a highly demanding task as the electromagnetic (EM) modes form a high-dimensional continuum. We here introduce an approach that permits a quantized description of the full EM field and its coupling to various emitters through a small number of discrete modes, without any restrictions on the emitter level structure. The low computational demand of this method makes it suitable for studying dynamics for a wide range of parameters. We illustrate the power of our approach for various hybrid metallodielectric structures.

Additionally, we show how to extend the approach to give direct access to photon correlations of the emitted light resolved in space, frequency, time and polarization for arbitrary electromagnetic environments. While experimental measurements of photon correlations have become routine in laboratories, theoretical access to these quantities for the light generated in complex nanophotonic devices remains a major challenge. Current methods are limited to specific simplified cases and lack generality. Within the macroscopic QED framework, we develop a practical tool to compute electric field correlations for complex quantum systems by including lossy two-level systems that act as field detectors within the system. The method correctly accounts for fully retarded light propagation to the detectors. We demonstrate the effectiveness and robustness of the proposed technique by studying the photon correlations of one and two emitters in close proximity to a plasmonic nanoparticle. The simulations show that even in these relatively simple configurations, the light statistics exhibit a strong angular dependence. These results highlight the importance of going beyond conventional quantum-optical approaches to fully capture the analysed physical effects and enable the study of the quantum light generation in realistic nanophotonic devices.

Thin Film Materials and Device Platforms for Quantum Photonics and Sensing Applications

Yong P. Chen[1,2,*]

[1]Purdue University, USA
[2]Aarhus University, Denmark
[*]corresponding author: yongchen@alum.mit.edu

Abstract: Functional optical thin film materials that can be incorporated into various heterostructures and (hybrid) device platforms are important for a wide range of quantum photonics and sensing applications. Of particular interests are 2D/thin film insulators/semiconductors that host optically active (quantum) emitters/sensor platforms such as 1) color centers, esp. NV-like spin defects; and 2) excitons, including Rydberg excitons that may also feature strong nonlinear interactions.

We will present our recent work developing and characterizing various thin film materials and device platforms for quantum photonics and sensing applications based on 1) spin defect centers in (exfoliated) h-BN, particularly with spin-selective excitations[1], exhibiting potentials in sensing magnetic fields and magnetic materials; and 2) exciton/Rydbergs in 2D/thin film semiconductors such as (exfoliated) transition metal dichalcogenides (TMDCs) and (synthesized) Cu_2O (grown by oxidization of Cu thin films/foils)[2,3], exhibiting potentials in sensing dielectric environment and other phase transitions in materials.

We acknowledge partial support from DOE, DOD, NSF, and Villum Foundation.

Abstract: Near-infrared quantum emitters have huge potentials in quantum technologies, especially for integrated photonics. By coupling PbS/CdS quantum dots to a CMOS-compatible epsilon-near-zero index substrate, we show improved emission directionality, increased saturation intensity and a 30-fold lifetime reduction, leading the way to advanced quantum optics applications.

Single photon emitters with near-infrared (NIR) emission at telecom wavelengths show significant potentials for optical quantum applications, specifically for integrated quantum photonic sensing and computation. Recent investigations related to quantum emitters demonstrate increased emission when they are coupled to an epsilon-near-zero (ENZ) environment. This can be attained by structural engineering of metamaterials and/or cut-off frequency of collection channels [1-4]. Further effects associated with the coupling to an ENZ environment include altering the emission directionality of radiative antennas due to electric field expulsion effects [5-7].

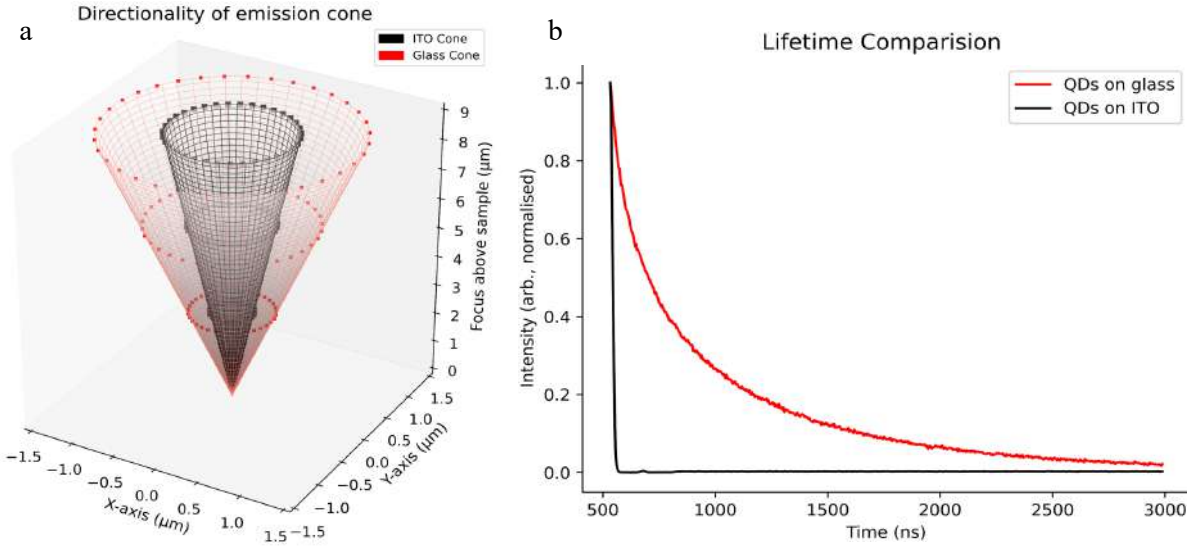

Figure 1: Modified emission properties of PbS/CdS quantum dots (QDs) via coupling to an epsilon-near-zero substrate. a) Emission cones for both QDs on indium tin oxide (ITO – black cone) and glass (red cone). An angular emission narrowing from 17.5° to 8.8° is reported. b) Comparison of emission lifetime for QDs on ITO vs QDs on glass. Quantum emitters placed on the ITO thin film display a thirty-fold reduction of emission lifetime if compared to emitters on the glass film.

Expanding on these findings, we experimentally tested emission and directionality improvements in quantum emitters coupled to an ENZ substrate. Specifically, we analyzed PbS/CdS (core/shell) quantum dots (QDs) on an indium tin oxide (ITO) substrate, where the broad crossover wavelength (1320 nm) closely aligns with the QD emission peak at 1350 nm. This coupling led to an increase in the relative intensity by a factor of four due to a narrowing of the emission cone from 17.5° to 8.8° for QDs on glass compared to those placed on ITO, respectively (see Fig.1,a). Additionally, a thirty-fold reduction in emission lifetime was recorded (see Fig.1,b) by comparing the same systems.

These results highlight the largely unexplored potential of transparent conductive oxides (TCOs) in integrated quantum optics applications at telecom wavelengths. With their ultra-fast optical nonlinearities, CMOS compatibility, and exceptional thermal and optical durability, TCOs can provide a robust foundation for key applications in all-optical photonics and integrated quantum optics [8, 9].

Integration of single-defect carbon nanotube photon sources into waveguide circuits for quantum applications

Abstract:
In this research, functionalized carbon nanotube single photon emitters are implemented in waveguide circuits for the development of chip-integrated quantum photonic applications at room temperature. Carbon nanotubes are drop-coated or deterministically positioned on waveguide cavities after which autocorrelation study and photoluminescence spectra demonstrate both single photon propagation and cavity enhancement.

Currently a rapidly growing research field at the heart of many emerging technologies, photonic integrated circuits (PIC) have enabled the realization of mass-manufacturable, stable, resilient and compact optical circuits for a large panel of applications. Environmental monitoring and telecommunications systems involving PICs are already commercially available and there is strong evidence that integrated quantum photonics applications will soon follow that path. However, scalable chip-integration of quantum light sources generating single photons at room temperature remains limited with current technologies [1]. Carbon nanotubes (CNTs) have been proposed as promising candidates but have yet to be demonstrated in functional quantum photonics circuits due to the stringent conditions indispensable for producing and manipulating photons with pure states [2,3]. To overcome these issues, a rigorous approach is required to find and implement on-chip solutions for proper CNT excitation and emission, waveguide coupling, further spectral filtering and adequate optical modulation [1]. The objective of this research is to develop such tools as a technological starting point for CNT-based quantum PIC applications.

Firstly, as a result of thorough excitonic analysis involving spectral, lifetime, polarization, brightness and autocorrelation measurements, (6,5) carbon-nanotubes with single defects have firstly been identified as a promising choice for chip integration [3]. A photonic integrated circuit characterization platform and associated automation algorithms have subsequently been realized and implemented to a photoluminescence measurement set-up for CNT circuit coupling analysis. Following, different types of photonic circuit fabrication processes have been developed and optimized in cleanroom. These circuits technologies have been used to realize a large variety of photonic nanostructures such as couplers, resonators, interferometers, waveguides, gratings or cavities.

CNTs have then been implemented both by drop-casting or deterministic positioning techniques and coupled to these circuits on evanescently coupled grating cavities that allow Purcell effect enhancement, demonstrating a sharpened and magnified photon-emission into waveguides. Finally, we also demonstrated single-photon emission at room temperature and waveguide photonic coupling of a deterministically positioned CNT in a low fluorescence lithium niobate waveguide circuit, readily available for electro-optical modulator processing. This way, we hope to demonstrate the first functional quantum PIC application that strives from CNT emission properties.

Quantum fluctuations in the propagation of light through a dielectric medium

Arghadip Koner[1*], Sricharan Raghavan-Chitra[1], and Joel-Yuen Zhou[1*]

[1]Department of Chemistry and Biochemistry, University of California, San Diego, United States
[*]corresponding author: akoner@ucsd.edu

Abstract: Classical linear optics traditionally dictates light propagation through media. However, in high-Q cavities, rare quantum vacuum fluctuations imprint additional information about the medium, beyond the linear susceptibility, directly onto the linear response, revealing novel quantum corrections to the classical framework and enabling new quantum-enhanced insights into material response.

Light is traditionally understood to propagate through dielectric media according to classical linear optics, where the material's refractive index, determined by its linear susceptibility, dictates the propagation and intensity of light. In the field of molecular polaritonics, this translates to the success of transfer matrix-based methods in modeling the linear spectra of the cavity strongly coupled to N=10^6-10^{10} molecules. This observation stands in stark contrast to the quantum electrodynamics (QED) perspective, which predicts quantum and nonlinear effects in the polaritonic dynamics due to the strong interaction between the light and the matter.

We solve this apparent contradiction in molecular polaritonics by modeling the polaritonic linear response using input-output theory. By mapping the polariton problem to a quantum impurity model, we show that in the thermodynamic limit ($N\to\infty$), the polaritonic linear response is completely captured by the linear susceptibility of the molecular ensemble, leading to the success of classical optics. We further obtain a general expression for the linear response of molecular polaritons, which evidences that this classical optical description is only correct in the thermodynamic limit and, in fact, there is a previously overlooked hierarchy of (finite-size) $1/N$ corrections containing signatures of nonlinear molecular processes like Raman scattering mediated by the quantum vacuum fluctuations of the cavity. These corrections lead to new features in the linear spectra beyond those predicted by classical optics, but are small due to an emergent separation of timescales in polariton dynamics and hence excluded from the spectra due to limited resolution in the low-Q cavities typically used in the experiments.

We further demonstrate that this departure from the conventional framework of light propagation is more general and becomes essential when photons are confined in a high-Q cavity, rare quantum vacuum fluctuations, and quantum correlations between the light and the matter can imprint additional information about the medium, beyond what is captured by the linear susceptibility, directly onto the electric field amplitude.

To reveal this effect, we studied a high-Q microtoroid resonator with analytes adsorbed on its surface and probed via a tapered optical fiber. The prolonged photon lifetimes and three-dimensional confinement permit a long interaction window, allowing the light field to "wait" for those entropically unlikely quantum vacuum fluctuations to occur and to imprint Raman signatures onto the linear absorption signal. This pathway to retrieving Raman details through linear absorption offers exciting possibilities in sensing technology, eliminating the need for intense light sources directly shining on the sample or complex phase matching and enabling straightforward implementation, reliable benchmarking, and straightforward signal enhancements. To underscore its experimental feasibility, we rigorously perform noise analyses using state-of-the-art technology, demonstrating that the observed signal clearly rises above the noise floor, indicating immediate applicability.

Unlike other weak-coupling phenomena, such as Purcell enhancement, which rely on increased decay pathways, our approach leverages photon confinement and long-lived modes to access rare, vacuum-mediated processes in the linear regime. This work expands the conceptual boundaries of weak-coupling cavity QED and opens new directions in linear and nonlinear optics, nanophotonics, precision spectroscopy, and quantum-enhanced sensing.

Abstract

In our work, we analyze phase transitions in single VO_2 nanoparticles, revealing statistical variations in their transition temperature, steepness, and phase stability. We also demonstrate a multilevel optical memory near room temperature. Our findings clarify nanoscale hysteresis mechanisms and establish VO_2 nanoparticles as a promising platform for advanced nanophotonic devices.

1 Introduction

Phase-change materials, known for their ability to transition between solid phases with distinct optical properties, are crucial for advancements in nanophotonics. They enable applications such as tunable metasurfaces and integrated photonic memories, where optical memory states are controlled by materials exhibiting multiple phases. Vanadium dioxide (VO_2) represents an efficient platform for volatile memory applications such as neuromorphic computing and reconfigurable metasurfaces due to its insulator-to-metal transition (IMT) at approximately 68°C. Single-crystal VO_2 nanoparticles (NPs) exhibit phase transitions at even lower temperatures, making them highly promising for enhancing bit compactness and reducing energy consumption. The coexistence of insulating and metallic phases at nanoscale offers an opportunity to expand the memory capacity of VO_2-based devices. However, previous studies have focused on VO_2 films and NP ensembles rather than individual NPs, which are essential for practical applications in optical data storage and tunable metasurfaces [1, 2].

In our study, we employ scanning transmission electron microscopy techniques to investigate phase transitions in individual VO_2 NPs [3]. Using electron energy loss spectroscopy (EELS) and annular dark-field (ADF) imaging, we investigated the spatial distribution of coexisting phases and hysteretic behaviors within NPs in real time. By analyzing hundreds of VO_2 NPs, we discovered that the transition width (the temperature range required to completely switch a NP from one phase to another) of IMT is three times greater than that of MIT. During backward MIT, on the other hand, the transitions of the NPs are very abrupt (narrow MIT widths) but spread over a larger temperature window. These results help to explain the behavior of polycrystalline VO_2 films, where the grain structure influences macroscopic phase transition properties. Leveraging the observed phase coexistence in VO_2 NPs, we also demonstrated a multi-level optical memory device. By controlling the IMT termination temperature, we were able to stabilize different transmission levels close to room temperature. While individual NPs do not seem to support stable coexisting phases at low temperatures, we show that carefully designed NP ensembles can enable persistent memory states. These findings strengthen the case for VO_2 as a viable material for low-power, high-density optical data storage and processing applications, neuromorphic computing, and integrated photonic circuits.

Abstract: The ability to program optical devices using non-volatile phase change materials with low losses is of importance in a wide range of applications. An overview will be presented of the developed materials platform together with proposed strategies of designing programmable devices using a deep learning neural network.

Programmable photonics using non-volatile phase change materials (PCMs) holds tremendous potential for next-generation technologies such as photonic computing, AI and quantum circuits [1]. Our group has introduced antimony selenide (Sb_2Se_3) as an ideal material for programmable silicon photonics [2,3]. Sb_2Se_3 offers low losses at near-infrared wavelengths including the telecommunications bands, a refractive index closely matched to silicon allowing for seamless integration into silicon-on-insulator (SOI) platforms, and a moderate crystallization temperature of around 200°C. Reversible switching over one million cycles is in principle possible [4], indicating endurance suitable for a range of applications requiring moderate numbers of switching cycles.

A topic of considerable interest is whether it is possible to achieve freeform control of light in integrated platforms similar to what is achieved using wavefront shaping in free space optics. The equivalent of a spatial light modulator would be the implementation of digitally programmable multi-port devices based on multimode interferometer (MMI) devices [3,5]. We have proposed to use patterns of weakly scattering perturbations imprinted onto the device to effectively mix modes and produce a fully programmable unitary operation. In order to find the appropriate patterns, our team has been able to successfully apply methods from neural network inverse design as a route alternative to more traditional topology optimization [5]. Recently we have implemented a neural-adjoint approach, where a forward surrogate network is used in combination with a gradient optimization scheme [6]. We successfully designed unitary operators using a coupled-waveguide array (CWG). The CWG holds advantages over MMIs by reducing the number of internal modes, thus reducing the outcoupling challenge, however at the cost of a slightly larger footprint.

The role of the thickness of the PCM used in SOI platforms is another parameter of considerable importance. In a series of systematic experimental studies [7] we look at the effect of increasing the thickness of Sb_2Se_3 from 20 nm – 100 nm thickness (Figure 1). A large increase in optical phase shift is achieved by increasing the thickness, resulting in a switching length over which π phase-shift can be achieved (L_π) of around 5 μm. The reduced phase shift comes at the cost of increased losses in the crystalline phase due to scattering by polycrystalline domains.

When applied to the digital programming of a MMI device, the number of pixels can be reduced down from above 30 pixels for the thinnest films to below 10 pixels for the thicker Sb_2Se_3 layers, thus indicating a potential reduction in complexity and write times for programmable devices.

In conclusion, our work combines experimental and theoretical advances in programmable photonic devices exploiting low-loss phase change technology and direct optical writing. Both coupled-waveguide and multimode interference based programmable devices hold promise as an alternative for existing interferometer meshes.

Tunable conducting polymer mid-IR plasmonic microantenna arrays

Pravallika Bandaru, Mohammad Shaad Ansari, Aleksandr Poliakov, Suraya Kazi, and Magnus P. Jonsson*

Laboratory of Organic Electronics, Department of Science and Technology (ITN), Linköping University, SE-601 74 Sweden
*corresponding author: magnus.jonsson@liu.se

Abstract: Actively tunable mid-IR plasmonic antennas show prospects for a broad range of applications, which rely on efficiently switchable materials. Here, we investigate the tunable mid-IR plasmonic response of conducting polymer microantenna arrays and demonstrate efficient and reversible on/off switching capability.

Summary: Although noble metals like gold and silver show strong plasmonic resonances, their tunability is limited due to fixed carrier density. Recently, Chen *et al*., introduced PEDOT (poly[3,4-ethylenedioxythiophene]) based dynamically tunable conducting polymer nanoantennas exhibiting plasmonic resonances in the near-IR regime. [1] These resonances could be chemically or electrically switched on/off by controlling the polaronic charge carrier concentration of the polymer, which switches the polymer between metallic (oxidized) and dielectric (reduced) states. [2,3]

Here, I will present our recent results on PEDOT microantenna arrays with plasmonic resonances at longer wavelengths in the mid-IR spectral range. [4] We find that the antenna arrays can provide clear asymmetric Fano-type plasmon resonances with peak position controlled by antenna size or array periodicity. Furthermore, we demonstrate complete and reversible chemical on/off switching of the mid-IR plasmonic response. This study can contribute to the developments in applications such as active mid-IR beam steering, active thermal sources, and the adaptive radiative cooling technology.

Programmable Polariton Nanophotonics with Phase-Change Materials

L. Conrads[1], and T. Taubner[1,*]
[1] I. Institute of Physics (IA), RWTH Aachen University, Germany

[*]corresponding author: taubner@physik.rwth-aachen.de

Abstract: We exploit the non-volatile insulator-to-metal transition of the plasmonic phase-change material In_3SbTe_2 for optical programming surface polariton resonators on polar crystals and doped semiconductors. The strongly confined resonance modes are investigated with scanning near-field optical microscopy. This study enables rapid prototyping of reconfigurable polariton resonators even with anisotropic 2D-materials.

Tailoring light-matter interaction is essential to realize nanophotonic components and can be achieved with polaritons, an excitation of photons coupled with the collective (plasmon) oscillation of charge carriers in metals and semiconductors or with phonons in polar crystals and 2D-materials leading to Surface Plasmon Polaritons (SPPs) and Surface Phonon Polaritons, (SPhPs), respectively. [1] Based on a reversible change in their refractive index [2], Phase-change materials (PCMs) enabled the modification of SPhPs propagation [3] and the on/off switching of SPhP resonators [4]. While ultraconfined resonances are in principle possible by restricting these polaritons to cavities, the directing writing of launching and resonator structures in PCMs has been so far elusive. Recently, the plasmonic PCM In_3SbTe_2 (IST) was introduced for programmable nanophotonics due to the ability of reversibly switching from an amorphous dielectric to a crystalline metallic state in the infrared. [5] This material IST has also enabled the fast fabrication of infrared metasurfaces for tailoring thermal emission [6] and infrared beam shaping on demand [7]. Here, now apply IST for the creation and modification of polaritonic cavities.

We investigate surface phonon polariton resonators optically programmed via laser irradiation in the plasmonic PCM IST on top of the phonon polariton hosting polar crystal silicon carbide with scanning near-field optical microscopy (s-SNOM). Circular resonators are reconfigured in their diameters to shift the resonance modes accordingly. In addition, smaller resonator diameters facilitate stronger field confinements up to a value of $\lambda/35$. The vast flexibility of direct programming resonators is highlighted by investigating square and triangular resonators featuring complex field distributions according to their unusual shape.[8]

Moreover, we apply the same principle to study infrared SPPs on doped semiconductors CdO and InAs covered with thin layers of PCMs. Conventionally, the small polariton confinement and the dispersion close to the light line aggravate real-space observation of SPPs in bulk materials in the infrared. Increasing the SPP confinement with thin dielectric layers modifies the SPP dispersion and allows for direct fabrication of resonators by locally switching the PCM.[9]

The concept of directly programming polariton resonators with PCMs without cumbersome fabrication techniques facilitates sub-wavelength polaritonic devices such as biosensors or optical data storage systems. The combination of PCMs with polariton-hosting materials can be easily extended to 2d hyperbolic and anisotropic crystals featuring lower losses and higher polariton propagation lengths. In most recent work, we investigate hyperbolic phonon polaritons in hBN above optically programmed resonator structures with IST and studied the different resonance modes. Polariton lensing is demonstrated with focusing structures and the focal point is tuned by reconfiguring the IST structures below.

Zero-static-power photonics using chalcogenide metacoatings with engineered volatile and non-volatile transitions

Behrad Gholipour[1*], Avik Mandal[1], Joshua Perkins[1], Mahirah Zaini[1], Abbas Sheikh Ansari[1], Yihao Cui[1] , Kwanghyun Kim[1]

[1]Nanoscale Optics Lab, Electrical and Computer Engineering Dept, University of Alberta

Abstract: We show that non-resonant, subwavelength nanoscale patterning that enables dispersion engineering of chalcogenide glasses through lithography-free, bottom-up growth and patterning techniques, paves the way to the realization of metacoatings with tunable optoelectronic properties without any stoichiometric changes to chemical composition through glancing angle deposition and interlayer nanostructuring techniques.

Training and running large artificial intelligence (AI) and machine learning (ML) models as well as emerging large language models (LLM's) and the push towards online learning, inference and, more broadly, artificial general intelligence (AGI), require staggering amounts of energy to train in years to come.

This is largely due to current hardware architectures' reliance on volatile transitions (for signal routing, switching and processing) such as carrier modulation and thermo-optic effects in silicon and its derivatives, transparent conducting oxides, and ferroelectrics. This creates an intense need for active thermal load management as volatile transitions require power to be maintained to the device at all times. This is a major obstacle to scaling up to increasingly dense chips and racks in hyperscale AI-centric data centres that would need ever more spacious rack layouts or energy-intensive cooling solutions to deal with the generated heat resulting from the volatile nature of all transitions used on the chip level. Going forward, zero-static power architectures are needed on the fundamental processing and memory component layers to enable scalable and environmentally sustainable systems.

The most scalable non-volatile transition available to us in nature is the phase transition commonly observed in chalcogenide semiconductors that relies on the reversible atomic rearrangement of an alloy using thermal, electrical, or optical stimuli between a reflective high conductivity crystalline and a transparent highly resistive amorphous phase. To this end, here we show that using phase change metacoatings, subwavelength thickness layers of chalcogenide phase change alloys nanostructured through bottom-up growth techniques can enable control of static optical properties as well as volatile and non-volatile transitions, with a view to photonic integrated circuits that will be the workhorse of emerging hyperscale AI-centric data centers. Notably, in these architectures, the mitigation of high insertion losses when introducing many of these alloys to the vicinity of waveguide platforms due to their inherent absorption across this band has resulted in devices with larger than necessary lateral footprints and/or poor modulation contrasts and an incessant search for low-loss/high switching contrast alloys.

Chalcogenide phase-change materials (PCMs) are high refractive index dielectrics across the visible/telecom band. We show that by making use of this high refractive index, mach-zender modulators (MZM's) with built-in memory functionality and zero static power consumption,

capable of 2π phase shifts, can be realized with active lateral footprints down to 10 μm. Furthermore, the patterning of these alloys on the subwavelength scale has demonstrated high-quality factor optically resonant devices under the umbrella of metamaterials and metasurfaces. In this realm, subwavelength nanostructuring can also offer non-resonant dispersion engineering of a given dielectric/plasmonic material. We show that non-resonant, lithography-free, subwavelength patterning, which enables dispersion engineering of chalcogenide glasses, paves the way to the realization of alloys with tunable static optoelectronic properties.

We then go on to show that volatile and non-volatile optical transitions can be tuned and engineered in PCMs without the need for stoichiometric changes to chemical composition through glancing angle deposition and interlayer nanostructuring, enabling ultra-compact phase/intensity modulators with tunable insertion losses.

Abstract: In this talk, I will discuss my group's recent work in the area of nonlocal metasurfaces, with an emphasis on reconfigurability and temporal transformations. The field of metasurfaces has been blossoming in recent years, but the need for fast and diverse reconfigurable response remains an outstanding challenge to be competitive as a photonic platform. In this context, we have explored various approaches, from thermal to electro-optical and all-optical modulations, leveraging the long-range collective interactions stemming from nonlocal metasurface designs to facilitate the reconfigurability control.

Metasurface tuning based on carrier manipulation

A. Tognazzi[1,2,*]

Abstract: Tuning the optical response of nanoscale objects can be achieved through different carrier types. We demonstrate two distinct approaches: all-optical modulation via free-carrier injection in silicon metasurfaces and iontronic tuning in organic mixed conductors. These strategies enable fast, broadband, and energy-efficient control, paving the way for next-generation tunable photonic devices.

Metasurfaces provide a versatile platform for shaping electromagnetic fields at the subwavelength scale, enabling control over polarization, wavefront, and nonlinear effects. However, achieving tunability in their optical response remains challenging due to the nanoscale dimensions of their building blocks. The ability to induce abrupt changes in phase and amplitude is essential for applications such as focusing, polarization control, nonlinear frequency conversion, and wavefront manipulation. Various strategies have been explored to achieve nanoscale control of metasurface behavior, leveraging liquid crystals, phase-change materials, and carrier excitation [1]. Among the fastest tuning mechanisms, electrical and optical stimuli offer promising solutions; however, achieving a large modulation depth often comes at the cost of slower response times. Here, we present two distinct approaches that exploit different types of carriers—electrons and ions—to achieve tunability with both high speed and large modulation depth. First, we demonstrate all-optical tuning in silicon metasurfaces by controlling free-carrier dynamics, enabling ultrafast modulation of optical properties. Second, we introduce iontronically controllable PEDOT:PSS films to create spatially varying refractive index profiles, allowing for phase control without the need for nanoscale patterning. Our results pave the way for next-generation tunable photonic devices, combining high-speed operation with energy efficiency and broad spectral tunability.

First, we employ free carrier excitation in Si to perform all-optical modulation in a high-contrast index grating (HCG). The HCG linear spectral properties are design by means of rigorous coupled wave analysis (RCWA) to obtain a sharp spectral feature, related to a guided mode resonance, in the third telecommunication window. The sharp spectral feature rigidly shifts upon carrier excitation through a pump beam in the Si absorption region, giving rise to large reflectivity modulation as shown in Fig. 1a. The spectral and temporal response can be described by means of a coupled rate equation model, to describe the out-of-equilibrium dielectric constant modifications, and RCWA to take into account the HCG geometry [2].

As an alternative approach to show the crucial role that carrier manipulation plays in tuning nanoscale devices, we now focus on a different type of carriers, namely positive ions in PEDOT:PSS. By properly arranging the electrical contacts in a three-terminal transistor configuration it is possible to control the refractive index of the material by inducing a migration of positive ion carriers [3]. Unlike previous capacitive configurations, our approach allows to induce a spatially varying control electric field between the source and drain electrodes, which results in a spatially varying refractive index (as shown in Fig. 1b). It is thus possible to achieve

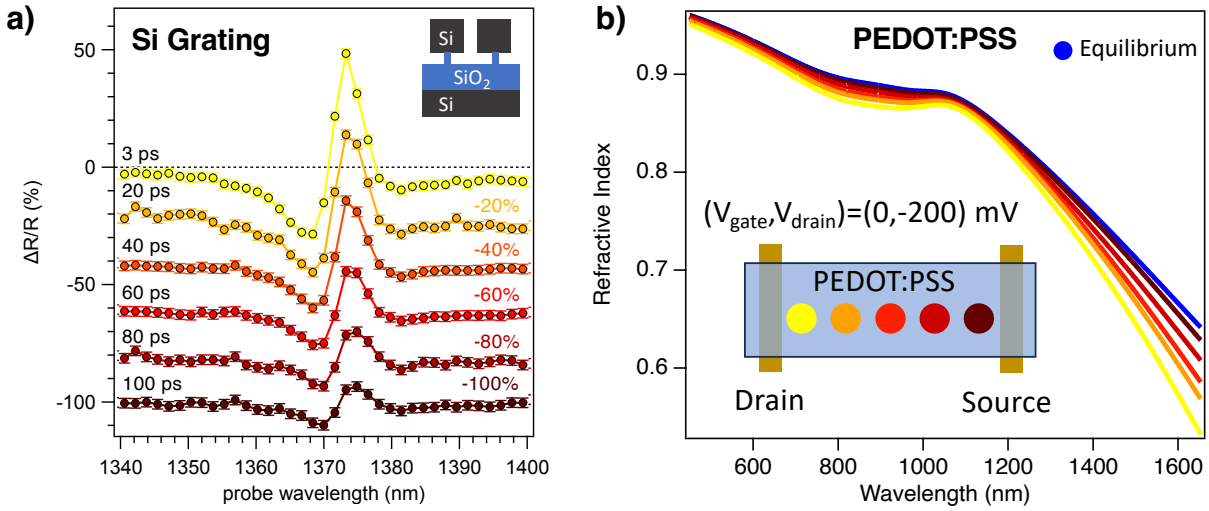

Figure 1: a) Experimental differential reflectivity as a function of the probe wavelength at different time delays. The inset display the cross-section of the metasurface. b) Refractive index real part as a function of the wavelength at four different positions between the source and drain electrodes. The inset shows the top view of the device.

a control over the phase of the electric field through the PEDOT:PSS film in a dynamic way without any patterning by changing only the drain potential V_{drain}.

Our findings enable next-generation tunable photonic devices with high speed, energy efficiency, and broad spectral control.

Dynamic Optical Control with VO_2 Metasurfaces

R. Camacho-Morales[1]

[1]ARC Centre of Excellence for Transformative Meta-Optical Systems (TMOS), Department of Electronic Materials Engineering, Research School of Physics, The Australian National University, Canberra, ACT 2600, Australia
*rocio.camacho@anu.edu.au

Abstract: We design reconfigurable VO_2-based metasurfaces for tuneable optics and imaging. By leveraging the phase transition of VO_2, we achieve a high transmission contrast ($\Delta T = 0.73$) at telecommunication wavelengths and demonstrate switchable imaging between phase contrast and brightfield modes, enabling dynamic control for advanced optical and computational imaging applications.

Metasurfaces are planar arrays of nanostructures engineered to manipulate electromagnetic waves with exceptional control. Their ability to tailor optical responses at the nanoscale has garnered significant attention. However, conventional metasurfaces face a fundamental limitation: their optical properties are fixed upon fabrication, observing a single optical response. To address this constraint, extensive research has focused on developing reconfigurable metasurfaces that dynamically control electromagnetic waves in response to external stimuli. Various tuning mechanisms have been explored, including carrier doping, mechanical deformation, and phase transitions [1].

In our work, we utilise vanadium dioxide (VO_2), a phase-change material, to design reconfigurable metasurfaces. When heated above its critical temperature (T_c = 68°C), VO_2 undergoes a transition from an insulating to a metallic state inducing a significant change in its optical properties, particularly in the near-infrared spectral range. This transition is volatile, as VO_2 naturally returns to its insulating state upon cooling to room temperature [2].

In the first part of my presentation, I will present our results on a VO_2-based metasurface designed for tuneable transmission. Specifically, I will discuss our approach to maximising the transmission contrast ($\Delta T = T_i - T_m$) of nanostructured VO_2 at telecommunication wavelengths. To achieve this, we developed numerical tools for electromagnetic simulations and structural optimisation, establishing the fundamental transmission limits for various geometries, including multilayer stacks and high-dimensional nanostructures. Our optimised design achieved a maximum transmission contrast of $\Delta T = 0.73$, with the corresponding VO_2 structure shown in Figure 1a. These findings provide a benchmark for future VO_2-based tuneable transmission filters [3].

In the second part of my presentation, I will introduce a VO_2 metasurface designed for switchable imaging, enabling dynamic control between phase contrast and brightfield imaging. Brightfield microscopy is a widely used imaging technique for examining microscopic samples that create contrast through amplitude variations via absorption. However, it cannot visualize phase variations in transparent samples, such as biological specimens. To address this limitation, we leverage the phase transition of VO_2 to design a metasurface that converts phase variations into intensity variations when VO_2 is in its insulating state. In contrast, brightfield imaging is enabled when VO_2 transitions to its metallic state. The metasurface consists of a silicon photonic crystal deposited on a VO_2 thin film. The photonic crystal is composed of a hexagonal array of cylindrical holes etched into an

amorphous silicon layer, supported by a quartz substrate (Figure 1b). This structure enables dynamic switching between different imaging modalities, highlighting the potential of VO_2-based metasurfaces for advanced imaging applications.

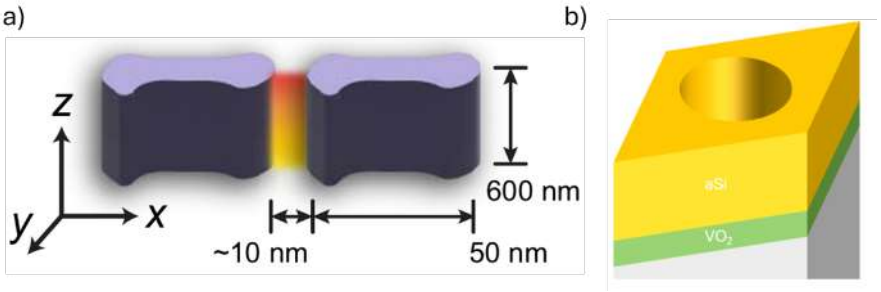

Figure 1. Optimal geometries of VO_2 nanostructures obtained for a) maximising transmission contrast ΔT and b) switchable imaging.

These results demonstrate the potential of VO_2-based metasurfaces for dynamically reconfigurable optical systems, paving the way for advancements in tuneable optical devices and computational imaging.

Abstract: To overcome the limitations of silicon, hybrid integration of materials is required including ferroelectric oxides to develop efficient Pockels based optical modulators.

Silicon photonics has emerged as a promising platform to address future challenges in many applications, including data communications, sensing, and optical communications, among others. However, the properties of silicon alone are not enough to overcome key limitations related to speed, power consumption, and scalability. In particular, silicon exhibits strong two-photon absorption (TPA) at telecom wavelengths and is centrosymmetric, which limits the use of its nonlinear optical properties, such as the Kerr and Pockels effects. To address these challenges, new strategies have focused on integrating novel materials into the silicon photonics platform.

The presentation will explore recent developments in materials with optical properties that complement those of silicon and silicon nitride. It will also highlight the integration of ferroelectric oxides including Lithium Niobate and doped zirconia (ZrO_2), into silicon photonics platforms. In particular, doped zirconia, which is compatible with Si technology, offers several advantages: it exhibits low propagation loss, a large bandgap energy that prevents TPA, a wide transparency window ranging from ultraviolet to mid-infrared, and supports both Kerr and Pockels effects, along with light emission[1,2]. These properties make doped zirconia a promising candidate for addressing key challenges in silicon photonics.

Abstract:

Chalcogenide phase change materials are being actively developed to tune the optical response of 3D displays, beam steering, and optical trap devices. We are studying dynamic control of metasurfaces through three different types of resonances, namely dielectric, plasmonic, and interband.

We aim to develop programmable metasurfaces composed of meta-atoms that can be progressively tuned across a full π-rad phase delay. We envision these materials finding widespread applications in 3D displays, beam steering devices, and dynamic optical traps for controlling cold atom clouds. The resonant frequency of a meta-atom can be controlled by either changing its size and geometry or by changing the intrinsic optical properties of the material from which it is composed. This talk focuses on the latter by exploiting dielectric, plasmonic, and interband resonances within chalcogenide phase change materials[1-6].

Many sulfide, selenide, and telluride materials (chalcogenides) exhibit multiple stable structural states at room temperature[7]. Structural transitions between these states can lead to large changes to the electronic band structure, which in turn produces refractive index contrast. In comparison to the negligible change in refractive index of oxides, like SiO_2, which is stable in glassy and crystalline forms (quartz), the refractive index contrast in phase change chalcogenides can be enormous. For example, the mid-infrared refractive index of the phase change material, $Ge_2Sb_2Te_5$ (GST), goes from ~4 to ~6 when it crystallizes[8], and the crystallization can occur in just 500 ps[9]. Clearly, these properties make chalcogenide phase change materials attractive for tuning and/or programming photonic devices.

We have now discovered, designed, and optimized a wide range of phase change materials that can be used to tune optical devices. In principle there are fundamentally two ways that these materials can be used in optical devices: (1) by using the change in their optical absorption (imaginary component of refractive index), or (2) by exploiting their change in the real component of refractive index. For metasurfaces composed of resonant meta-atoms, we have focused on developing ways to tune the real component of refractive index. Typically, we have been patterning these materials into meta-atoms and changing their dielectric resonances at below band gap energies via crystallization and amorphisation[2,5]. However, several tellurides, including elemental tellurium, are now providing a new option with interband resonances, using above bandgap light.

This talk will introduce our progress moving from infrared dielectric resonances in the common narrow bandgap tellurides, such as GST, to the discovery of Sb_2S_3, which has a band gap sufficiently large to allow dielectric resonances in the visible spectrum[1]. Finally, we will reconsider narrow bandgap tellurides, which can exhibit interband plasmonic-like resonances in the visible spectrum[10]. The presentation will introduce the intrinsic physical traits of these materials that allow them to support different resonances, and it will also show examples and demonstrations of how we exploited these resonances in tuneable metasurface devices.

Abstract: Photonic processors offer a route to analog computation with ultra-low latency and high efficiency. By combining nonvolatile optical materials (both phase-change and magneto-optic) with integrated photonics, we enable scalable photonic compute-in-memory architectures for high-speed matrix-vector operations in machine learning applications.

Photonics information processing strategies offer the unique ability to perform analog computation with ultra-low latency and high efficiency. However, designing compact and reconfigurable photonic architectures which scale well is a challenge. The combination of bistable optical materials (such as phase-change materials like $Ge_2Sb_2Te_5$) and integrated photonics is a promising approach which enables nonvolatile optical memory on-chip with low drift, compact footprint, and high-speed readout. This talk will focus on developing robust and scalable photonic memories using phase-change and magneto-optic materials (Ce:YIG)—together with wavelength division multiplexing and "in-memory" computing techniques—to enable high-speed matrix-vector operations for machine learning applications. Our work addresses key limitations in photonic compute-in-memory through two complementary nonvolatile optical memory technologies that enable practical, scalable architectures.

We introduce a multifunctional photonic memory cell that integrates phase-change materials ($Ge_2Sb_2Se_4Te_1$ and Sb_2Se_3) with a foundry-compatible PN junction in a micro-ring resonator. This hybrid approach uniquely combines coarse nonvolatile tuning via the PCM with high-speed volatile fine-tuning using the PN junction. Under forward bias, the junction acts as a microheater to program the PCM, while under reverse bias, it enables rapid adjustment of weights through the plasma dispersion effect. This dual functionality achieves a 400-fold increase in volatile tuning speed and a 10,000-fold improvement in efficiency over traditional approaches, with static power dissipation below 640 pW per device. We demonstrate 3.8-bit precision (14 distinct nonvolatile levels) while significantly extending effective cycling endurance by reducing the frequency of PCM reprogramming.

Addressing the fundamental endurance limitation of PCMs, we've also developed a non-reciprocal magneto-optic memory cell that leverages cerium-substituted yttrium iron garnet (Ce:YIG) on silicon micro-ring resonators. By simultaneously exciting clockwise and counterclockwise propagating modes in the resonator, we encode weights through the differential transmission resulting from magneto-optically induced resonance splitting. This approach delivers unprecedented performance: 2.4 billion programming cycles without degradation, 1 ns programming speed, 143 fJ/bit energy consumption, and approximately 3.5-bit precision. The non-reciprocal architecture also provides symmetric positive and negative weighting with improved extinction ratio while requiring smaller phase shifts than reciprocal approaches.

Both memory technologies integrate into a "broadcast and weight" architecture for matrix-vector multiplication, where our innovations specifically address the critical bottleneck of weight update time and energy. The multifunctional PCM-PN memory dramatically improves programming efficiency, while the non-reciprocal magneto-optic memory transforms the endurance limitation, enabling frequent reprogramming for large-scale computing algorithms. These developments represent significant steps toward practical photonic computing architectures capable of meeting the demands of next-generation machine learning applications, with future work focusing on increasing integration density, improving modulation efficiency, and further optimizing materials and device structures to enhance performance.

Abstract: By combining thermodynamics approaches, first principles simulations and experimental techniques we investigate and discover multifunctional materials (nitrides and high-entropy carbides) that combine tunable plasmonic properties in the near-IR/vis range and high mechanical and thermal resistance for applications in extreme and harsh conditions.

The manipulation of light on the deep subwavelength scale is essential for enhancing light-matter interactions and improving the performance of nanophotonic and thermal devices. The unique properties of plasmonic materials made them essential for a plethora of applications, ranging from energy to automotive, from wireless to medical and IoT. In particular, discovering multifunctional materials with tunable plasmonic properties, capable of surviving harsh environments (e.g., high temperature, and chemical or mechanical abrasion) is critical for advanced optical, thermal, and aerospace applications.

Here, we adopt massive high-throughput computational techniques, based on density functional theory, to design and characterize tunable plasmonic materials active in the near-IR and visible range. Starting from simple transition-metal crystals (such as nitrides) [1,2], we investigate the role of composition, off-stoichiometry and structural disorder in TiNx compounds [3], and we provide an efficient strategy to fine engineering stable, easy-to-grow hyperbolic metamaterial superlattices [4,5], with selected optical and extraordinary mechanical properties (e.g. hard materials).

Finally, by combining computational thermodynamics and first principles electronic structure techniques that allows us to predict synthesizable single-phase solid-state solutions (DEED) [6], we propose high-entropy transition-metal carbides (HECs) [7], which yielded plasmonic properties from room temperature to 1500K, as demonstrated by multi-technique experiments (ellipsometry, REELS, TEM-EELS) at varying temperature (see Figure 1). This new class of plasmonic materials may foster previously unexplored optical/mechanical applications (e.g. aerospace and security systems) in extreme conditions and ultra-high temperature.

Semimetal-based nanostructured thin films for sustainable reconfigurable plasmonics and photonics

Fernando Chacon-Sanchez[1], **Marina García-Pardo**[1], **Johann Toudert**[1], **and Rosalía Serna**[1*]

[1]*Instituto de Optica, CSIC, Serrano 121, 28006 Madrid, Spain*

Abstract: Elemental semimetal nanostructures (Bi, Sb) offer sustainable platforms for plasmonics and photonics, extending spectral range beyond that of noble metals. They enable advanced functionalities such as perfect absorption, structural coloration, and tunable optical responses via phase transitions, positioning them as versatile materials for next-generation optoelectronic and nanophotonic applications.

Plasmonic nanostructures and metasurfaces based on noble metals are well established as transformative components in sensing, imaging and photonic devices, owing to their ability to dramatically enhance light–matter interactions. However, the limited availability and high cost of these metals have stimulated extensive efforts to identify alternative materials that not only substitute noble metals, but also extend their operational spectral range and introduce novel functionalities to further advance nanophotonic performance. In this regard, semimetals have recently emerged as a promising class of unconventional platforms for both plasmonic and photonic applications.

In particular, the semimetals bismuth and antimony are relatively abundant elements in earth's crust that have emerged as promising candidates for sustainable photonic technologies due to its unique optical properties, moderate processing temperature, and low environmental impact. Whereas traditional noble metals whose plasmonic behavior is dominated by conduction electrons, in the case of Bi and Sb the origin of their plasmonic behavior relies on “interband plasmons” that arise from prominent interband transitions in the ultraviolet–visible range. As a consequence of these interband transitions it is derived the appearance of a spectral range with negative values in the real part of the permittivity at visible wavelengths, and an exceptionally high refractive index. For the case of Bi it has been shown that the refractive index can approach values as large as 10 in the infrared regime [1-2]. Making use of these unique properties we have designed and successfully fabricated metasurface thin film architectures based on Bi-nanostructures to enable different functionalities that include among others subwavelength perfect absorbers and efficient structural color devices [4-5]. In addition, Bi low melting point (~271 °C) facilitates energy-efficient manufacturing and enables a reversible solid–liquid phase change that allows modulating its optical response. Upon melting, Bi switches to a Drude-like metallic behavior with increased free-carrier contributions, while supercooled liquid states further expand the range of tunable optical responses. Making use of this properties we have developed reconfigurable photonic meta-surfaces for optical switching presenting state-of-the-art values for reversibility and cyclability [6-7].

In this presentation I will review these recent results and discuss how these robust transitions can be harnessed for fast optical modulators, multilevel data storage, and reconfigurable photonic circuits, especially where intermediate supercooled states enable analog tuning. Beyond switching applications, Bi strong

visible–UV absorption and high infrared refractive index hold promise for advanced sensors, photovoltaics, and thermal imaging devices.

Abstract: Metasurfaces, composed of sub-wavelength nanostructures, enable precise light control but are typically static. Integrating Phase Change Materials (PCMs) allows tunability for real-time photonic devices. However, conventional fabrication is costly and complex. This work explores combining soft Nano Imprint Lithography with other methods to create low-cost, large-area tunable metasurfaces.

Managing the propagation of light and its properties with ever greater control and efficiency has become a major challenge in nanophotonics. This can be achieved using large arrays of sub-wavelength metallic or dielectric nanostructures known as metasurfaces. These structures are typically static, "fixed-by-design", meaning that their optical properties are predeterminated by their design. The next major milestone in metasurface development is the integration of tunability by incorporating Phase Change Materials (PCMs) such as $Ge_xSb_yTe_z$ or low-loss Sb_2S_3 alloys. Since PCM alloys can reversibly switch between their amorphous and crystalline states, exhibiting distinct optical and electronic contrast, they are ideal candidates for coupling with dielectrics metasurfaces. This approach enables the development of tunable photonic devices[1–3] (e.g. waveguides, phase shifters, absorbers…) capable of dynamically altering displayed information in real time. However, in most cases, integrating PCM in photonic devices relies on conventional top-down microfabrication techniques (standard lithography, lift-off, etching) which are costly, complex, difficult to implement on chalcogenides, and result in limited active surface areas.

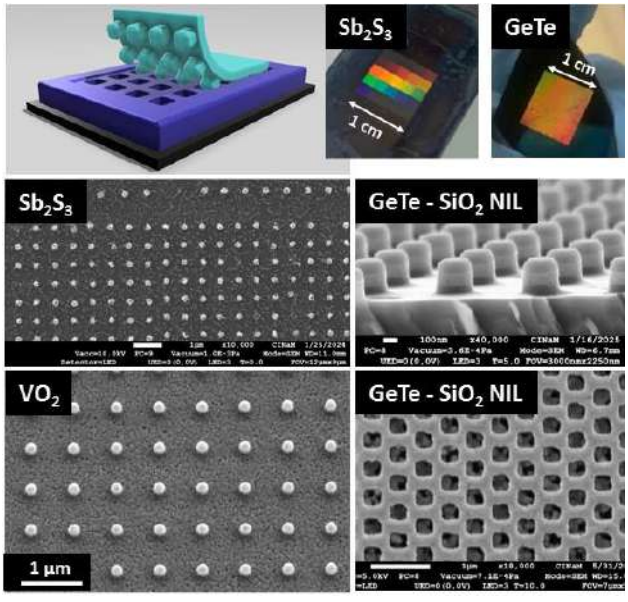

***Fig. 1**: Soft-NIL process scheme and SEM images & photos of various metasurfaces obtained by direct soft-NIL of inorganic based inks (Sb_2S_3, VO_2) or by combining soft-NIL dielectric metasurface with PCM (GeTe).*

In this work, we present recent progress, key achievements and future perspectives on combining soft Nano Imprint Lithography (soft-NIL) methods[4,5] with other methods (such as liquid deposition[6] or PVD) to elaborate PCM metasurfaces with various structural features (e.g. pillars or well arrays) of different dimensions and pitches (see Fig.1). Conducted in collaboration with Solnil, this research aims to move beyond traditional

fabrication methods to achieve low-cost, large-area active metasurfaces on diverse substrates. Finally, initial demonstrations of the switching capabilities of such metasurfaces will also be presented.

Programmable Infrared Geometric Phase Metasurfaces with the Plasmonic Phase-Change Material In_3SbTe_2

L. Conrads[1,*], and T. Taubner[1]
[1] I. Institute of Physics (IA), RWTH Aachen University, Germany

[*]corresponding author: conrads@physik.rwth-aachen.de

Abstract: We exploit the non-volatile insulator-to-metal transition of the plasmonic phase-change material In_3SbTe_2 for optical programming metasurfaces for infrared beam-shaping. We tailor the geometric phase of metasurfaces with rotated crystalline In_3SbTe_2 rod antennas to achieve beam steering, lensing, optical vortex beams and holography. Our approach enables rapid-prototyping of customized infrared meta-optics.

Conventional optical elements are bulky and limited to specific functionalities, contradicting the increasing demand of miniaturization and multi-functionalities. Optical metasurfaces enable tailoring light-matter interaction at will, especially important for the infrared spectral range which lacks commercially available beam-shaping elements. A convenient approach for programming plasmonic metasurfaces relies in direct laser writing nanoantennas directly with the novel plasmonic phase-change material PCM In_3SbTe_2 (IST). IST can be reversibly switched from an amorphous dielectric phase to a metallic crystalline one upon laser irradiation.[1] This material has been previously exploited for resonance tuning by reconfiguring the antenna shapes themselves [2,3], tailoring thermal emission of metasurfaces [4,5], and programming surface polariton resonators [6,7] directly. However, rapid-prototyping of complex IST metasurfaces for real-world applications has not been shown yet. Tailored phase-modulated metasurfaces with the plasmonic PCM IST promise arbitrary beam-shaping in the infrared spectral range.

Here, we exploit direct laser writing for programming large-area infrared metasurfaces at 9 µm operation wavelength and investigate their respective functionalities. First, we demonstrate beam steering metasurfaces with varied supercell periods to obtain different beam deflection angles. Second, we design and investigate a metalens with a focal length of 11.5 cm. Third, we exploit the orbital angular momentum of light and verify the mediated topological charges by revealing the spiral intensity pattern. Then, the phase profile of a metasurface hologram is designed with the Gerchberg-Saxton algorithm and combined with the phase profile of a magnifying lens, highlighting an easy way for combining multiple functionalities within a single metasurface. Finally, we use a diffractive neural network for designing a single hologram metasurface featuring two different hologram patterns at certain distances behind the metasurface.[8]

The concept of directly programming metasurfaces with IST antennas is much simpler, more cost-effective and faster compared to cumbersome fabrication techniques such as conventional lithography involving multiple costly and complex etching and design steps. The turnaround times of designing, fabricating and characterizing a new functional metasurface is only a fraction compared to established fabrication methods of metasurfaces. The operation wavelength of the metasurfaces is only given by the length of the rotated antennas and can be easily scaled to target the entire infrared range. Hence, our demonstrated concept paves the way towards fabrication of large-area metasurfaces within hours, enabling rapid-prototyping of customized infrared meta-optics for sensing, imaging and quantum information.

Abstract: This research aims to develop an active, continuously reconfigurable metasurface by integrating a low-loss chalcogenide phase-change material, Antimony Selenide (Sb_2Se_3), with a Silicon dielectric metasurface. The objective is to create a metasurface that should be able to modulate various aspects of light, including amplitude modulation, comprehensive 2π phase control and dynamic optical switching.

Metasurfaces facilitate control over optical phenomena such as transmission, reflection and polarisation, paving the way for compact and efficient devices beyond the limits of traditional optics [1]. While passive metasurfaces have driven advancements, their fixed optical properties post-fabrication limit real-time adaptability. To overcome this limitation, active tunable metasurfaces have been developed, which can respond to external stimuli such as electric, thermal or optical inputs [2]. Among various strategies for achieving tunability, this research focuses on the integration of Phase change materials (PCMs), specifically the chalcogenide Sb_2Se_3. Sb_2Se_3 is a low loss chalcogenide capable of undergoing rapid and reversible phase transition between amorphous and crystalline states. This transition can be triggered by optical, thermal or electrical stimuli. Unlike traditional chalcogenides such as GST and GSST, Sb_2Se_3 offers minimal absorption loss in both the Amorphous and crystalline phases, particularly in the NIR region around 1550nm telecommunications wavelength [3].

To explore tunable optical responses, this study involves integration of Sb_2Se_3 with a silicon-based – dielectric metasurface. The silicon metasurface was fabricated using deep UV lithography (**Figure 1**), followed by Sb_2Se_3 coating via RF magnetron sputtering and thermal annealing to induce crystallization.

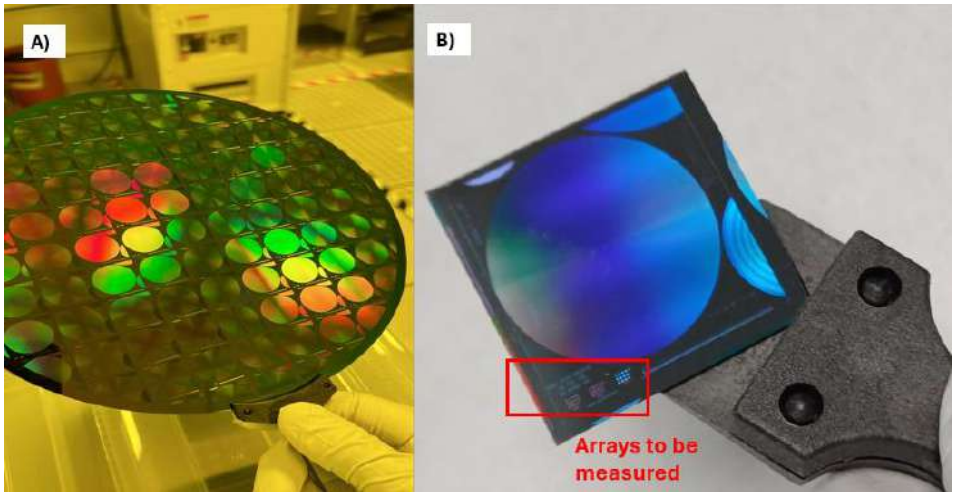

Figure 1: A) The metasurface reticle duplicated multiple times on the wafer. B) Chip cleaved from the wafer for deposition and measurements.

A protective ZnS: SiO2 capping layer was added to prevent oxidationa and ensure stability. Post fabrication, SEM imaging was conducted to examine the pillar geometry and to measure the thickness of the deposited PCM (**Figure 2**). The results revealed that the pillars exhibited rounded cone shape rather than intended square profile. To account for these structural variations, we employ modelling using the finite-difference time-domain (FDTD) method in Lumerical, optimising the design and analysing the effects of the geometry and phase change material on resonance tuning.

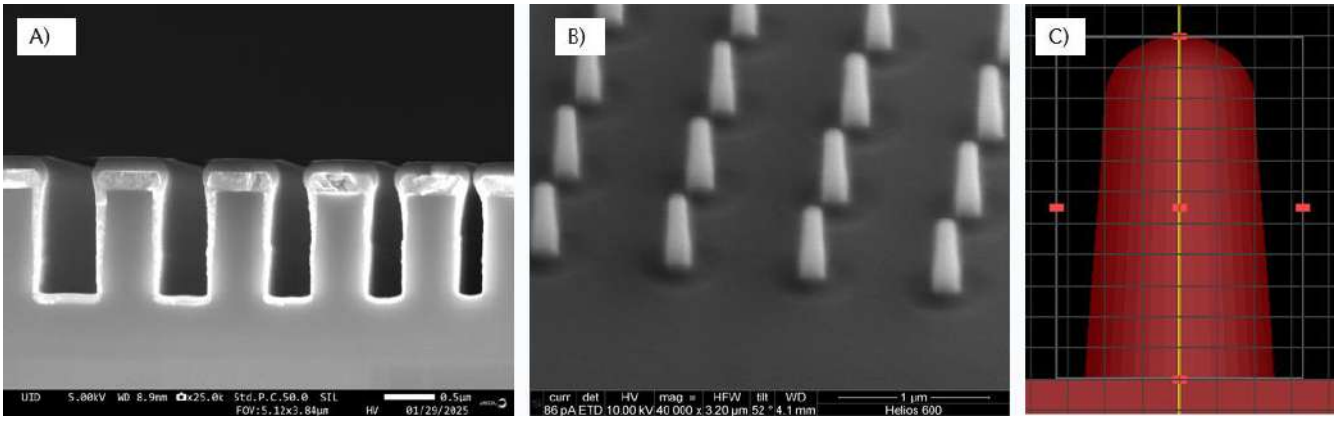

Figure 2: A) SEM cross-section of test bars showing the deposited PCM. B) Tilted view of 300nm wide pillars, providing insight into the vertical geometry of the pillars. C) Rounded cone model of the silicon pillars simulated in the Lumerical FDTD.

Initial experimental results demonstrate that the phase transitions of Sb_2Se_3 enable effective amplitude control and Mie resonance tuning. The Mie resonances redshifted upon the integration of Sb_2Se_3 and are further influenced by the dimensions of the metasurface. The metasurface exhibits high transmission with minimal loss, providing distinct contrasts between the amorphous and crystalline states of PCM. This makes it a promising candidate for telecommunications applications, including high-speed data transfer and optical modulators.

Currently, we are focusing on laser induced phase transition in the PCM to achieve optical switching. Moving forward, we aim to assess continuous switching performance by testing the metasurfaces stability and durability under multiple switching cycles. This will involve evaluating optical properties and ensuring consistent and reproducible control. In conclusion, the research focuses on developing a reprogrammable metasurface that alters both amplitude and phase while ensuring consistent efficiency across multiple switching cycles.

Abstract

Reconfigurable integrated photonic devices rely on phase-change materials for their ability to transition between states with distinct optical properties under external stimuli. In this work, we present a novel reconfigurable photonic switch that operates at room temperature, utilizing integrated spin crossover nanoparticles to enable efficient, reversible switching with enhanced performance.

Multiple platforms have been developed for integrated photonics, such as InP, SiN, and GaAs. However, these technologies require specialized fabrication facilities and are not compatible with CMOS processes. In contrast, Silicon-on-Insulator (SOI) can benefit from existing microelectronics infrastructureproviding a cost-effective and scalable solution. Despite this, silicon lacks intrinsic electro-optic modulation capabilities, a limitation that can be addressed through the integration of active materials. Phase-change materials (PCMs), such as transition metal oxides and dichalcogenides, serve as active media for integrated photonics. Their distinct optical properties in different phases enable the development of reconfigurable nanophotonic devices. However, traditional PCMs still present significant drawbacks. For instance, VO_2 undergoes a volatile phase transition near room temperature (RT), affecting its stability [1], while the crystalline phase of GeSbTe (GST) exhibits a high extinction coefficient, resulting in significant optical losses in certain applications [2].

Both of these problems can be overcome using specially designed PCMs based on the spin crossover (SCO) phenomenon. SCO materials provide a versatile platform for actively tuning optical properties, as they can transition between low-spin and high-spin states in response to external stimuli such as temperature, pressure, or light. These transitions are also associated with changes in volume, magnetic behavior, electrical properties and color (Fig 1.a). Moreover, these materials can be chemically engineered to tailor their properties for specific applications [3] while maintaining their hysteretic behavior (and consequently, their bistability) even at the nanoscale [4]. By incorporating SCO nanoparticles (NPs) into a polymer matrix, it is possible to harness their advantageous properties while mitigating fabrication challenges.

In this work, we present a reconfigurable optical switch by integrating PMMA-embedded SCO NPsinto silicon micro-ring resonators (MRRs), enabling efficient and tunable performance (Fig 1.b). The distinct hysteretic optical response, with a width of approximately 25 ^{o}C and centered near room temperature, enables a reliable bistable switch for low-power integrated photonics (Fig 1.c). The results of our work pave the way for a novel kind of reconfigurable, low powered, low-cost and reliable integrated photonic devices based on polymer-integrated SCO nanomaterials. This could enable dynamic, on-demand control of optical signals in real time, facilitating a wide range of applications, from data processing to adaptive optical systems.

Abstract: This talk presents a novel platform for dynamically engineering local strain in suspended 2D materials via nano-indentation. We demonstrate a measurable and reversible shift in the photoluminescence spectra in suspended two-dimensional materials. We further show that various types of strain distributions can be designed.

Strain engineering in two-dimensional (2D) semiconductors has recently unveiled captivating nanophotonic phenomena, including localized bandgap tuning, exciton funneling, and the development of site-specific single-photon emitters. Despite notable advancements in the theoretical framework surrounding nanoscale strain engineering, experimental efforts face challenges due to unintended strain in solid-state devices, complicating the connection between local strain environments and material responses. We have developed a novel strain engineering platform aimed at exploring complex strain distributions by transferring 2D material flakes onto closely patterned nanostructures, facilitating the investigation of various strain distributions like uniaxial, biaxial, and triaxial strain within one flake. The strong emission from thicker flakes makes gallium selenide (GaSe) an excellent candidate for examining the correlation between local strain and optical responses. In this presentation, we will discuss the dynamic local strain engineering of suspended 2D material flakes using a unique micromechanical spring that features specially designed nanoscale probes to induce symmetry-controlled localized strain. By conducting strain engineering measurements on suspended 2D materials instead of patterned substrates, we eliminate unintended strain effects from the surrounding environment. This research establishes a new platform for enhancing the quantitative understanding of material properties in relation to complex local strain in two-dimensional materials for quantum photonics applications.

Central to our approach is the design and fabrication of a silicon-on-insulator (SOI) based micro-spring with patterned nanoscale probes (MTS) at its apex, as shown in Figure 1(a,b). While AFM probe-based indentation induces in-plane biaxial strain at the point of contact, control over the probe geometry introduces an additional degree of freedom to tune the local strain distribution. Specifically, the MTS is designed to induce out-of-plane deformation and in-plane strain in suspended 2D materials by mechanical force, which allows for continuous tuning of the strain magnitude while performing optical and electrical characterization. The dynamic strain engineering platform has been applied to study tunable photoluminescence (PL) in 2D materials at room temperature, as shown in Figure 2(c,d).

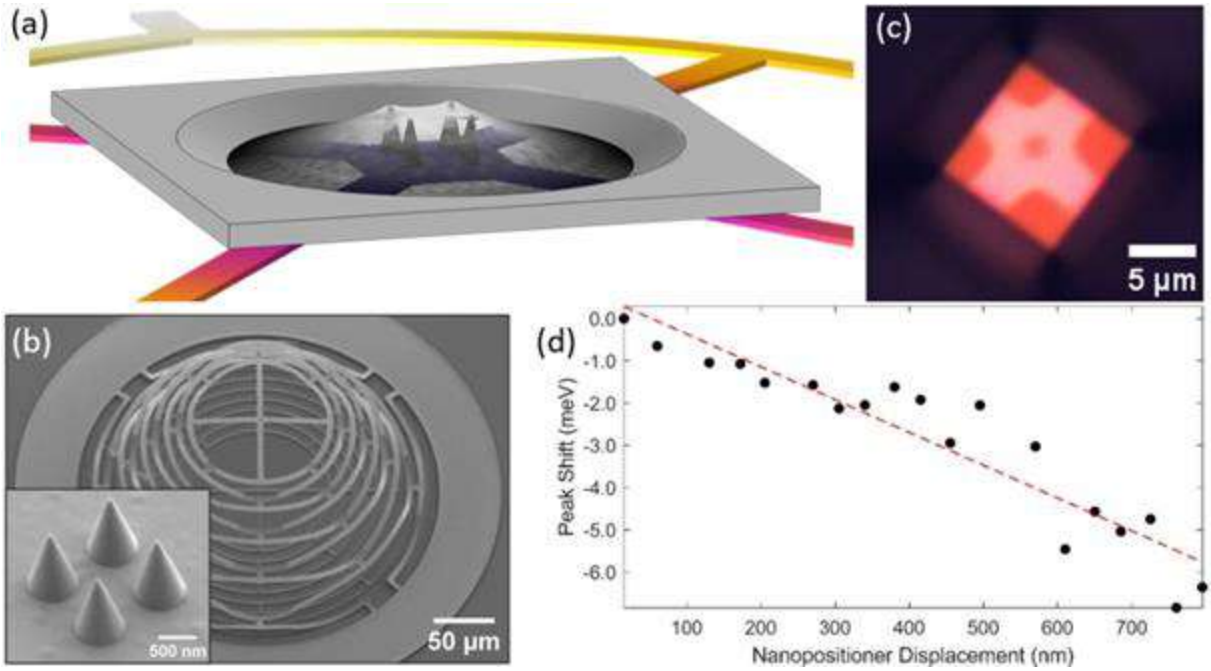

Figure 1 (a) Schematic of an MTS for inducing switchable out-of-plane deformations in suspended 2D materials. (b) SEM images of a fabricated MTS. The inset shows tips at the center of the spring. (c) Optical image of a flake of GaSe suspended on a square aperture and in contact with an MTS. (d) The center wavelength of PL red-shifts when the MTS induces higher out-of-plane deformation (larger strain).

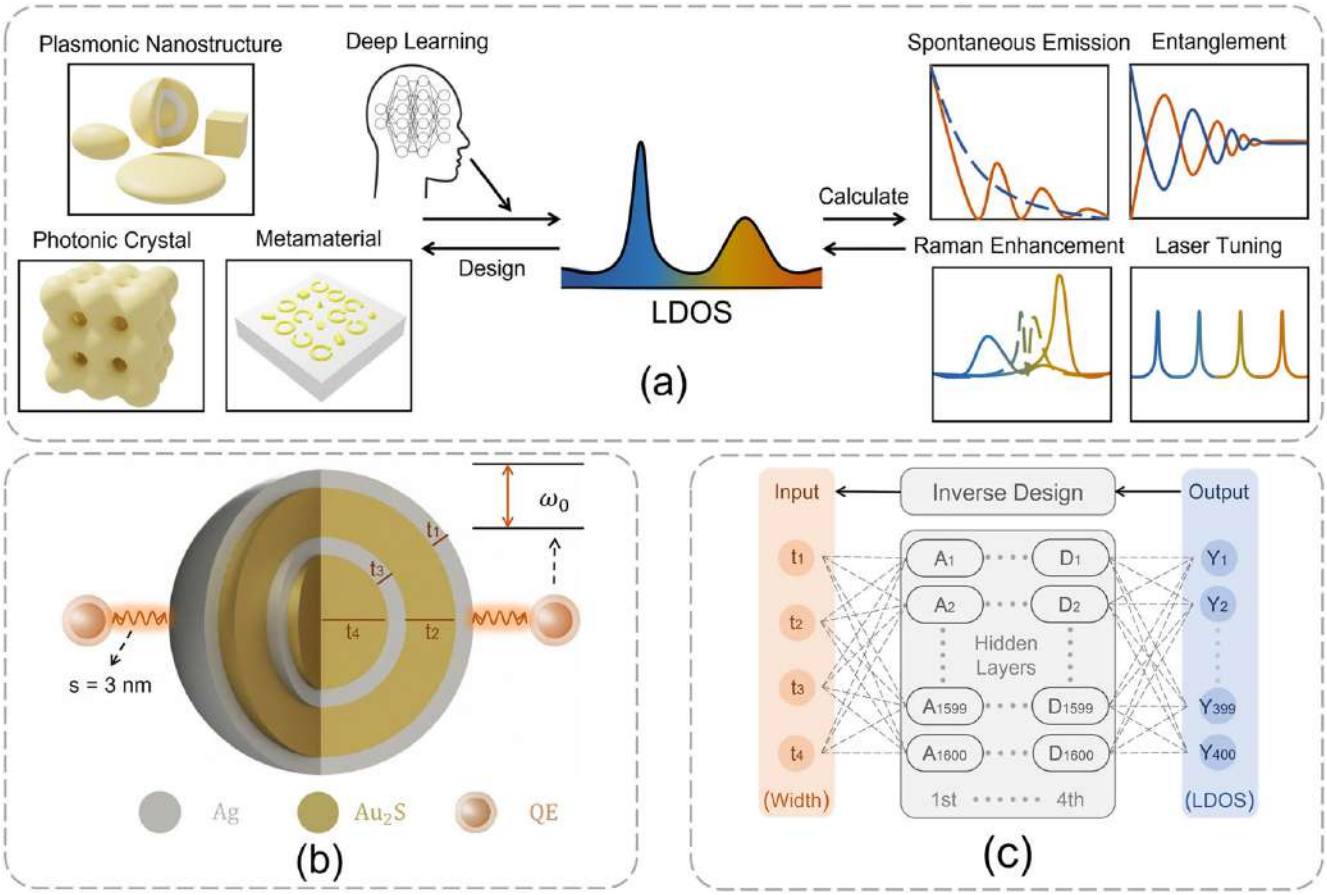
Abstract: We introduce and experimentally demonstrate a nanoscale polarization-entangled photon pair source utilizing a plasmonic metasurface that is strongly coupled to an epsilon-near-zero (ENZ) material.

Polarization-entangled photon pair sources are essential for diverse quantum technologies, such as quantum communication, computation, and imaging. However, the generation of complex polarization-entangled quantum states has long been constrained by the available nonlinear susceptibility tensor of natural nonlinear crystals, necessitating a cumbersome and intricate setup for additional coherent superposition or post-selection. In this study, we introduce and experimentally demonstrate a nanoscale polarization-entangled photon pair source utilizing an artificially-engineered metamaterial platform. This platform is based on a plasmonic metasurface that is strongly coupled to an epsilon-near-zero (ENZ) material. By precisely engineering resonances at both pump and signal/idler wavelengths, and leveraging the field enhancement provided by the ENZ effect, the photon pair generation efficiency of the 68-nm-thick metasurface is significantly boosted. More notably, the ENZ metasurface platform facilitates versatile manipulation of the system's anisotropic second-order nonlinear susceptibility tensor, enabling direct control over the polarization states of the photon pairs, which leads to the generation of a polarization-entangled Bell state without the need for additional components. Our approach opens a new avenue for the simultaneous photon pair generation and quantum state engineering in a compact platform.

Lighting the Future: Advancing Quantum Nanophotonics with Forward & Inverse Designs

Lin Wu*

Singapore University of Technology and Design (SUTD), 8 Somapah Road, Singapore 487372



*Corresponding author: lin_wu@sutd.edu.sg

Abstract: This talk explores cavity quantum electrodynamics (Cavity-QED) design strategies from forward and inverse perspectives, highlighting case studies like quantum plasmonic sensing. We introduce advancements in quantum nanophotonics, combining the local density of states with deep learning to innovate and optimize design processes, offering a transformative pathway for quantum photonics.

We will revisit our theoretical proposals in forward design, presenting new experimental insights through case studies such as quantum plasmonic immunoassay sensing[1] and the recent demonstration of deterministic positioning and alignment of single-molecule excitons in plasmonic nanodimers for strong coupling[2]. Additionally, we will introduce our multidimensional hotspot nanoengineering approach for deterministic plexcitonic strong coupling at the single-emitter level, with a focus on substrate-mediated hotspot engineering[3] and the spectral localization of single-nanoparticle plasmons through photonic substrate engineering[4].

Furthermore, we will explore an innovative all-plasmonic spatio-spectral localized (SSL) system consisting of a gold bowtie array on a gold substrate[5], producing high-Q spectral-localized modes through the lattice's collective response, particularly surface lattice resonance (SLR). This SSL system enables tunable coupling between localized surface plasmon resonance (LSPR) and SLR, facilitating precise alignment with quantum emitters to form quasi-bound states that protect room-temperature quantum coherence. We will also discuss a generalized model[6] for probing spectral hole-burning (SHB) mechanisms in non-Hermitian scattering problems, advancing the design of tailored optical devices with enhanced performance.

Recent advances in inverse-design approaches have reshaped the landscape of nanophotonic structures by enabling the discovery of optical designs based on desired functional characteristics. Most studies so far have focused on light's interaction with these nanophotonic structures. However, when quantum emitters (QEs)—such as atoms, molecules, and quantum dots—are introduced to couple with these structures, the light-matter interactions become more complex, creating the rapidly evolving field of quantum nanophotonics. Quantum functionalities depend on the intrinsic properties of the QE and the electromagnetic environment it experiences, often described by the local-density-of-states (LDOS). We introduce a generalized inverse-design framework in quantum nanophotonics[7], using LDOS as a bridge to connect nanophotonic structures with quantum functional characteristics. As a case study, we examine a system where QEs are placed on a single multilayer shell–metal–nanoparticle (SMNP). By applying fully connected neural networks to model the LDOS of SMNP, we inverse-design and optimize its geometry based on LDOS to achieve desirable quantum characteristics in two quantum nanophotonic problems: spontaneous emission and entanglement. Our work introduces deep learning into the quantum optics domain, advancing the design of quantum devices.

Superresolution for Nanometer-Scale Optical Imaging

Robert W. Boyd
Department of Physics, University of Ottawa, Ottawa, ON Canada
Institute of Optics, University of Rochester, Rochester, NY USA
boydrw@mac.com

Abstract: Quantum imaging is a research area that seeks to produce "better" images using quantum methods. We review recent research in this field, especially in the context of applications in biomedicine.

Traditional microscopy is limited in its resolution to approximately 400 nm. Many objects of interest to technology and biomedicine, for example, have feature sizes of much smaller dimensions. In this talk, we review methods to achieve higher resolution. One means to achieve superresolution, and the topic of this presentation, is to use quantum imaging methods.

Quantum imaging is a research area that seeks to produce "better" images using quantum methods. The image can be better in one of several different ways. It might possess better spatial resolution, it might display better signal-to-noise ratio, or it might be able to be formed using a very small number of photons. From an operational standpoint, we can consider quantum imaging to be an imaging modality that seeks to exploit the quantum properties of the transverse structure of light fields. In this presentation, we describe several different recent examples of advances in the field of quantum imaging.

One such example is afforded by quantum phase imaging. Many biological materials, especially cellular materials, possess very small contrast in terms of the amplitude of a light field transmitted through the material. However, the transmitted field does show significant structure in terms of the phase of the transmitted light. Many of these materials are optically quite fragile and cannot withstand a high intensity light field. High intensities are required for certain applications such as short-exposure imaging to monitor the dynamical changes in the structure of the material. The problem with optical damage is aggravated through use of short illumination wavelengths, which are normally required in order to obtain good spatial resolution of the image. These difficulties can largely be mitigated through use of quantum imaging methods. For example, quantum imaging can make optimum use of a small number of photons in an image-bearing field. Also, the spatial resolution can be limited not by the wavelength of light being used but by some fraction $1/N$ of this wavelength, where N is the number of photons in the quantum state that interrogates the object to be imaged. A quantum phase-imaging setup similar to the one used in our recent work is shown in Fig. 1. In our work, we were able to achieve a spatial resolution 1.7 times better than that of a classical imaging system with the same numerical aperture. Moreover, the measured phase shift of the light transmitted through the sample was 2.0 times larger than that of a classical imaging system.

Other examples of quantum imaging methods will be described in this talk. Quantum imaging has been shown to be a versatile method for enhancing the performance of optical imaging systems. One can expect additional improvements in imaging performance to be developed in the coming years.

Nanophotonic interfaces for integrated quantum technologies

H. Siampour*

School of Mathematics and Physics, Queen's University Belfast, University Road, Belfast BT7 1NN, UK
* h.siampour@qub.ac.uk

Abstract: In this talk, I will present my research on developing nanophotonic interfaces for integrating solid-state quantum emitters. This includes nanoscale optical positioning of single emitters in nanomaterials for efficient waveguide/cavity coupling, plasmonic enhancement of single-photon emission at the zero-phonon line, and deterministic photon-emitter interfaces in chiral nanophotonic waveguides.

The development of chip-integrated optical components for the scalable implementation of solid-state qubits has become a key focus in advancing photonic quantum technologies, such as quantum communication, as well as distributed quantum computing and sensing. A critical aspect of integrating these systems is on-chip excitation, where quantum emitters are excited via waveguide modes rather than locally.[1] This approach enables precise quantum operations and device miniaturization, making it particularly relevant for deterministic photon-emitter interfaces.[2] In such systems, controlling light polarization and propagation within waveguides facilitates the unidirectional transfer of spin-carrying photons (flying qubits) between solid-state emitters (stationary qubits).[3]

Furthermore, leveraging slow-light effects in photonic crystal waveguides or nanoscale confinement of light in plasmonic waveguide-cavity systems leads to a significant enhancement of the spontaneous emission rate due to the Purcell effect.[2,4] This enhancement is particularly important for suppressing decoherence sources in solid-state environments and improving coherent operation.

In this talk, I will discuss recent progress in developing nanophotonic interfaces for the chip-integration of solid-state quantum emitters. I will cover nanoscale optical positioning of nanodiamonds containing single emitters for efficient waveguide excitation[1], plasmonic cavity coupling for the realization of Purcell-enhanced coherent photons[4] and unidirectional waveguide coupling[5]. Experimental results demonstrate a 42-fold enhancement of the spontaneous emission rate of nitrogen-vacancy (NV) emitters coupled with a plasmonic cavity. Additionally, precise placement of a nanodiamond at the constructive interference node of a Bragg reflector enables unidirectional emission coupling into a plasmonic waveguide mode.

In the second part of this talk, I will introduce a remote excitation protocol for deterministic photon-emitter interfaces in a quantum dot (QD)-waveguide system. In this approach, a single QD is excited in-plane via a photonic crystal waveguide through its nearest p-shell optical transition.[3] By exploiting the chirality of the waveguide mode, we achieve both directional absorption and emission, leading to a substantial enhancement in directional contrast, as measured for the Zeeman components of the waveguide-coupled QD.

Our remote excitation scheme achieves high directionality ($\geqslant 0.95$) across approximately 56% of the waveguide area, significantly overlapping with the Purcell-enhanced region where the electric field intensity peaks. In contrast, local excitation methods – using an out-of-plane excitation beam focused directly on the QD – achieve only ~25% overlap. This enhanced approach increases the likelihood of placing QDs in regions with both high Purcell enhancement and high directionality. Experimental results show a six-fold enhancement in the decay rate of a chirally coupled QD, achieving 90% directional contrast under remote excitation. This

corresponds to a β-factor of ~97%, as confirmed by FDTD simulations. This remote p-shell excitation protocol sets a new benchmark for waveguide quantum optics, effectively combining Purcell enhancement with high directionality. It lays the foundation for on-chip excitation in spin-based solid-state quantum technologies operating in the high β-factor regime.

Nanoscale Gap-Plasmon-Enhanced Superconducting Photon Detectors at Single-Photon Level

Yu-Jung Lu[1,2]*

[1]Research Center for Applied Sciences, Academia Sinica, Taipei 11529, Taiwan
[2]Department of Physics, National Taiwan University, Taipei 10617, Taiwan
*E-mail: yujunglu@gate.sinica.edu.tw

Single-photon detectors have been widely studied for decades because of their unique capability to resolve photon numbers, enabling many applications in quantum information technologies. Compared to other types of single-photon detectors, niobium nitride (NbN) superconducting nanowire single-photon detectors are promising candidates and are commercially available today. However, the absorption coefficient of superconducting NbN in the visible range is typically low, resulting in low quantum efficiency and low signal-to-noise ratios. In the present work, we use a novel approach to enhance the visible-light photoresponse in NbN superconducting microwire photon detectors (SMPDs) by integrating them with gap plasmon resonators (GPRs). This talk describes how we observe the plasmonic NbN SMPDs can achieve a 233-fold enhancement in the phonon-electron interaction factor (γ) compared to pristine NbN SMPDs under resonant conditions with illumination at 532 nm. The nonlinear photoresponse in the visible region is attributed to the gap-plasmon resonances that disrupt the Copper pairs that break the superconducting state to normal. In addition, an impressive detection efficiency of 98% was achieved using these plasmonic SMPDs. Our results open new opportunities for designing sensitive quantum detectors for quantum information processing, quantum optics, imaging, and sensing at visible wavelengths. The detailed mechanisms and possible applications will be discussed.

Quantum Radar with Undetected Photons

Diego Dalvit
Los Alamos National Laboratory
dalvit@lanl.gov

Abstract: Quantum sensing promises to revolutionize sensing applications by employing quantum states of light or matter as sensing probes. Photons are the clear choice as quantum probes for remote sensing because they can travel to and interact with a distant target. Existing schemes are mainly based on the quantum illumination framework, which requires a quantum memory to store a single photon of an initially entangled pair until its twin reflects off a target and returns for final correlation measurements. Existing demonstrations are limited to tabletop experiments, and expanding the sensing range faces various roadblocks, including long-time quantum storage and photon loss and noise when transmitting quantum signals over long distances. We propose a novel quantum sensing framework that addresses these challenges using quantum frequency combs with path identity for remote sensing of signatures (“qCOMBPASS”). The combination of one key quantum phenomenon and two quantum resources, namely quantum induced coherence by path identity, quantum frequency combs, and two-mode squeezed light, allows for quantum remote sensing without requiring a quantum memory. The proposed scheme is akin to a quantum radar based on entangled frequency comb pairs that uses path identity to detect/range/sense a remote target of interest by measuring pulses of one comb in the pair that never flew to target, but that contains target information ``teleported" by quantum-induced coherence from the other comb in the pair that did fly to target but is not detected. This work was recently published in

D.A.R. Dalvit et.al., Quantum Frequency Combs with Path Identity for Quantum Remote Sensing, PRX **14**, 041058 (2024).

Controlling Multiple Quantum Dots using Structured Light

Suraj Goel[1], Sheena Shaji[1], Julian Wiercinski[1], Antoine Borel[1], Natalia H. Valencia[1], Moritz Cygorek[1], Erik Gauger[1], Brian Gerardot[1] and Mehul Malik[1]*

[1]Institute for Photonics and Quantum Sciences, Heriot-Watt University, Edinburgh, United Kingdom

Abstract: We demonstrate the control of multiple, distinct quantum dots on one cryogenic sample via spatial light modulation, allowing us to observe cooperative emission from up to five dots and Hong-Ou-Mandel interference from two dots enabled by multi-plane optical circuits.

Semiconductor quantum dots are bright and deterministic sources of narrow linewidth single photons that play a vital role in quantum optical technologies, with applications ranging from quantum communication networks and photonic quantum computing. Platforms that involve processing multiple photons at the same time often employ a single quantum emitter providing a stream of photons which are then multiplexed in time [1]. This approach introduces a bottleneck in the generation rates of multi-photon quantum states, significantly limiting the scalability of such architectures. Moreover, the time-space demultiplexer used in these platforms often introduces line-shifts between the multiplexed photons, poorly affecting their indistinguishability. One could potentially introduce additional quantum dots from independent samples to improve this scalability, however this would require additional cryostats owing to the cooling requirements of these quantum dot samples. The ability to collect and manipulate light from multiple independent quantum emitters located randomly on a single sample promises a path towards scalability but remains an outstanding challenge. Here we demonstrate this capability by spatially structuring the optical excitation and collection modes to coherently control and observe quantum interference from up to five distinct quantum dots located on one sample.

In our approach, we employ structured excitation and collection with spatial light modulators (SLMs) to search for, identify, and specifically address nominally identical quantum dots that emit indistinguishable photons. Additionally, the structured collection can be used to erase the spatial “which dot” information of the indistinguishable photons coupled into a single-mode fiber (single core of multi-core fiber as shown in Fig. 1a) to induce cooperative emission [2,3]. Using this technique, we are able to scale the distance between two accessible quantum dots on a single sample by more than 40 times as compared to the previous state of the art (Fig. 1b) when considering measurement-induced cooperativity [2]. Using our scalable technique, we are able to observe bunching in the second-order coherence of cooperatively emitted photons from up to n=5 quantum dots for the first time, as shown in Fig. 1c.

We can go one step further and employ a programmable linear optical circuit implemented on a multi-plane light converter (MPLC) [4] to multiplex and interfere the collected photons from independent quantum dots. The use of an MPLC enables the programmability of optical circuits in the spatial degree-of-freedom of light. This is achieved via an inverse-design technique known as a wavefront matching, where a circuit is implemented by multiple phase screens and free-space propagation, allowing us to realise arbitrary operations on the emitted photons [5]. As a proof-of-concept demonstration, we program a 2x2 beam-splitter operation within the MPLC allowing photons from two independent quantum dots to interfere. The photon statistics are measured as a

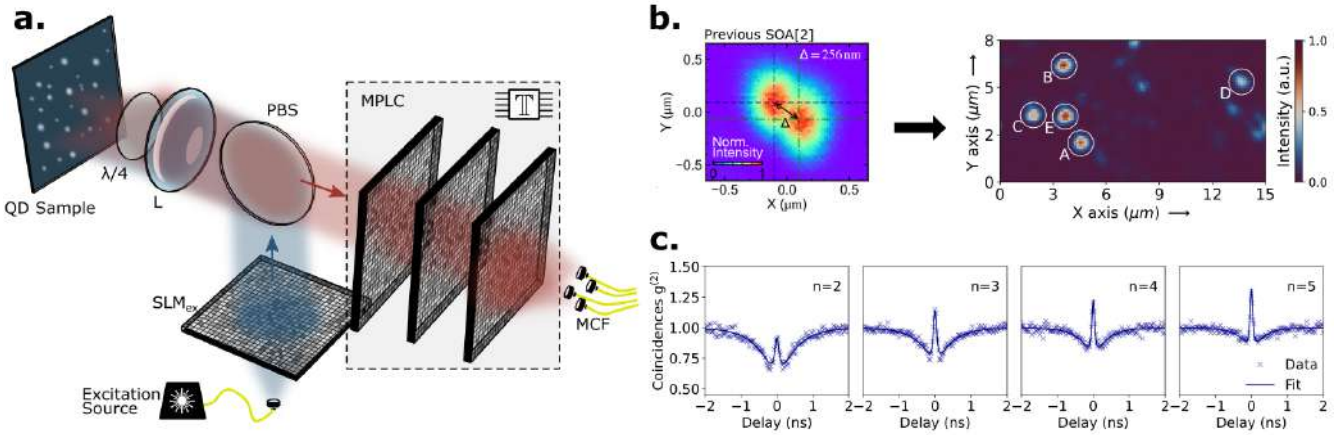

Fig. 1: Control of single-photon emission from multiple quantum dots using multi-plane light conversion (MPLC)}: (a) Structured excitation using a spatial light modulator (SLM_{ex}) is used to simultaneously excite multiple quantum dots (QDs) on a sample. The corresponding emission is manipulated by a multi-plane light converter (MPLC) to be coupled into individual channels of a multi-core fibre (MCF). (b) Characterised map of five independent quantum dots (labelled A-E) on a sample compared to previous state of the art (adapted from Ref. [2]). (c) Measurement-induced cooperative emission of up to five indistinguishable emitters obtained from the second-order correlation function measured via a Hanbury Brown and Twiss setup. Note that only one MCF core is used in this measurement.

second-order correlation function between light from different cores of the multi-core fiber, resulting in a two-photon Hong-Ou-Mandel dip. In this experiment, we observe a zero-delay HOM visibility of approximately 80%, successfully violating the bound necessary to demonstrate quantum interference. We are currently working towards scaling this up in terms of the number of dots and the programmability of our circuits. Our method serves as a powerful tool for interconnecting optical circuits with quantum dots and paves the way towards scalable and efficient quantum information processing.

Multimode and collective strong coupling in plasmonic nanocavities

A. Crookes[1], B. Yuen[1], and A. Demetriadou[1]
[1]University of Birmingham, UK
Corresponding author: a.crookes@bham.ac.uk

Abstract: Strong coupling in plasmonic nanocavities is often treated within a single mode approximation. However, here we show that off-resonant modes in-fact play a crucial role. In particular, we identify three regimes: single mode, multi-mode, and collective multimode strong coupling; advancing the understanding of quantum dynamics in realistic plasmonic nanocavities.

Plasmonic nanocavities provide a promising platform for exploring the quantum properties of light and matter. [1]. In particular, they enable a unique pathway to the strong coupling regime due to their deep subwavelength mode volumes [2]. However, most theoretical descriptions of strong coupling use a single-mode approximation – following their success in dielectric cavities. In contrast, plasmonic systems support a dense collection of modes that often also have large coupling strengths [3]. In general, the origin and impact of these modes on the quantum dynamics is not known.

In this work [4] we show that off-resonant plasmonic modes play a crucial role in strong coupling. In particular, we show that n strongly coupled plasmonic modes introduce up to $n(n+1)/2$ oscillation frequencies in the quantum dynamics. The amplitudes and frequencies of these oscillations depend on the detunings and coupling strengths of each mode and therefore, we also identify three distinct regions depending on these parameters: (i) single mode, (ii) multimode, and (iii) collective multimode strong coupling. In the single mode coupling regime, the quantum dynamics are governed by a single resonant mode. In the multimode coupling regime, the off-resonant modes become significant and produce multiple distinct oscillation frequencies, and in the collective coupling regime (which occurs past a critical dipole moment) the light-matter interaction is dominated by a single ultrafast oscillation. This ultrafast oscillation is due to the collective coupling with multiple modes, and is over one order of magnitude faster than if a single mode approximation is made. The collective multimode coupling regime is highlighted in Fig. 1

In Fig 1. (a) we show a single quantum emitter (QE) interacting with a common plasmonic system, the nanoparticle on mirror (NPoM) cavity. The electric field profile of the quasinormal modes (QNMs) in the gap centre are shown in Fig 1 (b) and are labelled with the index $\xi = (\ell 0)$. To determine their effect on strong coupling, we first consider a single QE with transition frequency $\omega_0 = \omega_{(10)} = 283$ THz and dipole moment $\boldsymbol{\mu} = 72\ \hat{\mathbf{z}}$ D. In Fig. 1 (c) we show the quantum dynamics when including interacting modes up to $\xi = (\ell_{\text{max}}0)$. For a single mode ($\ell_{\text{max}} = 1$) the QE exchanges energy with the cavity at a single (Rabi) frequency. However, as more modes are included in the interaction, the quantum dynamics become more complicated. In particular, when $\ell_{\text{max}} = 9$ the evolution is dominated by a single ultra-fast oscillation due to collective coupling with multiple modes.

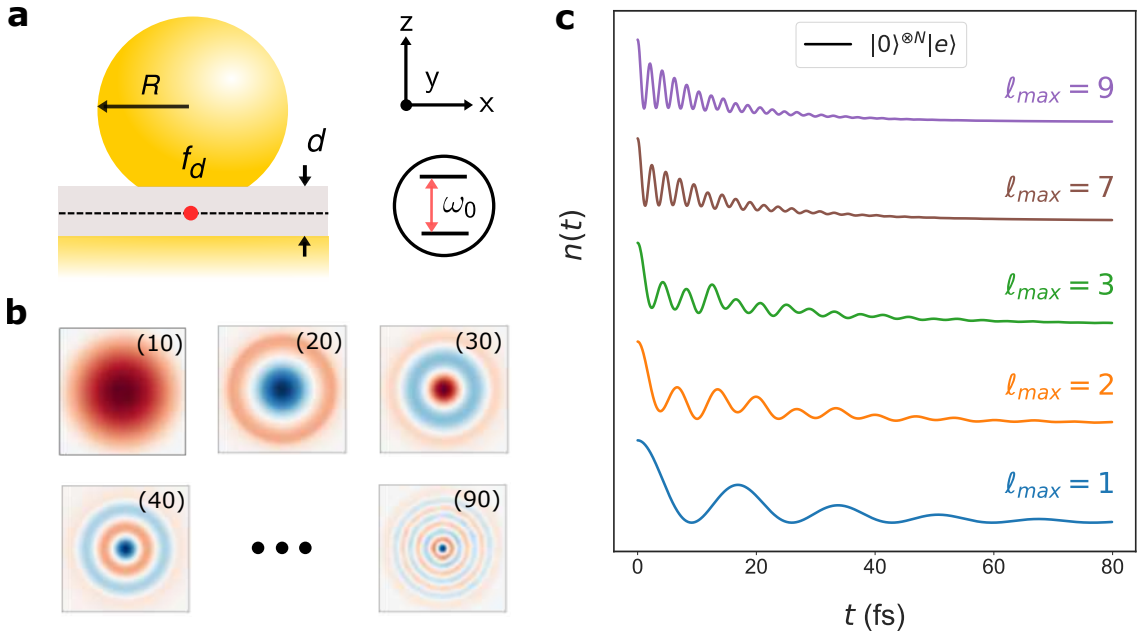

Figure 1: Multimode strong coupling **a** Schematic of a nanoparticle on mirror (NPoM) cavity; a single QE is placed at the gap centre. **b** Electric field $E_z(x, y, 0)$ of the first nine $\xi = (\ell 0)$ quasinormal modes (QNM's). **c** Evolution of the QEs excited state population $n(t)$ when including interacting modes up to $\xi = (\ell_{\max} 0)$ for $\ell_{\max} = 1, 2, 3, 7, 9$ where the QE has frequency $\omega_0 = \omega_{(10)} = 283$ THz and dipole moment $\boldsymbol{\mu} = 72\ \hat{\mathbf{z}}$ D

These insights advance the understanding of quantum dynamics in realistic plasmonic systems, and multimode cavities in general. In addition, the collective ultra-fast presents significant opportunities for enhanced precision and control of quantum systems, improved sensing, and for enabling faster and more efficient manipulation of quantum states in quantum information technologies.

Colored Quantum Random Walks as a Route to Floquet States in Plasmonic Systems

Z. Jalali-Mola[1], O. Hess[1,*]
[1]School of Physics and CRANN Institute, Trinity College Dublin,
University of Dublin, Dublin 2, D02 PN40, Ireland

Abstract: Plasmonic and metasurface platforms enable exploration of topological Floquet phenomena in nanophotonics. We show that colored quantum random walks exhibit Floquet states without external driving. Using SU(3) symmetry, we uncover color-induced band mixing, topological bands, and bound states in the continuum, offering a new route to quantum photonic control.

Bound states in the continuum (BICs) are localized states that reside within bulk electronic or photonic dispersion bands, allowing for lossless transport and propagation. Building on this concept, topological bound states in the continuum (TBICs) incorporate key topological features—such as bulk-boundary correspondence and edge-state protection—to enable robust, backscatter-free transport and directional propagation [1–3].

Here, we show that lower-order dispersive TBICs naturally arise as Floquet systems via colored quantum random walks (cQRWs) on discrete lattice structures [4]. By employing the SU(3) group to describe the walker's spatial evolution, the cQRW inherently realizes Floquet dynamics without requiring external periodic driving. Through tunable rotation parameters, we reveal unconventional edge-state behaviors, including localized states within topological band gaps and dispersive TBICs that manifest as edge states embedded within bulk topological bands. These TBICs exhibit controllable group velocity and precise excitation dynamics, emerging as intrinsic features of the cQRW framework. CQRWs can be implemented in nanophotonic platforms, such as plasmonic metasurfaces or plasmonic waveguide networks, where the lattice comprises arrays of plasmonic nanoparticles or dielectric resonators forming a discrete periodic system. Here, the internal degrees of freedom—"colours"—are encoded through plasmonic mode hybridization, different polarization states, or spatial resonances, with periodic modulation inherently embedded in the system.

A discrete-time quantum random walk (QRW) evolves through a periodic sequence of unitary operators (U) acting on a Hilbert space composed of two subspaces: the particle's position states and the coin space. The coin operation is governed by rotations within the SU(3) group space, while the walker's motion is dictated by an alternating sequence of rotation and hopping operations. These operations, with tunable parameters and directions, define the walker's dynamics, which are encapsulated by the unitary operator:

$$\boldsymbol{U}(\theta_1,\theta_2)=\boldsymbol{T}_y\boldsymbol{R}(\theta_2)\boldsymbol{T}_x\boldsymbol{R}(\theta_1),\quad \boldsymbol{T}_i=|i,\mathfrak{R}\rangle\langle i,\mathfrak{R}|+|i-1,\mathfrak{G}\rangle\langle i,\mathfrak{G}|+|i+1,\mathfrak{B}\rangle\langle i,\mathfrak{B}|\,, \tag{1}$$

where, $\boldsymbol{T}_{x/y}$ are the hopping operators that control movement along the x and y directions respectively, and $\boldsymbol{R}(\theta)=e^{i\boldsymbol{S}\theta/2}$, is the coin rotation operator, defined using operators $\boldsymbol{S}$ from the SU(3) symmetry group.

To characterize the system's topology, we compute the Chern number for each energy band by numerically evaluating the band curvature. The obtained Chern numbers and the corresponding topological properties of the system, as functions of the rotation parameters (θ_1,θ_2),

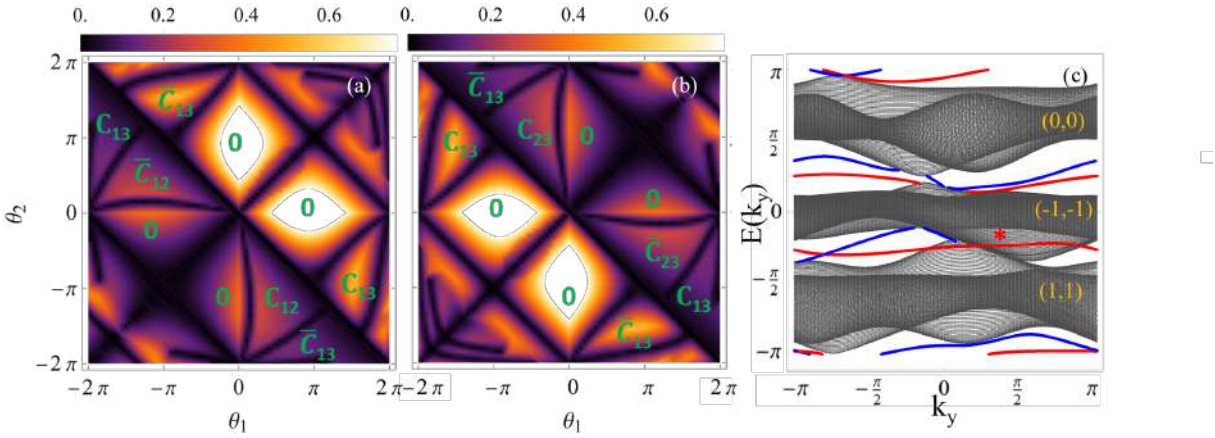

Figure 1: Energy gaps, Chern numbers and Edge States in the rotation plane (θ_1, θ_2). Panels (a) and (b) depict the energy gaps Δ_{12} and Δ_{23}, corresponding to the separations between the first and second bands and the second and third bands, respectively. The Chern number of each region is denoted as $(C_{ij} = (C_i = 1, C_j = -1) = -\bar{C}_{ij})$, indicating the topological characteristics of bands i and j. Panel (c) presents the energy spectrum of two semi-infinite structures, highlighting localized edge states. Edge states at the left and middle boundaries are distinguished by blue and red, respectively. The rotation parameters are set to $(\theta_{1L}, \theta_{2L}, \theta_{1R}, \theta_{2R}) = (\pi\ \ 3, -\pi, -2\pi, 3\pi)$.

are presented in Fig. 1, where green numbers indicate the values within each gapped region. Darker regions, where the energy gap closes, delineate the boundaries between distinct topological phases. We now examine scenarios involving media with non-trivial topological properties, ensuring at least one gap closing occurs between them. Analyzing different topological configurations of the QRW reveals that while both media share the same non-trivial topological characteristics, in addition to chiral edge states, mid-gap edge states also emerge. These states, marked by a red star in panel (c), coexist with the gapless bands but remain unhybridized with the bulk extended states. They appear as dispersive topological bound states in the continuum (TBICs) that are robust against random disorder. Unlike flat bands and higher-order TBICs, these TBICs arise within a semi-infinite configuration and exhibit a dispersive nature.

Abstract

We propose a periodically poled triple-resonance metasurface capable of generating photon pairs with high brightness and broad bandwidth in both frequency and momentum.

Photon pairs from spontaneous parametric down-conversion (SPDC) with broad bandwidth are highly desired in many quantum technologies [1]. In particular, broad frequency and momentum bandwidths are essential for realizing the promise of quantum advantages in quantum communications and quantum metrology. However, achieving broad bandwidth in both frequency and momentum while maintaining a high rate remains a challenge for both conventional nonlinear crystals and recently emerging nonlinear metasurfaces [2–4]. In this work, we address this challenge by introducing a periodically poled triple-resonance metasurface comprising a binary silica grating atop a periodically poled lithium niobate (PPLN) film (Fig. 1a) [5].

As studied before [4], such a metasurface supports high-Q guided mode resonances (GMRs) to enhance SPDC. The novelty in this work lies in two aspects. First, here we not only excite GMRs at the photon-pair wavelengths (red lines in Fig. 1(b, c)), but also at the pump wavelength (blue lines in Figs. 1(b, c)), realizing the so-called triple-resonance SPDC. The quasi-phase matching (QPM) condition between three waveguide modes is further satisfied by using a PPLN film with a poling period determined by the phase mismatch between three waveguide modes. Second, we employ a binary grating design to simultaneously optimize the input coupling of the GMR at the pump wavelength and the output coupling of the GMRs at the photon-pair wavelengths during the SPDC.

With triple resonances, the sum frequency generation (SFG), and thus the inverse SPDC, is further amplified by more than four orders of magnitude when compared to the previous double-resonance case (Fig. 1d). Most interestingly, since GMRs have a weak dispersion along k_z and a linear dispersion along k_y (Fig. 1b), the triple-resonance SPDC is supported in a broad range near the degenerate point for the same pump. This leads to enhanced photon-pair generation with a broad momentum bandwidth even under a Gaussian pump (Fig. 1e). The photon-pair frequency is related to the resonance frequencies of the GMRs at each position and thus broadband as well. Overall, the predicted SPDC rate is as high as 102 MHz/mW with

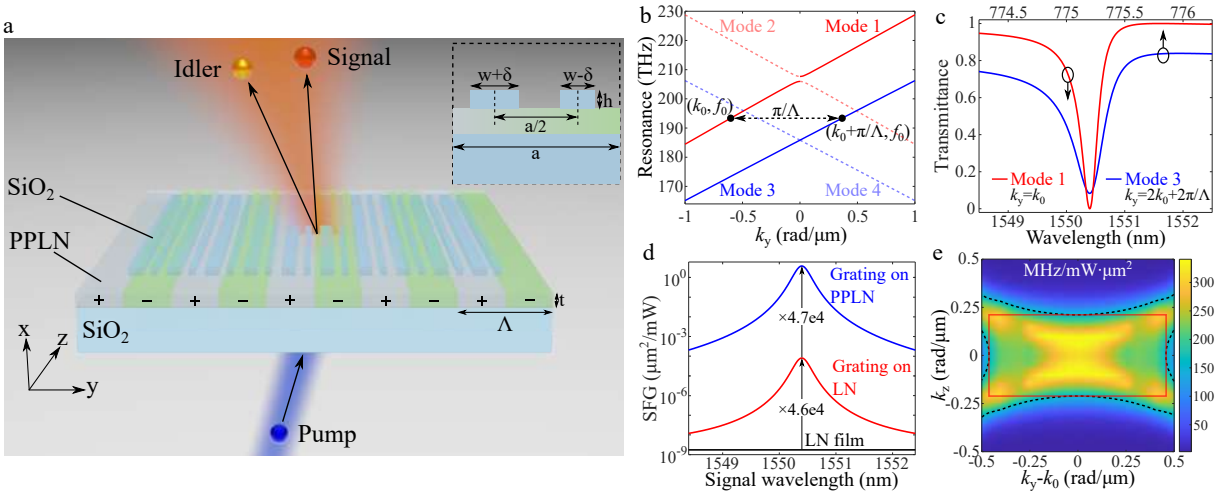

Figure 1: **a** Proposed metasurface including a binary SiO_2 grating ($h = 200nm$, $a = 810nm$, $w = 0.25a$, $\delta = 75nm$) on a PPLN film ($t = 300nm$, $\Lambda = 4a$). **b** Resonance frequency of the first- (Mode 1 & 2) and second-grating-order (Mode 3 & 4) GMRs as a function of k_y when $k_z = 0$. The coordinate axes are halved when plotting Modes 3 & 4. The GMRs at the two black dots satisfy the QPM condition in SPDC. **c** Transmission spectra of the metasurface near the photon-pair and pump wavelengths at the QPM directions. **d** SFG efficiency for the triple-resonance, double-resonance, and no-resonance cases. **e** SPDC spatial emission pattern from the metasurface under a Gaussian pump with a beam waist of $200\mu m$.

a frequency bandwidth of 165 nm around 1550 nm and a momentum bandwidth of 13° × 6°. This improves the state-of-the-art by more than 1000 times in rate and 10 times in bandwidths. Such a broadband and bright photon-pair source could stimulate the performance improvement of various free-space quantum photonic technologies, such as quantum imaging.

Highly directional photon-emitter interactions in slow-light waveguides

H. Siampour*

School of Mathematics and Physics, Queen's University Belfast, University Road, Belfast BT7 1NN, UK
* h.siampour@qub.ac.uk

Abstract: In this talk, I will present our work on remote excitation of a single quantum emitter in a slow-light waveguide. Exploiting waveguide chirality, we achieve both directional absorption and emission, resulting in 90% directional contrast and a β-factor of ~97%. This approach advances waveguide quantum optics for spin-based quantum technologies.

The development of chip-scale quantum optical circuits has become a key focus in advancing quantum technologies, including computing, communication, and sensing. A critical component for integrating these systems is on-chip excitation, where quantum emitters are excited via waveguide modes rather than locally.[1] This approach enables precise quantum operations and device miniaturization, making it particularly relevant for chiral quantum systems. In such systems, controlling light polarization and propagation within waveguides enables unidirectional information transfer.[2]

A key parameter in waveguide quantum optics is the β-factor, which quantifies the coupling efficiency of emitted photons into the waveguide mode. High β-values are essential for observing quantum-optical effects, such as single-photon nonlinearities, and are especially significant when quantum emitters are placed at chiral points within the waveguide. At these points, emitters can introduce spin-dependent phase shifts, with potential applications in quantum spin-networks and spin-based quantum technologies. While significant progress has been made in chiral emission from quantum dots (QDs), directional absorption in such systems, particularly at high β-factors, remains largely unexplored.

In this talk, I will present our results on an integrated semiconductor chip where a single QD is excited in-plane via a photonic-crystal waveguide through its nearest p-shell optical transition.[3] By exploiting the waveguide mode's chirality, we achieve both directional absorption and emission, leading to a substantial enhancement in directional contrast, as measured for the Zeeman components of the waveguide-coupled QD. Our remote excitation scheme enables high directionality ($\geqslant 0.95$) across approximately 56% of the waveguide area, significantly overlapping with the Purcell-enhanced region where the electric field intensity peaks. In contrast, local excitation methods, which use an out-of-plane excitation beam focused directly on the QD, achieve only ~25% overlap. This enhanced approach increases the likelihood of placing QDs in regions with both high Purcell enhancement and high directionality.

We experimentally demonstrate a six-fold enhancement in the decay rate of a chirally coupled QD with 90% directional contrast under remote excitation, corresponding to a β-factor of ~97%, as calculated using FDTD simulations. Our remote p-shell excitation protocol sets a new benchmark for waveguide quantum optics, combining Purcell enhancement with high directionality, and lays the foundation for on-chip excitation in spin-based solid-state quantum technologies operating in the high β-factor regime.

Quantum metasurfaces of quantum emitters arrays

Uri Israeli[1], Ada Krasnosky[1], Itai David[1], Shahar Levi[1] , and Rivka Bekenstein

[1]Racah Institute of Physics, Hebrew University of Jerusalem, Jerusalem 91904, Israel
*corresponding author: rivka.bekenstein@mail.huji.ac.il

Abstract: We implement quantum metasurfaces by deterministically preparing atomic-like arrays in sub-wavelength spacing. These devices are promising tools for cavity-free quantum optics and the generation of large-scale atom-photon entanglement.

Light control has taken a new path following the invention of metasurfaces [1] with incredible manipulation of almost every light property by scattering. The new system we analyzed of quantum metasurfaces extended this control to quantum properties. Quantum metasurfaces are made out of two-dimensional atomic arrays that control light quantum state by scattering [2] without the need of nanostructures or cavities. This was soon followed by experimental realizations with ultra-cold atomic arrays [3,4] proposals employing these arrays for various quantum applications, such as extending quantum memory and generating entanglement [5,6]. However a system that will enable robustness and scalability is still to be found.

The basic principle behind quantum metasurfaces is that two-dimensional arrays of atoms can be prepared in superposition states of reflectivity and transparency. This is done by employing the enhanced response of subwavelength atomic arrays along with inter-atomic long-range interactions and quantum control [2]. Hence, scattering of single photons sequentially off these arrays generates atom-photon entanglement. While this analysis the employment of long-ranged Rydberg interactions that naturally display themselves in atomic systems, it is still lacks implantation with emitters that do no exhibit these properties. The latter would be crucial for implantations with quantum emitters is a solid-state based system, that naturally offers scalability.

Here, we present an implementation with atom-like emitters and specifically with Silicon-Vacancy centers in diamond [7]. In our new experiment we are able to prepare emitter-like arrays deterministically and probe the light-atom interaction. The next-generation low-temperature experiment we are currently working on will enable access to the long coherence time of the electronic spin of the Silicon-Vacancy centers. Employing this long coherence time along with our developed protocols [8,9] enables generation of large scale atom-photon entanglement.

Abstract: Manipulating the optical landscape of single quantum dots (QDs) is essential to increase the emitted photons output. In this work, we exploit the Kerker condition for precise control of single GaAs QDs emission directivity when embedded in AlGaAs nanocylinders, as proved by angle-resolved PL micro-spectroscopy experiments and confirmed by theory.

The convergence of quantum optics and nanophotonics has led to major advances in controlling light-matter interactions at the nanoscale. Quantum dots (QDs), as reliable single-photon emitters, are central to emerging quantum technologies in communication, computation, and sensing. Realizing their full potential requires precise control of their emission, which can be achieved by engineering the surrounding photonic environment to channel photons into well-defined optical modes [1]. Micro- and nano-optical architectures—such as gate-tunable microcavities, micropillars, and photonic crystal waveguides—have been developed to enhance photon extraction while preserving high indistinguishability (up to 99%) [2], achieving end-to-end efficiencies above 50% [3]. These structures also enable compact, chip-integrated designs.

Among emerging strategies, the Kerker condition has gained attention as a means to tailor the emission properties of QDs, by strategically integrating them with optical nanostructures. This unidirectional scattering mechanism is based on the interference of electromagnetic multipolar moments induced in the Mie scatterers [4]. The Kerker effect leverages interference between electric and magnetic dipole modes in Mie-resonant particles to achieve unidirectional scattering—either forward (in-phase, first Kerker condition) or backward (out-of-phase, second Kerker condition). All-dielectric nanostructures exploiting this principle offer a promising platform for QD integration [5], though experimental demonstrations remain limited.

Here, we tested both theoretically and experimentally the behavior of few GaAs-based QDs working as quantum emitters embedded within AlGaAs dielectric nanoresonators, and exploited the Kerker condition to modify the emission directivity based on the position of the QDs within the nanodisks.

We fabricated the optimized structures based on numerical simulations and measured their emission properties. By employing an innovative fabrication method, we created AlGaAs nanodisks on a AlO_x transparent

layer with a low number of QDs (about 8 -12 dots for cylinder) located at two different heights within the pillar, which correspond to forward and backward scattering Kerker conditions. Changing the vertical position of the dots by just 80 nm, we found a dramatic increase of the PL directivity from QDs due to the different Kerker condition. In fact, performing a statistical analysis on more than 150 QDs, we observed a dramatic enhancement of the PL intensity by more than one order of magnitude (about 14 times) when the emitters resided close to the top of the nanodisks, demonstrating the efficacy of the Kerker effect. Angle-resolved photoluminescence (PL) spectroscopy revealed a strong dependence of the angular emission pattern on the position of the QDs within the base area of the pillar. The experimental results aligned very well with the theoretical simulations.

The integration of QDs with nanostructures leveraging the Kerker condition not only advances our fundamental understanding of light-matter interactions, but also opens pathways to practical applications, from quantum information processing to advanced sensing technologies.

Metamaterials for Sustainable Energy and Environmental Solutions

Computational Design of Crystalline Chalcogenides for Intermediate-Band Solar Cells

M. Cagnoni[1]
[1]Politecnico di Torino, Italy
matteo.cagnoni@polito.it (corresponding author)

Abstract

Intermediate-band solar cells are a promising concept to exceed the Shockley-Queisser limit. Yet, photo-converting materials fully exploiting the intermediate-band paradigm remain elusive thus far. In this contribution, their possible realization with Earth-abundant crystalline chalcogenides is explored by state-of-the-art computational methods.

The intermediate-band solar cell is a concept developed to outperform today's commercial devices based on the Shockley-Queisser model. The latter employ a conventional semiconductor to convert sunlight photons into charge carriers, and selective contacts to order their motion and establish a net electric current (Figure 1a). The reliance on a single photon absorption onset (valence-conduction inter-band transitions) imposes a trade-off between photo-generated current and voltage. In fact, more carriers are available with a smaller valence-conduction gap (higher current), while more energy can be extracted per carrier with a larger one (higher voltage). This limits the maximum achievable efficiency to ∼30% [1, 2].

In intermediate-band solar cells, electronic states are introduced within the gap of the photo-converting material (Figure 1b). This allows electrons to be excited from the valence to the conduction band via an additional pathway that involves the absorption of two sub-gap photons. Compared to conventional semiconductors, the current-voltage trade-off is improved, because more charge carriers are photo-generated for the same valence-conduction band gap. As a result, the power conversion efficiency limit is boosted to ∼45% [3].

The potential to combine high performance with systemic simplicity makes intermediate-band solar cells very appealing. Yet, these devices have failed to outperform Shockley-Queisser ones thus far. This can be attributed to the use of sub-optimal photo-converting materials. In fact, these are often realized by heavily doping conventional semiconductors used in Shockley-Queisser solar cells, such as GaAs, to introduce the needed intermediate states. Not only the

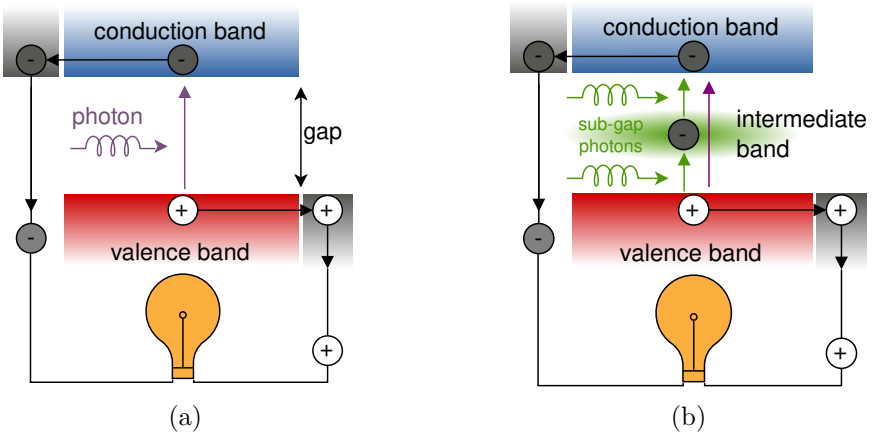

Figure 1: Working principle of a) Shockley-Queisser and b) intermediate-band solar cells.

resulting optical properties are far from optimal (for example, the valence-conduction band gap of GaAs is ∼1.4 eV, against the optimal value of ∼2.4 eV), but also the electrical properties are significantly degraded; indeed, the introduction of intermediate states as deep impurity levels strengthen Shockley-Read-Hall non-radiative recombination [4].

It has been argued that Shockley-Read-Hall non-radiative recombination can be inhibited by delocalizing the wave function of the intermediate states [5]. This can be accomplished by increasing the dopant concentration until the Mott transition occurs. Alternatively, one could use crystalline materials that inherently possess an intermediate-band electronic structure. This second approach is particularly appealing, because the intermediate-band paradigm is implemented by the material as it is, with possibly reduced fabrication complexity and better material quality. Yet, only a few studies have explored this concept, many of which only discuss the presence of an intermediate band, without subsequent material optimization and assessment of the corresponding solar cell efficiency limit [6, 7].

In this contribution, a step is made in this direction, by exploring the opto-electronic properties of Earth-abundant chalcogenides, such as IA:VIA compounds, and their possible optimization for intermediate-band solar cells. In particular, the following aspects are discussed, based on state-of-the-art computational methods:

1. optimization of electronic structure and optical properties by chemical substitution;
2. interplay between Fermi level position and intermediate-band solar cell efficiency limit;
3. possible approaches to adjust the Fermi level position by shallow defects.

Abstract

Aiming to advance next-generation photovoltaic architectures, we explore radiative cooling as a cooling system for multi-junction solar cells under high concentration. Additionally, we investigate the feasibility of metalenses for micro-concentrating photovoltaics, offering high design flexibility and compactness to enhance system efficiency.

To achieve high-efficiency photovoltaic systems, beyond improving the solar cells at the device level, two key approaches are better thermal management and concentrated photovoltaics (CPV). In this work, we investigate the potential of radiative cooling in high-concentration multi-junction (MJ) solar cells and the feasibility of a metalens-based micro-concentration system (μ-CPV). Radiative cooling, which relies on heat dissipation via infrared radiation through the atmospheric transparency window (8–13 μm), offers a cost-effective, passive approach for cooling solar cells [1]. Building on our previous findings on radiative cooling for MJ solar cells [2], we now focus on high-concentration scenarios. We demonstrate that placing a larger radiative cooler beneath the solar cell improves thermal management, achieving acceptable temperatures without the need for additional non-radiative systems. This approach is especially well-suited for CPV, where solar cells are significantly smaller than the system itself.

μ-CPV aims to enable compact, high-efficiency photovoltaic systems by miniaturizing CPV components, enhancing both performance and commercial viability [3]. However, such systems remain complex, particularly due to the need for multiple optical elements and the associated manufacturing challenges. Metalenses, with their design flexibility and compactness, offer a promising solution by integrating essential CPV requirements—such as uniform intensity and aberration correction—into a single optical component. Research in this area is still in its early stages, with some review papers addressing related aspects but not covering the practical realization of these metalenses, such as component dimensions [4]. To bridge this knowledge gap, we discuss the feasibility and challenges of developing metalens-based solar concentrators for μ-CPV, presenting preliminary results.

Figure 1a presents a schematic of our system, illustrating the detailed balance model for the solar cell/radiative cooler stack. The temperature is assumed to be uniform throughout the system and determined by the thermal equilibrium condition, set by zero net power exchange:

$$P_{\text{net}} = P_{\text{rad}}^{\text{RC}} \in P_{\text{atm}} + P_{\text{con}} + P_{\text{rad}}^{\text{SC}} + P_{\text{elec}} \in P_{\text{Sun}} = 0 \tag{1}$$

The terms related to the solar cell are calculated using the Shockley-Queisser model for series-connected MJ solar cells. The first three terms are scaled by the area ratio factor, $f_{\text{A}} = A_{\text{RC}}/A_{\text{SC}}$, to account for the radiative cooler larger area. More details are provided in [2]. Figure 1b shows the temperature of a three-junction (3J) solar cell, composed of GaP/GaAs/Ge (1.87/1.4/0.67 eV), for different concentration factors and area ratios, calculated by solving Equation 1. The solar cell temperature can be reduced to acceptable values ($T < 350$ K)

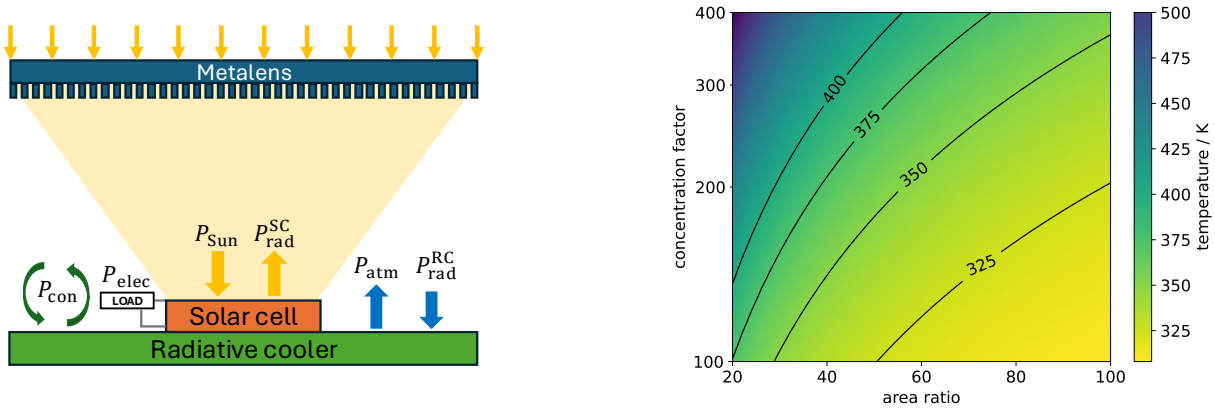

Figure 1: (a) Schematic of the system, illustrating the detailed balance model. (b) Temperature of the 3J solar cell for different concentration factors as a function of the area ratio.

for high concentration factors by simply increasing the radiative cooler's area in typical wind conditions ($h_c = 10.6\,\mathrm{Wm^{-2}K^{-1}}$) [1], as experimentally shown for a single junction solar cell in [5].

The metalens in Figure 1a acts as the concentrator in our system. Designing metalenses for μ-CPV requires satisfying key criteria such as broad bandwidth, uniform intensity, and achromatic performance. The achievable dimensions of an achromatic metalens are constrained by the group delay, as discussed in the literature [6]. We compute the geometric concentration factor, $C_g = A_{\text{metalens}}/A_{\text{solar cell}}$, and calculate the required group delay for various metalens sizes and numerical apertures. Using a non-imaging optics approach, we derive the phase profile and assess feasibility by comparing the calculated group delay with the maximum achievable values reported in the literature [7]. Given the small size of miniaturized solar cells [3], our results suggest that high concentration is theoretically achievable with metalenses for μ-CPV. In conclusion, the combination of radiative cooling and a metalens-based micro-concentration system shows strong potential for advancing next-generation photovoltaic systems.

Abstract: Multipole engineering is employed to enhance backscattering in core-shell spherical particles by optimizing the refractive index contrast. By aligning the electric dipole with the magnetic quadrupole in a TiO_2 particle, a significant increase in backscattering is achieved. These findings are highly relevant for passive radiative cooling applications.

Backscattering has been shown to play a crucial role in achieving high solar reflectance, as evidenced by studies that quantify its impact. These studies utilize simulations, asymmetry parameter analysis, and Maxwell/Mie theory-based methods to optimize their designs. In general, research incorporating specific backscattering calculations highlights its essential role in attaining high reflectance levels (Felicelli et al., 2022; Huang et al., 2021; Li et al., 2022; Lin et al., 2023).

Here, we study the enhancement of the backscattering of core-shell spherical particles by leveraging the refractive index contrast between the core and the shell using multipole engineering. By shifting the electric dipole to overlap with the magnetic quadrupole, we demonstrate that backscattering is significantly amplified (see Fig 1.), following a similar approach to that presented in the study by Liberal et al. (2015).

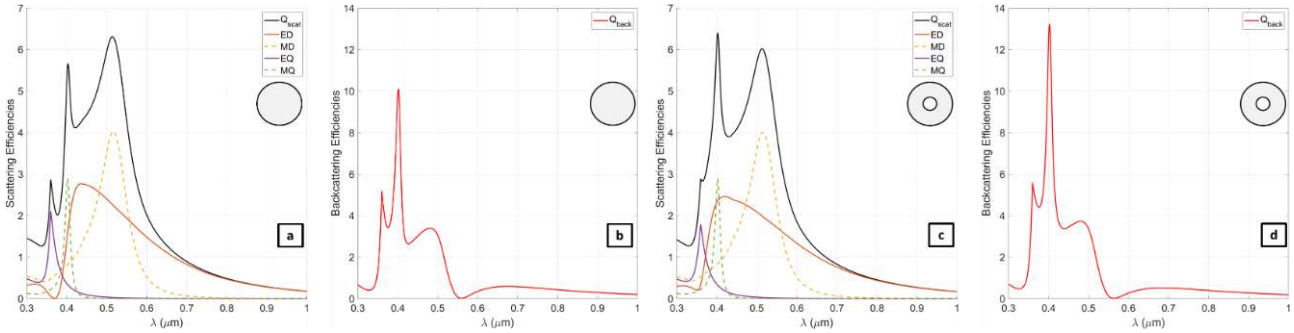

Figure 1. Evolution of the scattering after the transformation of a nanoparticle from a solid TiO_2 sphere (outer radius equal to 100 nm) to an air-cored core-shell (inner radius equal to 30 nm). (a and c) Scattering efficiency (black) and individual contributions from the electric (solid lines) and magnetic (dashed lines) multipoles. (b and d) Backscattering efficiencies for the homogeneous sphere and the core-shell particle.

Figure 1 (c-d) shows how even the amplification of backscattering directly affects the total scattering efficiency, creating a new maximum for that particle around 0.4 μm. Considering this effect, determining the optimal ratio between particle size and air gap dimensions within the core is essential to maximizing the improvement in scattering efficiency. Figure 2 shows the comparison of the ratio (Eq. 1) between backscattering/scattering efficiencies for an homogeneous particle and a core-shell one with a fixed air core equal

to 0.3 times the outer particle radius. These representations allow us to identify the optimal particle dimensions and core-shell configurations that maximize backscattering, showing that the ratio increase is more significant in core-shell particles and that the wavelength at which maximum backscattering occurs can be optimized by adjusting the outer radius.

$$Ratio = \frac{Q_{back}}{Q_{scatt}} \quad (1)$$

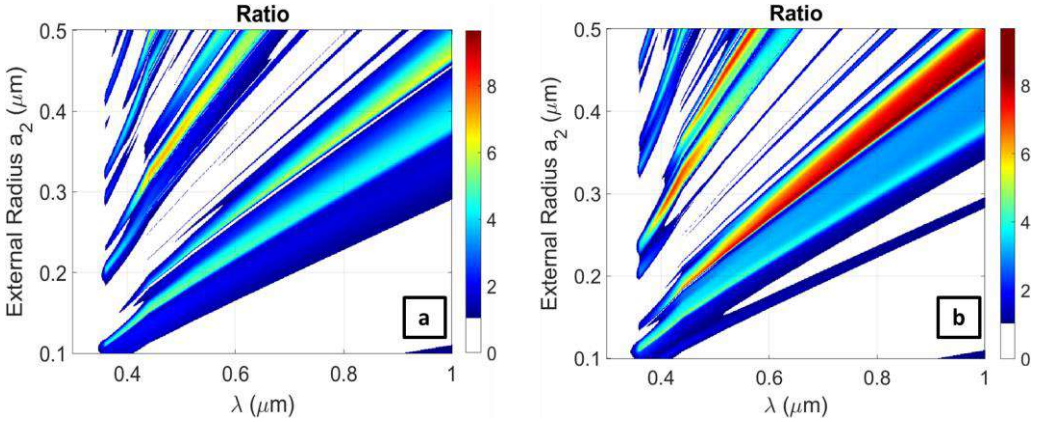

Figure 2. Heat map showing the ratio between Backscattering and Scattering efficiencies for different particle radii (from 0.1-0.5 µm). Values less than 1 are shown in white. (a) homogeneous TiO2 particle; (b) air-cored particle with radius equal to 0.3 times the shell radius.

In conclusion, multipole engineering allows for precise quantification of backscatter contributions from particle size and core-shell configurations. The next phase of this study involves employing FDTD simulations to design randomized particle clusters, enabling the development of structures with enhanced backscattering in the visible solar spectrum. This approach aims to achieve high broadband reflectance while improving net radiative cooling efficiency by minimizing parasitic solar absorption.

Abstract: Over the past four years, the MIRACLE project has been dedicated to developing innovative cement-based materials with radiative cooling properties. This work highlights some of the most promising results achieved, emphasizing the significant impact of these new concretes in reducing building energy consumption and mitigating the urban heat island effect.

Radiative cooling technology [1] utilizes the atmospheric transparency window (8-13 μm), called Atmospheric Window (AW), to passively dissipate heat from the Earth to outer space. All bodies in the Earth are in continuous exchange of energy with the sun and the atmosphere, with a net balance of power that depends on the incoming solar and atmospheric radiation, the emitted radiation and non-radiative heat exchanges. The key concept here is that the incoming and reflected solar radiation is short wave (~0.5 μm), while the incoming and outgoing thermal radiation is long wave (~10 μm). This spectral separation underpins most of the technologies which have envisaged radiative cooling, and justifies why it is so relevant to search for materials with high solar reflectivity, high emissivity in the AW and low non-radiative heat losses (low U-values).

So far, this technology has attracted wide interest from both fundamental and applied sciences, due to its a priori potential in multiple applications like building cooling, renewable energy harvesting, or even dew water production. However, currently the development of this technology is in a bottleneck, where the scientific progress has been largely based on either (i) fanciful 1D and 2D photonic metamaterials [2,3] containing scarce and expensive materials with negligible potential impact in any real-world energy solution; or (ii) hierarchically porous polymer coatings [4,5] which can be scalable, but at the cost of expensive industrial manufacturing processes, sacrificing spectral selectivity performance and suffering unavoidable durability issues (e.g. ultraviolet UV degradation).

In this context, the MIRACLE project [6] envisioned a new science and technology to turn low-tech concrete and cement-based materials into high-tech eco-friendly photonic metamaterials. In particular, over the las four years the MIRACLE project has constructed and tested several revolutionary Photonic Meta-Concrete (PMC) devices whose response to light was engineered for exhibiting radiative cooling ability.

As a matter of fact, and after several works linking the microstructure and properties [7,8,9], some of the realizations of MIRACLE enabled new concrete formulations with very high solar reflectance and emissivity in the atmospheric window. Indeed, these concretes were capable of delivering positive cooling powers and remain in sub-ambient temperature regime even on very hot days under intense solar irradiation. Of course, these properties were obtained without compromising the intrinsic mechanical resistance and/or the *per se* good durability of the cementitious matrices, something pivotal for scaling the technology.

In the face of increasing global warming, these "miraculous" concretes play a crucial role in advancing Nearly-Zero-Energy Buildings (NZEB) and contributing to the global strategy for reducing CO_2 emissions. Our projections indicate that in hot regions where heating demand is minimal, these materials can lead to drastic reductions—over 50%—in building energy consumption and associated CO_2 emissions. Furthermore, our climatic studies confirm that these innovative concretes are highly effective in mitigating the urban heat island effect.

This work was supported by the MIRACLE project. This project has received funding from the European Union's Horizon 2020 research and innovation programme under grant agreement No 964450. Manipulation of silver thicknesses of patterned metal by nanosphere lithography and electroplating for a smart window

Cheng-Yuan Xiao[1] and Tsung-Yu Huang[1,*]

[1.]Department of Materials Engineering, Ming Chi University of Technology, New Taipei, Taiwan

[*] Author e-mail address: huang.tsungyu@mail.mcut.edu.tw

Abstract: By regulating solar heat, smart windows mitigate the overall vicious cycle fueled by global warming. Our electrochromic approach integrates electroplated silver and nanospheres, enabling transmittance from 0% to clarity. Surpassing traditional systems, this flexible technology delivers dynamic sun modulation, enhanced performance, and improved energy efficiency, significantly boosting global architectural sustainability.

In response to global warming, sustainable development has become a critical focus. Currently, buildings in both developed and developing countries consume a significant amount of energy, accounting for 30% to 50% of total societal energy consumption. Heating and cooling systems constitute 40% of the energy consumed by buildings. [1,2,3] As a result, achieving a balance between indoor comfort and energy savings has become a major challenge. To address this, scientists have proposed smart windows to enhance indoor temperature comfort while conserving energy. Smart windows utilize various mechanisms, such as thermochromic, photochromic, and electrochromic technologies, among which electrochromic windows offer the flexibility to switch modes according to environmental conditions. However, previous studies have shown that electrochromic mechanisms typically involve voltage-induced switching between two or more stages, lacking the desired flexibility. In this study, we propose a novel approach by combining nanosphere lithography with reactive ion etching (RIE) to create uniform and discontinuous nanospheres, as shown in **Figure 1(a)**. Subsequently, transparent electrode materials are deposited to form structured electrodes, followed by simple electrochemical deposition of a silver metal film. In the initial phase of this research, we used simulation software to ensure the reliability of the experiment and explored deposition parameters to achieve higher-quality transparent conductive electrodes. Silver plating was then employed to dynamically adjust transmittance. The result is a new type of transparent conductive electrode with dynamic tuning capabilities, allowing for a seamless transition between a transmitting window and a reflecting mirror, achieving electrochromic effects. In the early stages of the experiment, we used simulation software to model the structured electrode's behavior under applied voltage during electrochemical reactions. Over time, the thickness of the silver film changed, leading to significant variations in the window's transmittance, as illustrated in **Figure 1(b)**. In subsequent experiments, we tested the transmittance and resistivity of indium tin oxide and gold as transparent electrodes using electron beam evaporation and thermal evaporation techniques. This part of the study is crucial for the transparency of the window and the subsequent electrochemical mechanisms. Therefore, we measured the transmittance of the samples using UV-Vis and the resistivity of the films using a four-point probe, as shown in **Figure 2**. We will further optimize the parameters to enhance the performance of the transparent electrodes and conduct electrochemical experiments to achieve a final seamless smart window.

Abstract: solution-processed ITO-based thin films and heterostructures are investigated by spectroscopic ellipsometry for application as metamaterials in the visible and near-infrared spectral ranges. Effective medium approximations are used to assess their optical and structural properties, optimizing their design for smart windows. This study advances active photonic crystals for on-demand photonic devices.

Photonic crystals (PhCs) are complex multi-layered dielectric systems that allow the spectrally resolved management of electromagnetic radiation. In their passive form, their response is univocally fixed upon fabrication; conversely, active PhCs may reversibly vary their optical response upon application of an external stimulus. These systems can be exploited for several applications, including smart windows and tunable daytime radiative cooling [1]. By leveraging PhCs in this way, researchers aim to develop smart windows with on-demand photonic capabilities, significantly enhancing the efficiency of photonic and solar-energy devices.

Among the various approaches explored in this field, electric-field-tuned PhCs based on indium-tin oxide (ITO) have garnered significant attention. ITO, one of the most widely studied transparent-conductive oxides (TCOs), exhibits remarkable tunability in its optical properties, making it a prime candidate for such applications. In this poster, we present a detailed ellipsometric characterization of ITO-based thin films and ITO/silica multilayers fabricated using solution-processing techniques [2]. We exploit the diagnostic capabilities offered by spectroscopic ellipsometry to evaluate the relation between the spin casting deposition parameters and the resulting optical and structural (i.e. porosity, surface roughness) properties of the films. Additionally, we utilize effective medium approximation (EMA) models, originally developed to describe nanocrystalline ITO films [3], to extract and interpret the broad-band optical properties of both individual layers and complex multilayer structures. By implementing EMA-based modeling, we aim to refine and optimize the design of ITO-based coatings for tunable radiative cooling applications.

This approach not only enhances our fundamental understanding of the material system but also facilitates the development of next-generation smart coatings, paving the way for more efficient and adaptive thermal management solutions in architectural and energy-related technologies.

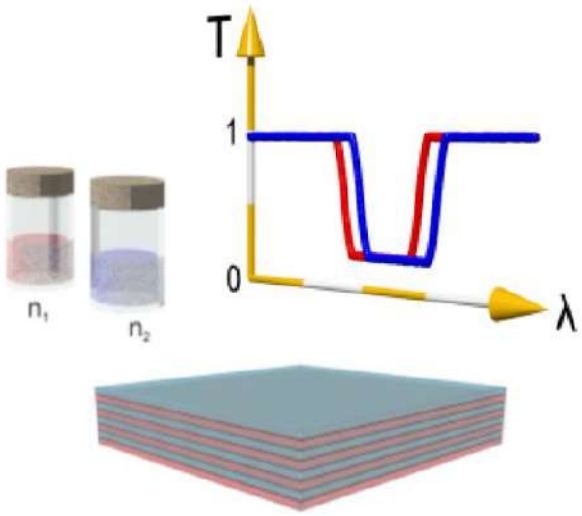

Figure 1. Concept for a tunable photonic crystal based on a Bragg reflector design, where one of the two materials is a transparent-conductive oxide.

Abstract: We found that approximately 18％ of large crystal enantiomeric excess (CEE) is observed in sodium chlorate chiral crystallization from a solution on a Mie resonant silicon (Si) metasurface excited by circularly polarized light. Numerical analyses implied that the CEE was caused by chiral optical force acting on chiral crystalline clusters.

Chiral light-matter interaction between circularly polarized light (CPL) and chiral materials has motivated researchers to control chirality of materials by CPL such as chiral photosynthesis by CPL.[1] However, the resulting chiral asymmetry is known to be very small and typical enantiomeric excess (e.e.) is 0.5-2%.[2] This situation arises from intrinsically weak chiral light-matter interaction between CPL and chiral materials. It is necessary for chirality control by light to enhance chirality of light. Recently, it has been discovered that the chiral light-matter interaction can be enhanced by enhancing the optical chirality of light field.[3] The light field with optical chirality stronger than that of CPL is called superchiral field. Recent numerical simulations have shown that superchiral fields can be generated in near-fields of Mie resonance in dielectric nanoparticles.[4] The question whether the superchiral field causes e.e. larger than that induced by CPL attracts much attention. However, it is not easy to evaluate e.e. in the chiral products synthesized in the nano-scaled superchiral near-field because the amount of the product is very small. This hinders the demonstration of effectiveness of superchiral near-field on chiral synthesis. A system including amplification process of the chiral products is necessary to investigate the effectiveness of the superchiral field. Here, we focused on chiral crystallization, where achiral molecules solidify into chiral crystal, by regarding rapid crystal growth after the chiral nucleation as an amplification process. We demonstrate that statistically significant CEE can be observed by inducing sodium chlorate ($NaClO_3$) chiral crystallization from a solution on a Mie-resonant silicon (Si) metasurface whose near-field of Mie resonance is expected to be superchiral.[5]

A metasurface with polycrystalline Si (poly-Si) nanodisk square array was fabricated by ultraviolet nanoimprint lithography. A platinum-palladium thin film (1 nm) was coated on the metasurface by sputtering. Mie resonance at 532 nm was confirmed by comparing dark-field spectrum and finite-difference time-domain (FDTD) simulations. Chiral crystallization of $NaClO_3$ was induced from microdroplets of aqueous solution on the metasurface by the irradiation with 532 nm continuous-wave *l*- and *r*-CPL focused by an inverted optical microscope. The handedness of the resulting crystals was identified using a polarized microscope. Chiral asymmetry of the obtained crystals was evaluated by counting each enantiomorph out of 100 crystallizations with the metasurface and 25 crystallizations without the metasurface using *l*- and *r*-CPL, respectively.

The 25 crystallizations without the metasurface using *l*- and *r*-CPL yielded 13 *d*-crystals and 13 *l*-crystals, respectively. On the other hand, the 100 crystallizations with the metasurface using *l*- and *r*-CPL yielded 57 *l*-crystals and 61 *d*-crystals, respectively. These results indicate the effectiveness of superchiral field beyond CPL. The magnitude of enantioselective optical force acting on $NaClO_3$ chiral crystalline clusters due to the excitation of superchiral field was estimated to be in the order of 1 fN in the vicinity of the Si nanosidks by FDTD method. Several previous studies have shown that a few fN force can transport nanoparticles with the radius of several tens of nanometers in liquids. Therefore, the enantioselective optical force can be the cause of the large CEE by changing the incident frequency of *d*- and *l*-chiral crystalline clusters to a crystal nucleus.

PURCELL BROADENING AND LAMB SHIFT FOR DNA-ASSEMBLED NEAR-INFRARED QUANTUM EMITTERS

Abstract: We harness the precision of DNA origami to assemble single fluorophores within plasmonic nanocavities. We observe an interplay of quantum effects, including giant Purcell broadening and pronounced Lamb shifts. These effects enable substantial spectral reshaping by redirecting the single molecule's emission into detuned near-infrared plasmonic modes.

Leveraging our scalable DNA-origami approach, we explore the plasmonic modes of nano-dimers and tailor them in nano-dimer-on-mirror (NDoM) plasmonic nanocavities to create a distinct radiative near-infrared (NIR) plasmonic mode. In these hybrid structures, a single fluorophore is precisely positioned within a narrow gap—on the order of 4–5 nm—between gold nanoparticles, ensuring that the Purcell factor is maximized while the gap remains tightly confined. This configuration not only enhances the local density of optical states (LDOS) but also paves the way toward achieving lifetime-limited emission, a crucial requirement for generating indistinguishable single photons for quantum nanophotonic applications.
Our experimental study, carried out at both room and cryogenic temperatures, reveals that coupling the fluorophore to the engineered nanocavity leads to dramatic spectral reshaping. Specifically, while the bare fluorophore exhibits a narrow zero-phonon line (ZPL) under low-temperature conditions, embedding it in an NDoM configuration induces a significant broadening of the ZPL—attributable to an enormous Purcell enhancement—and a pronounced Lamb shift that red-shifts the emission. This cooperative interplay between Purcell broadening and the Lamb shift facilitates energy transfer from the primary visible emission into a far-detuned NIR mode, even when the plasmonic resonance lies well outside the natural emission bandwidth of the molecule.

By independently engineering both the radiative and total LDOS, our nanocavity platform unlocks new regimes of cavity quantum electrodynamics (QED) where electronic transitions, molecular vibrations, and photonic modes interact in a highly controlled manner. The robust design allows us to decouple the radiative decay rate from nonradiative losses, thereby optimizing the emission properties of the coupled system. Detailed electromagnetic simulations confirm that the radiative efficiency and Purcell factor can be fine-tuned by altering the nanocavity geometry and the precise positioning of the fluorophore, a feature that is pivotal for achieving tailored spectral responses. The experimental data corroborate these predictions, demonstrating not only an enhancement of the overall photon budget but also a selective feeding of emission into the NIR mode.

These findings have significant implications for the development of broadband single photon sources, which are essential for secure quantum communication protocols and scalable quantum information processing. By exploiting the giant Purcell effect and the associated Lamb shift, our approach circumvents limitations inherent

to traditional organic emitters, offering a pathway to realize lifetime-limited single photon emission. Moreover, the platform is versatile enough to accommodate different fluorophores, allowing for fine adjustments of the spectral output based on specific application requirements.

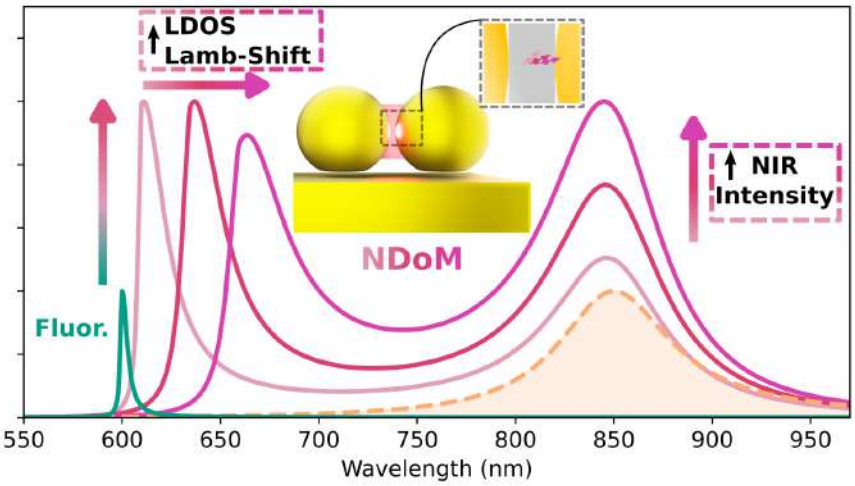

Figure 1 – Single fluorophores embedded in nano-dimer on mirror (NDoM) structures experience fluoroscence enhancement as well as Purcell broadening, leading to coupling to the NIR plasmonic mode, and pronounced fluorescence reshaping

In summary, our work demonstrates a powerful method for manipulating light–matter interactions at the single-molecule level. The ability to reshape emission spectra by harnessing engineered plasmonic modes, coupled with the control over LDOS, heralds a new era in nanoplasmonic cavity QED. This advance not only enhances our understanding of fundamental photonic processes but also lays the groundwork for practical applications in quantum optics, including the realization of indistinguishable photon sources and highly efficient NIR emitters.

Abstract: We fabricate a 2-dimensional (2D) square lattice array of silicon nanospheres on a polydimethylsiloxane (PDMS) substrate from a colloidal suspension of silicon nanospheres by a bottom-up process, and demonstrate the reflectance modulation via switching on and off the lattice Kerker effect by uniaxial strain.

1. Introduction

In a 2D array of resonant nanoparticles, resonance of individual nanoparticles interferes with the lattice mode of the periodic structure producing a collective lattice resonance (CLR), whose resonance properties depend strongly on the lattice constant[1]. The property of the CLR can be controlled by external stimuli like mechanical deformation[2]. In this work, we produce a large area 2D square lattice array (0.7 cm × 1 cm) of crystalline silicon nanospheres (Si NSs) having Mie resonances in the visible and near-infrared range on a flexible PDMS substrate, and demonstrate that the reflectance spectra are modulated by mechanical force via the lattice Kerker effect. We start with numerical simulations of the reflectance spectra to find the condition where the lattice Kerker effect occurs. We then produce a 2D square lattice array of Si NSs from the colloidal suspension[3] and demonstrate the reflectance modulation by uniaxial strain.

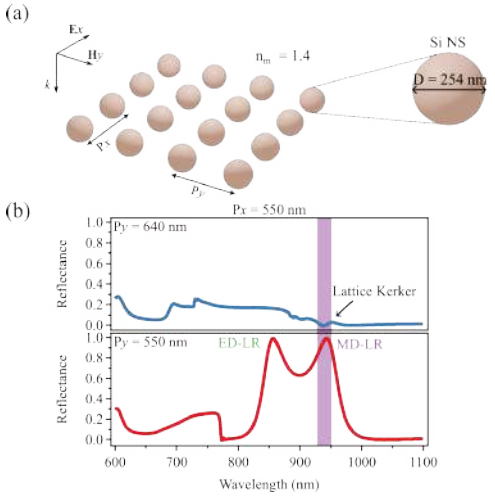

Figure 1. (a) Model structure of a Si NS 2D array. Si NSs are embedded in a medium with the refractive index of 1.4. The NS array is illuminated from the top by a plane wave polarized in the *x*-direction. (b) Calculated reflectance spectra. (red) P*x* = 550 nm, P*y* = 550 nm, (blue) P*x* = 550 nm, P*y* = 640 nm.

2. Numerical simulation

Figure 1a shows a model structure of a Si NSs 2D square lattice array embedded in PDMS (n_m = 1.4). The diameter of a Si NS is 254 nm. The 2D array is illuminated from the normal to its surface by a *x*-polarized plane wave. Figure 1b (red) shows the calculated reflectance spectrum when the lattice constants in the *x* (P*x*) and *y* (P*y*) directions are 550 nm. The two resonance peaks are lattice resonances arising from the electric dipole resonance (ED-LR) and magnetic dipole resonance (MD-LR) of Si NSs. When P*y* is increased to 640 nm at fixed P*x* (blue), the reflectance at ~ 940 nm almost disappears. This is due to the red shift of the ED-LR resonance, which causes the overlapping with the MD-LR resonance. Overlapping of the two resonances cancels the far field radiation (lattice Kerker effect) and suppresses the reflectance strongly. Therefore, by dynamically controlling the lattice constant, we can modulate the reflectance.

3. Preparation of Si NS square lattice array by a bottom-up process

In order to experimentally demonstrate dynamic control of the reflectance in 2D array of Si NSs, we produce it from the colloidal suspension[3] shown in Figure 2a. The transmission electron microscope (TEM) image shows that Si NSs are well defined with a high sphericity. Figure 2b shows the capillary-force assisted particle assembly procedure of the 2D array. We use a square lattice hole array made on PDMS as a template. The hole diameter is 300 nm, and the pitch is 550 nm. To fill the holes with Si NSs, a Si NSs suspension with the average diameter of 254 nm is dropped on the template and dragged by a guiding glass. Figure 2c shows a scanning electron microscope (SEM) image of the produced Si NS square lattice array. The holes are selectively filled with single Si NSs of almost the same size.

4. Mechanical modulation of the reflectance

Figure 2d (red) shows the measured reflectance spectra of the fabricated 2D array under the *x*-polarized light illumination. Peaks assigned to ED-LR and MD-LR are observed. When the 2D array is stretched in the *y*-direction with the strain of 15% (blue), the reflectance at ~ 910 nm is strongly suppressed. This is consistent with the calculated results in Figure 1b and can be explained by the lattice Kerker effect. The observed reflectance modulation is reversible for at least 100 times stretching-releasing cycles.

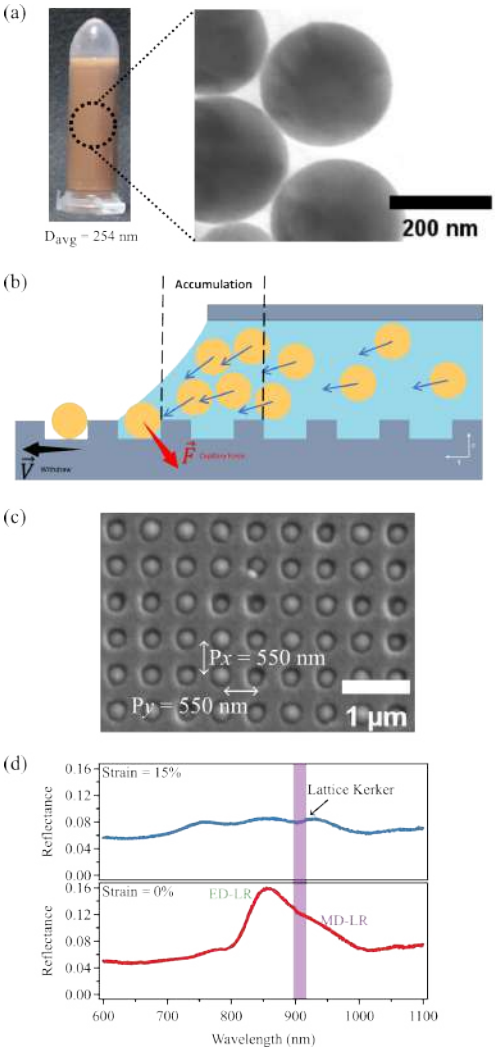

Figure 2. (a) Photo of colloidal suspension of Si NSs, and corresponding TEM image. (b) Schematic illustration of the procedure to fill holes in a template with Si NSs. (c) SEM image of a Si NS 2D array. (d) Measured reflection spectra. (red) Without strain, and (blue) 15% strain in y-direction.

5. Conclusion

We have succeeded in producing a Si NS square lattice array from the colloidal suspension on a flexible PDMS substrate by a bottom-up process. The 2D array shows ED-LR and MD-LR reflectance peaks in the visible and near-infrared range, and the peak wavelengths can be controlled by mechanical strain. We showed that overlapping the two resonances results in strong suppression of the reflectance due to the lattice Kerker effect. The reflectance modulation is reversible for at least 100 times, and thus the produced flexible metasurface works as a mechano-tunable optical component.

Enhanced linear and nonlinear single-particle spectroscopy within plasmonic nanocavities

O.S. Ojambati

Department of Applied Nanophotonics, Faculty of Science and Technology,

University of Twente, the Netherlands

o.s.ojambati@utwente.nl

Abstract: Plasmonic nanocavities localize and enhance optical fields in sub-diffraction-limited mode volume. Here, we harness the nanocavity to reveal linear and nonlinear optical signatures of sub-10 nm particles. The beauty of our approach is that it also enables label-free spectroscopy of freely diffusing single proteins, elucidating parameters that modify the dynamics.

Sub-diffraction-limited particles play crucial roles in nanomedicine, spectroscopy, catalysis, biomedical imaging, and nano-devices. Observing and imaging the tiny particles (diameter < 10 nm) in a label-free way is an interesting challenge for many optical techniques, due to the low scattering cross-section of these particles.

In this talk, I will describe how plasmonic nanocavities enhance the optical signatures of individual sub-10nm particles. Plasmonic nanocavities confine optical fields to extremely low mode volume (< 50 nm^3), and efficiently localize intense light intensity on the nanoparticles. Moreover, the nanocavity also enhances the scattered field by the nanoparticle, thereby enabling enhanced linear and nonlinear spectroscopy.

We demonstrate that the nanocavity enables the detection of a single metallic nanoparticle down to 1.8 nm in diameter [2]. The nanoparticle inside the nanocavity forms a strongly-coupled system revealed as anti-crossing modes in darkfield extinction spectroscopy. The strong coupling effect provides a nonlinear wavelength dependence on the nano-object diameter, which results in a high sensitivity.

Furthermore, we harness the subwavelength spatial confinement in the nanocavity to probe third-order optical nonlinearity of individual nanoparticles [3]. We performed Z-scan technique on the nanocavity, which enables accurate determination of nonlinear parameters, namely, the nonlinear refractive index and nonlinear absorption coefficient. Quantifying these parameters of individual nanoparticles is essential for nano-optical devices such as optical limiters, saturable absorbers, and optical switches. Our results remarkably show the nonlinear optical properties can be measured using only a few photons per pulse.

Additionally, we develop coupled nanocavities to probe the dynamics of individual proteins. The coupled nanocavities form a metasurface that enhances optical fields in unconstrained space. Our fast time-dependent surface-enhanced Raman spectroscopy measurement demonstrates that single protein dynamics is largely influenced by several factors, including surface functionalization, acidity of solvent, and electrostatics interactions.

DNA Origami-Based Rhodium Dimers as a New Type of UV-Plasmonic Nanoantennas

Karol Kołątaj[1*], Nicco Corduri[1], Guillermo Acuna[1*]

[1] Department of Physics, University of Fribourg, Chemin du Musée 3, Fribourg CH 1700, Switzerland

[*]corresponding authors: guillermo.acuna@unifr.ch, karol.kolataj@unifr.ch

Abstract: The DNA origami technique has been extensively used to arrange plasmonic nanoparticles for various photonic applications. Here, we present a new type of such nanoantennas based on UV-active rhodium nanocubes, which can be used for label-free fluorescence or resonance-SERS measurements of biologically important molecules, such as proteins and DNA.

Plasmonic nanoparticles have attracted considerable attention due to their ability to concentrate light at the nanoscale, resulting in significant enhancements of phenomena such as surface-enhanced Raman scattering (SERS) and fluorescence. To fully exploit the potential of plasmonic nanosystems, it is necessary to arrange nanoparticles in precise configurations with high accuracy. One of the most effective methods for synthesizing plasmonic nanoantennas is the DNA origami technique, which enables the precise, programmable assembly of nanoparticles into highly ordered structures, resulting in enhanced optical properties that cannot be achieved through traditional synthesis methods.

So far, all plasmonic nanostructures created using this technique have employed nanoparticles with optical responses in the visible and infrared regions. However, recent advances have made it possible to synthesize nanoparticles with a broader range of optical properties, including those that interact with ultraviolet (UV) light.[1] UV-active nanoparticles offer interesting possibilities, as many biological molecules absorb light in this range. For example, use of such nanoparticles enabled the label-free measurement of protein autofluorescence.[2] As a result, constructing DNA origami-based nanodevices with UV nanoparticles opens new avenues for detecting biologically relevant molecules, such as proteins and DNA, through fluorescence and resonance-SERS measurements.

In this contribution, we present the synthesis of plasmonic nanoantennas based on DNA origami and rhodium nanocubes, which is the first report of the use of UV-plasmonic nanoparticles to construct such nanosystems. Firstly, we optimized a detachment of polyvinylpyrrolidone (PVP) from the nanoparticle surface, which was later exchanged with DNA strands. The resulting DNA-functionalized Rh nanoparticles were precisely arranged on the surface of DNA origami, creating plasmonic nanoantennas, as shown in Figure 1a, with a remarkable 72% yield. These nanostructures are well-suited for applications in surface-enhanced Raman scattering (SERS) and fluorescence enhancement. To evaluate the performance of the constructed nanostructures in enhancing light-matter interactions, we conducted optical simulations, as shown in Figure 1b. Additionally, we examined the optical responses of nanoparticles with different shapes (see Figure 1c) to identify the optimal configuration for future nanosystems.

Solving Maxwell's Equations Using Polarimetry Alone

J. Olmos-Trigo[1*]
[1]Faculty of Optics and Optometry, Universidad Complutense de Madrid, Madrid 28037, Spain.
Corresponding author: jolmostrigo@gmail.com

Abstract: Maxwell's equations are solved when the amplitude and phase of the electromagnetic field are determined. Generally, the Stokes parameters can only capture the amplitude and polarization state of the electromagnetic field in the radiation (far) zone. Therefore, the measurement of the Stokes parameters is, in general, insufficient to solve Maxwell's equations. In this talk, we solve Maxwell's equations for a set of objects widely used in Nanophotonics using the Stokes parameters alone. Our method for solving Maxwell's equations endows the Stokes parameters an even more fundamental role in the electromagnetic scattering theory.

The determination of the amplitude and phase of the electromagnetic field at all points in space solves Maxwell's equations [1]. Currently, electromagnetic software packages can provide the numerical solution to Maxwell's equations. However, solving Maxwell's equations in the optical laboratory is nearly infeasible. One needs to measure the components of the scattered field at all points of the radiation zone. On top of that, the internal field induced in the excited object is experimentally inaccessible. In stark contrast, the Stokes parameters can be readily measured using a photodiode and waveplates [2]. The Stokes parameters can capture the amplitude and polarization state of the electromagnetic field in the radiation (far) zone. Therefore, the measurement of the Stokes parameters is, in general, insufficient to solve Maxwell's equations.

In this talk, we demonstrate that a measurement of the Stokes parameters at a single scattering angle is sufficient to solve Maxwell's equations for a set of objects [3, 4]. Notably, several works have tackled such objects in different branches of Nanophotonics. To the best of our knowledge, this study represents the first method capable of solving Maxwell's equations experimentally and from a measurement of the Stokes parameters. This feature endows the Stokes parameters, mostly used to get insight into the polarization state of the electromagnetic radiation, an even more fundamental role in the electromagnetic scattering theory.

Multivalency Studied at the Single Molecule Level via Plasmon Enhanced Fluorescence

K.R. Okholm[1], S.W. Nooteboom[2], P. Zijlstra[2] and D. S. Sutherland[1*]

[1]Interdisciplinary Nanoscience Center (iNANO), Faculty of Natural Sciences, Aarhus University, Denmark
[2]Dept. Appl. Physics and Science Education, Eindhoven University of Technology, The Netherlands

Abstract: Plasmon enhanced fluorescence was used to allow the study of weak dynamic interactions during multivalent binding at the single molecule level at the microsecond timescale. Molecular architecture changes the interactions and here we extend the concept of effective concentration to separate effects from size and structure/flexibility.

Summary:

The interaction of macromolecules via multiple weak interactions, so called multivalency, is a key feature present throughout nature for example in the recognition of pathogens by the immune system or the activation of signaling pathways via a concentration dependent pathway. The dynamic intramolecular interactions allow strong binding of a macromolecule to a multivalent target via the summation of multiple weak interactions. The avidity, the apparent increased binding affinity, is conceptually understood as a local concentration effect leading to enhanced rebinding of the individual binding motifs of a multivalent molecule. Overall avidity can be measured via a range of techniques but the study of dynamic intramolecular interactions is only accessible via single molecule approaches such as single molecule FRET. Current approaches are generally limited to millisecond timescales while many biological interactions and dynamics occur on the microsecond timescale. Here we present a plasmon-enhanced fluorescence platform to give highly enhanced photon count and potential for faster measurements in the microsecond regime [1]. We apply this approach to the study of multivalency with the nanoparticle as a multivalent, ligand-presenting object [2]. Using a Holliday Junction (HJ) as a model system we binding of constructs being 1, 2 and 3 ligands and study the role of construct structure and size on avidity. The HJ shows structure-dependent restriction of binding with limited binding of the third ligand. Addition of flexible extensions leads to overall reduced avidity from the longer arms and reduced local concentration, but importantly with activated trivalent binding. The dynamics within a single binding event can give information on the switching between states and the rate of binding/rebinding of the individual monovalent interactions within the multivalent interaction. We develop a theoretical framework extending the concept of effective concentration to separate effects from size from effects such as molecular structure and flexibility. Using the single molecule multivalent binding platform we study the role of ligand concentration and demonstrate super-selectivity for trivalent constructs [2]. The approach based on plasmonic nanoparticle-enhanced fluorescence gives a distance-based signal which both facilities single molecule measurements with low back ground and signal enhancement, but also enables the study of dynamics with a single molecule binding event Making use of the high time resolution in the microsecond regime we study intramolecular dynamics during bivalent binding events allowing the study of binding/unbinding of individual interactions within a multivalent binding[1].

We demonstrate that single molecule studies of multivalent constructs can measure avidity and dynamics of multivalent binding events and has the potential to guide the design of multivalent therapeutic constructs.

Abstract: We investigate light emission control from single emitters using plasmonic nanostructures. Analyzing various plasmonic configurations, we offer general insights into the enhancement of the emitted photoluminescence and other key parameters like radiative decay rates, Purcell factors and quantum yields, to guide the design of novel devices for future nanophotonic applications.

Optical nanoantennas are nanostructures that strongly interact with light through the excitation of localized surface plasmonic resonances. These resonances result from the collective oscillations of free electrons within the metal, generating enhanced electromagnetic fields in subwavelength volumes. This phenomenon has been exploited in numerous applications in nanophotonics, including enhanced spectroscopy, sensing, and imaging.

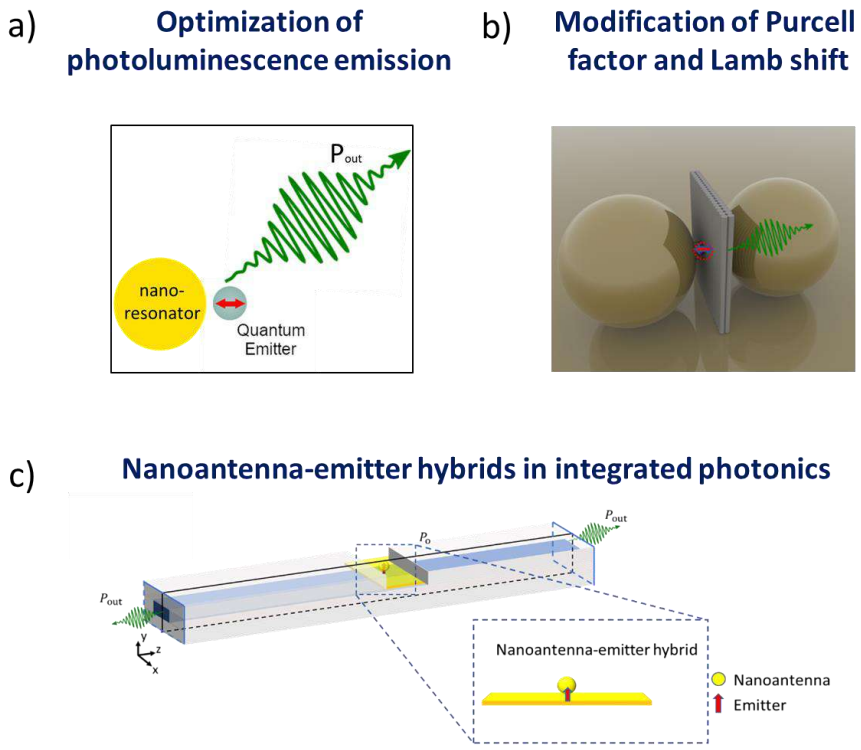

Figure 1. Light emitted from single emitters placed in a variety of plasmonic scenarios: a) A quantum emitter in close proximity to a single nanoresonator. b) Fluorophore placed in a plasmonic nanocavity within a nanodimer on a mirror (NDoM) configuration. c) Nanoantenna-emitter coupled to an etched SiN waveguide.

Notably, plasmonic nanoantennas can serve as a versatile platform for controlling the efficiency of light emission and the optical properties of single emitters—such as organic molecules, quantum dots, or nitrogen-vacancy centers in nanocrystals—by modifying their electromagnetic environment.

In this work, we present a comprehensive theoretical investigation of the light emitted from single emitters placed in diverse plasmonic scenarios (see Figure 1), focusing in the following key aspects:

i) We explore how plasmonic nanoantennas—varying in shape and size— modify the photoluminescence emission of a single emitter across multiple plasmonic configurations (Figure 1a). These include single and dimer gold nanorod antennas, plasmonic nanocavities, patch nanoantennas, and hybrid photonic-plasmonic cavities [1-4].

ii) We show that the emission spectra from a single molecule can be tailored by placing it within a plasmonic nanocavity formed by a gold nanodimer deposited on a mirror substrate, which radically alters the local photonic environment and introduces a very large Purcell Factor and Lamb Shift (Figure 1b). The theoretical predictions are in good agreement with the experimental results of collaborators that use DNA origami techniques to precisely position emitters within the nanoantennas [5].

iii) We explore the integration of an antenna-emitter hybrid system with a waveguide, to achieve efficient emission of light into the latter. Specifically, we consider a nanoparticle-on-a-mirror (NPoM) structure with a quantum dot positioned at the narrow gap between a metallic nanoparticle and a metallic surface [6], which are coupled to a SiN waveguide [7] (Figure 1c).

This work thus provides a comprehensive guide for enhancing light emission from quantum emitters using plasmonic nanostructures, offering insights for future advancements in the design of nanophotonic devices and on-chip applications.

[*]corresponding author: f.vollmer@exeter.ac.uk

Abstract: Plasmonic nanoparticles enhance optical fields. I demonstrate the application of plasmonic enhancers in Whispering Gallery Mode (WGM) sensing using optical microcavities. These enhancers have enabled significant advances in thermo-optoplasmonic (TOP) sensing of single molecules, including measurements of their absorption cross-sections, enzyme thermodynamics, and protein dynamics. They have also facilitated the development of microlasers with single atomic ion and molecule sensitivity, the detection and discrimination of neurotransmitters down to attomolar concentrations, and the observation of nanoparticle catalysis through plasmonic tip engineering. Furthermore, I present recent progress in the use of plasmonic enhancement for the detection of chiral molecules, ranging from monolayers and bilayers to nanoscale shells.

Abstract: Nanoscale photon sources exhibit a dipole-like emission pattern, limiting their incorporation into on-chip devices. Nanoantennas can control their radiation pattern, but often involve lossy plasmonic nanoparticles. Here, we show that a single dielectric nanoparticle can direct the emitted light of a nearby nanoemitter, allowing for geometrical and spectral light routing.

Summary: Nanoscale photon sources such as fluorescent molecules exhibit a dipole-like emission pattern, significantly limiting the amount of light that can be collected and hampering their incorporation into flat on-chip optical components. Therefore, developing directional optical emitters with tunable angular responses in the visible range is crucial for applications ranging from designing efficient integrated optical systems to high-sensitivity screening of molecular species. While optical antennas have been introduced to control the radiation pattern of nanoemitters, the overall sizes of the reported systems are typically larger than the wavelength of the radiation, and the designs often involve high-loss plasmonic nanoparticles. Researches attempts to design compact directional plasmonic antennas rely on achieving unidirectional emission through interference between electric multipoles. Alternatively, interference between electric and magnetic resonances have recently been explored as an alternative to enhance nanoantenna directivity based on the Kerker condition. However, this approach remains largely unexplored. However, this unidirectional emission happens only for complex structures, for specific positions of the emitter around the nanoantenna and in a narrow wavelength.

Individual low-loss high-index dielectric nanoparticles (HID NPs) can overcome these limitations as they can also generate electric and magnetic dipole responses, whose interference can strongly affect their scattering pattern.[29] It has been theoretically shown that a single HID NP is sufficient to direct the light emitted by a neighboring dipole.[1,2] Moreover, a single HID NP promises to have more advantages, as it has been proposed to be able to reverse this directionality depending on the emission wavelength,[2] and to be able to either collect or reflect the emitted light by tuning the particle-emitter distance.[1] However, those effects have never been demonstrated experimentally, mainly due to the difficulties of placing an individual dipole emitter in the proximity of the NPs with high accuracy.

In this work we show, for the first time, that emission directionality can be tuned at the single-molecule level using a single silicon nanoparticle that is deterministically coupled to a single fluorescent molecule using the DNA origami technique. This approach allows manipulation of the emitter's position relative to the Si NP with

nanometer precision. By varying the emitter-NP distance, NP size, and fluorescent molecule (and thus emission range), it is demonstrated that a silicon nanoparticle functions as a broadband directional nanoantenna in the visible range with high robustness to geometrical variations, as opposed to commonly used designs. We further show that a displacement of the emitter around the NP can yield to a change in the emission angle (beam steering behavior), which, so far, has only been theoretically predicted.[3] Furthermore, we observed, for the first time with a single nanoparticle, a change in emission direction as a function of the emission wavelength, i.e., color routing,[2] with a strong dependence on the distance between the NP and the emitter. This results as well in a change in the collector/reflector behavior of the NP at certain wavelengths as theoretically predicted.[1]

Abstract: Metal nanoparticle arrays support lattice plasmon resonances with enhanced optical and photothermal responses. In this work, we fabricate square grids of 100 nm colloidal Au NPs with tunable parameters through optical printing and explore how lattice spacing and size affect resonance properties, also comparing experimental results with simulations.

Metal nanoparticles (NPs) act as nanoantennas in the visible range due to their localized surface plasmon resonances (LSPR), allowing them to efficiently collect light, concentrate it in nanoscale volumes, and transfer its energy to the material's charge carriers and phonons.[1] Thus, they act as sources of electromagnetic fields, charge, and heat at the nanoscale, which can be tuned remotely by using light. These capabilities have given rise to the field of nanoplasmonics and motivated the use of NPs in numerous nanotechnology applications. When NPs are arranged in ordered arrays, collective modes can emerge, known as lattice plasmon resonances.[2] These collective modes show an enhanced optical response compared to individual NP resonances, with higher quality factors. Additionally, collective resonances can be tuned by modifying lattice parameters and exhibit enhanced photothermal responses.[3] While the properties of these lattices have been extensively studied through simulations, their fabrication and experimental demonstration remain challenging.

In this work, we use the optical printing technique, which enables the deposition of arbitrary colloidal NP arrays on substrates.[4] The versatility of this method in modifying lattice parameters, such as diameter of the NPs (d), size of the array (N) and interparticle distance (a) (Figure 1 a), allows us to fabricate arrays of spherical gold NPs in a simple manner, a morphology that is difficult to achieve using other methods like lithography. We present here the fabrication of different square periodic arrays of 100 nm spherical Au NPs having different a and N (Figure 1b), investigating how these parameters influence the presence and intensity of lattice resonances. We also compared the optical response with simulations, considering the intrinsic disorder of the arrays due to the fabrication method, obtaining excellent agreement between them.

This work contributes to the development of new photonic devices for light and heat manipulation at the micro- and nanoscale.

Cooperative electron-vibron interactions in Surface-Enhanced Raman Scattering (SERS)

Miguel Ángel Martínez-García[1], and Diego Martín Cano[1*]

[1] Departamento de Físíca Teórica de la Materia Condensada and Condensed Matter Physics Center (IFIMAC), Universidad Autónoma de Madrid, Madrid, Spain

[*]corresponding author: diego.martin.cano@uam.es

Abstract: We identify cooperative electron-vibron interactions between near-resonant and non-resonant electronic levels in SERS. Using an open-system quantum model, we demonstrate how Raman interference leads to large modifications in SERS peak intensities. This mechanism generates enhanced nonclassical photon correlations, reshaping conventional assessments of optomechanical contributions in SERS spectra and quantum observables.

The discovery of significant enhancements in Raman molecular signals near metallic surfaces, attributed to surface plasmons and charge-transfer effects, paved the way for the initial experimental validations of single-molecule vibrational spectroscopy and the initiation of SERS research. Despite strong supporting evidence of these findings, there have been debate and discrepancies regarding the mechanisms responsible for generating SERS and explanations for anomalous spectroscopic features when compared to conventional Raman spectroscopy [1]. Motivated by the need to elucidate such SERS processes, several pioneering studies have investigated cavity optomechanical models, treating vibrations and photons with equal complexity to account for their nonlinear contributions in off-resonance [2] and near-resonance SERS [3], respectively.

In this work we identify cooperative electron-vibron interactions occurring between both near-resonant and non-resonant electronic levels [4]. By developing an open-system quantum model based on fundamental molecular interaction principles, we illustrate how Raman interference, involving both resonant and non-resonant components, can lead to several orders of magnitude modifications in SERS peak intensities beyond previous optomechanical predictions. This cooperative optomechanical mechanism enables the generation of strongly enhanced nonclassical correlations between Stokes and anti-Stokes photons, observable via photon-counting measurements. Our findings reveal coherent Raman enhancements and suppressions that reshape conventional assessments of the optomechanical contribution to SERS spectra and its quantum mechanical signatures.

Abstract: We fabricated a periodic SiC nanoparticle array embedded in a flexible polymer. Photoluminescence enhancement was demonstrated by placing it on the top of phosphor (YAG:Ce^{3+}) plate. the SiC sticker outperforms the TiO_2 nanoantenna sticker with identical design.

Silicon carbide (SiC) can be a good Mie-tronics ingredient because of its higher refractive index and a lower extinction coefficient than those of TiO_2 [1]. In the research field of power-electronics, SiC is intensively explored as wide-bandgap semiconductors. Heavy demands from the power-electronics community to reduce the numbers of crystalline defects and dislocations have developed high-quality crystal growth technologies of these materials, and the nanophotonics research community can make use of these crystals to fabricate metasurfaces.

We fabricated a periodic SiC nanoparticle array embedded in a flexible polymer, which is applicable as a sticker to stick to any clean surfaces to control light [2]. Starting from the epitaxial 3C-SiC thin films on Si substrates, the nanoparticle array was fabricated by combining electron beam lithography and dry etching. After coating the nanoparticles with a polydimethylsiloxane (PDMS) film, the Si substrate on the backside was etched away to obtain the free-standing SiC nanoparticle array embedded in the PDMS film. The optical measurements show that the resultant nanoantenna sticker supports surface lattice resonances. Because of the flexibility of the sticker, the resonances can be tuned by mechanical deformations. Photoluminescence enhancement was demonstrated by placing it on the top of phosphor plate.

Abstract

Dielectric nanoresonators have proven to be efficient platforms for chiral sensing due to high-quality-factor resonant states that increase chiral light-matter interaction and boost circular dichroism. We theoretically show that a proper combination of such resonant states significantly increases the chiroptical response to a level that should be measurable in experiments.

1 Results and discussion

Chirality is a non-identity of an object to its mirror image. This fundamental property is inherent in many organic molecules, chemical compounds, and drugs, and crucially affects living organisms. The same molecules of the opposite handedness (enantiomers) can act as a drug or a toxin, respectively [1]. Therefore, the detection of molecular handedness is a cornerstone problem of biology, chemistry, and medicine. Measuring circular dichroism (CD), which is the difference in absorbance of left-handed (L) and right-handed (R) circularly polarized light by chiral molecules, is a standard approach to distinguish the opposite enantiomers. The main obstacle is extremely small values of CD signal in a natural chiral medium. This is where nanophotonics comes into play. The use of resonant states of plasmonic and dielectric nanostructures allows us to significantly enhance chiral light-matter interaction and increase CD [2, 3].

Recently, a general electromagnetic theory of chiral light-matter interaction in arbitrary resonators has been developed [4]. In the framework of this theory, the chiroptical response can be disentangled into a sum of five contributions, namely, nonresonant interaction, resonance shift, changes in the excitation and emission of resonances, and modal crosstalk.

In this study, we explore the later mechanism, the modal crosstalk, and implement it on a dielectric metasurface [Fig. 1(a)] that supports quasi-bound states in the continuum (quasi-BICs) – resonant states with extremely high quality factors, which have attracted a lot of attention in the nanophotonic community over the last decades [5]. We demonstrate that a proper combination of quasi-BICs guarantees a huge boost of the chiroptical response, including the differential transmittance $\Delta T = T_{\mathrm{L}} \in T_{\mathrm{R}}$. By selecting two nearly degenerate, orthogonally polarized quasi-BICs, we demonstrate a ΔT enhancement on the order of 10^3 and an absolute value of ΔT on the order of 10^{-2} [Fig. 1(b)], which seems feasible for detection in standard spectrometers.

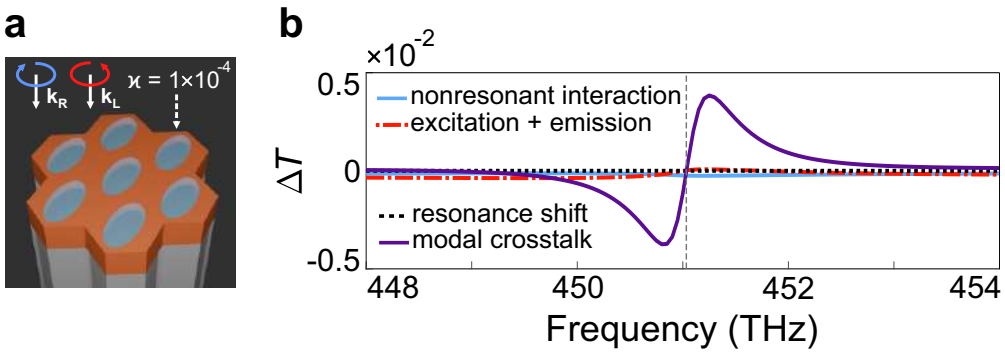

Figure 1: (a) Dielectric metasurface design with an inserted chiral analyte. (b) The chiroptical response ΔT from the system. ΔT is disentangled into five mechanisms (changes in the excitation and emission of the resonances are united into one class), and the modal crosstalk unambiguously dominates.

Abstract: We associate a 4-polarization camera with a 4-wave diffraction grating to achieve single-shot imaging of the vectorial electromagnetic field associated to nanostructures at the sample plane of an optical microscope. We illustrate the technique on lithographic and colloidal nanoparticles and metasurfaces.

Optical characterization methods in nanophotonics may be complex to implement, or fall short by providing only basic light intensity measurements, overlooking the intricate complexity inherent in many nanophotonic structures, in terms of spectral or polarization response. To address these limitations, we introduce an optical microscopy technique, both powerful and simple to implement, designed to capture the full complex vectorial electromagnetic field at the image plane of a microscope. This technique is based on the implementation of a 4-wave diffraction grating (QLSI grating [1]), associated with a polarized camera. We show how this advance enables quantitative tensorial characterization of nanophotonics sample, namely the determination of the complex polarizability tensor of anisotropic nanoparticles, and the mapping of the complex optical conductivity tensor of 2D materials and metasurfaces. This accessible method enables a detailed and comprehensive exploration of nanophotonic samples, paving the way for enhanced metrology, understanding and control of light-matter interactions at the nanoscale.

Abstract: We developed a nanoporous gold core–shell SERS nanoprobe enabling sensitive thiram detection down to 10^{-8} M. Incorporating TFMBA as an internal standard allows simultaneous evaluation of nanoparticle quality and concentration. This versatile platform offers potential for environmental monitoring, food safety, and biomedical diagnostics.

The rapid and sensitive detection of small pesticide molecules is essential for environmental monitoring and food safety. Here, we present a highly efficient surface-enhanced Raman spectroscopy (SERS) nanoprobe featuring a gold core surrounded by a nanoporous shell, synthesized via a dealloying strategy. The nanoporous structure serves as a network of SERS hotspots, significantly amplifying the Raman signal while providing a high surface area for small pesticide molecules to efficiently penetrate and bind within the pores. This ensures precise and selective detection at ultralow concentrations. To enhance the probe's functionality, we incorporated 4-trifluoromethylbenzoic acid (TFMBA) as a Raman reporter on the gold core. Acting as an internal standard, TFMBA enables dual functionality: in the dry state, its characteristic Raman signals allow assessment of nanoparticle quality, such as synthesis efficiency and structural integrity. In solution, the TFMBA signal provides a quantitative measure of nanoparticle concentration, ensuring reliable and consistent performance during pesticide detection. After systematic optimization, the nanoprobe demonstrated exceptional sensitivity, detecting thiram molecules at concentrations as low as 1×10^{-8} M in the dry state, with a broad detection range from 1×10^{-2} to 1×10^{-8} M. In aqueous solution, the nanoprobe achieved quantitative detection over a range of 1×10^{-2} to 1×10^{-6} M, with a detection limit of 1×10^{-6} M. Additionally, we developed an SNP-based visualization method for intuitive detection of pesticides at concentrations as low as 10^{-8} M. We envision that this nanoporous Au core/SERS nanoprobe, with its universal SERS hotspots and internal standards like TFMBA, could extend beyond pesticide detection to enable sensitive detection of larger biomarkers, such as antibodies, highlighting its potential as a versatile tool for environmental monitoring, food safety, and biomedical diagnostics.

Advanced Theoretical Methods for Nanoplasmonics and Molecular Plasmonics

Emission Quenching in Plasmonics – Understanding and Countering It

Jacob B. Khurgin
Johns Hopkins University

Plasmonic structures are well known for enhancing light emission through the Purcell effect. While they significantly increase radiative decay rates, this does not always translate to higher overall emission efficiency. In fact, in many cases, the efficiency can be lower than that of emitters without plasmonic enhancement—a phenomenon known as luminescence quenching.

In this talk, I will present a simple coupled-mode theory that attributes quenching to emission into higher-order nonradiative modes of plasmonic structures. This framework allows for the strategic placement of emitters to optimize efficiency. Moreover, the theory reveals that breaking symmetry mixes radiative and nonradiative modes, thereby mitigating quenching—an effect observed in dimers, nanoantennas, and disordered plasmonic structures. Finally, the model also provides insight into why quenching does not occur in plasmon-enhanced Raman scattering.

Modeling Plasmonics and Molecular Plasmonics from an Atomistic Perspective

C. Cappelli[1,2 *]

Abstract: This study presents an atomistic yet classical approach coupled to a QM Hamiltonian, to predict plasmonic properties of nanostructured materials. The method enables large-scale simulations, also capturing quantum effects. Remarkably, it accurately reproduces computed reference data and experiments.

The optical response of plasmonic nanostructures can be tuned by varying their shape, size, and chemical composition [1]. Peculiar phenomena arise when a molecular system is adsorbed on the surface of plasmonic materials, ranging from surface-enhanced spectroscopies to photocatalysis [2]. The accurate description of the optical properties of the plasmonic substrates is thus crucial for an understanding of the physical phenomena occurring at the plasmon resonance frequency.

We present an atomistic, yet classical, approach to predict the plasmonic properties of nanostructures of complex shapes. The method is general enough to describe any plasmonic material, including noble metal nanoparticles (Ag and Au) [3] and metal alloys [4]. The approach is also coupled to a quantum mechanical (QM) description of the molecular system adsorbed on the nanostructure surface [5]. The resulting mixed QM/classical method is then extended to various spectral signals, e.g. surface-enhanced Raman scattering.

We show that our classical approach for plasmonics can correctly reproduce reference ab initio data [3], and experimental trends [3-4], and can be applied to large-scale nanoplasmonic simulations (more than 1 million atoms). By properly accounting for the atomistic discretization of matter, we can accurately describe the nanoplasmonics of systems dominated by quantum effects, such as subnanometer junctions [3,6], geometrical defects [8], and Gold picocavities [8]. Finally, we discuss the current challenges in the prediction of surface-enhanced spectroscopies, analyzing the performance of our methods, also by comparison with experiments [5].

This work has received funding from the European Research Council (ERC) under the European Union’s Horizon 2020 research and innovation programme (grant agreement No. 818064).

A computational Maxwell solver for nonlocal Feibelman parameters in plasmonics

Lorenz Huber[1] and **Ulrich Hohenester**[1*]

[1]Institute of Physics, University of Graz, Universitätsplatz 5,8010 Graz, Austria
[*]corresponding author: ulrich.hohenester@uni-graz.at

In extreme vicinity of metallic nanoparticles, quantum surface effects play a significant role. We develop a computational Maxwell solver based on the boundary element method, accounting for quantum corrections through mesoscopic boundary conditions with nonlocal Feibelman parameters. We demonstrate the versatility and accuracy of our approach for various model systems.

Optical excitation of plasmonic nanoparticles allows light confinement in subwavelength volumes and can lead to strong field enhancements (1). When dealing with sharp particle features, gaps, or quantum emitter field variations on the nanometer scale, quantum surface effects become significant.
Recently, it has been suggested to account for such quantum effects through mesoscopic boundary conditions (2) that incorporate frequency-dependent Feibelman parameters (3). In this paper, we develop the methodology and implement mesoscopic boundary conditions into a computational Maxwell solver based on the boundary element method (BEM) (4). Unlike previous approaches (5), we additionally consider Feibelman parameters that are nonlocal in the parallel direction to the metal interface, providing a more accurate description of quantum effects as suggested by recent results from time-dependent density functional theory simulations (6).

We further developed a modified Mie theory incorporating nonlocal Feibelman parameters and show for sodium spheres perfect agreement with BEM simulations. When refining the mesh discretization in the BEM approach, the numerical error is shown to monotonically decrease. Notably, the computational cost of the novel scheme is comparable to that of normal BEM simulations, making our approach ideal for future investigations of different particle geometries and materials. This would make Feibelman parameters accessible to a broader community and would establish mesoscopic boundary conditions as an integral part of plasmonics simulations.

We acknowledge Tomáš Neuman, Antton Babaze, Andrei Borisov, and Javier Aizpurua for providing nonlocal Feibelman parameters obtained from ab-initio calculations and for their valuable discussions. This work has received support from the FWF under project P 37150**.**

Time-dependent quantum/continuum modeling of plasmon-enhanced electronic circular dichroism

Abstract: We present a multiscale real-time approach to study plasmonic effects of a metal nanoparticle (NP) on the electronic circular-dichroism spectrum of a chiral molecule interacting with it. The method is based on a quantum description of the molecular system is coupled to a classical representation of the NP.

The enhanced sensitivity and response of chiral molecules in the presence of NPs have been thoroughly investigated experimentally [1], and theoretical literature was dedicated to a dipole-like description of the chiral molecule [2], usually within a master equation for the quantum states of the molecule.
Modeling the plasmonic-enhanced CD spectrum within the quantum-chemistry framework, beyond a dipole-like representation of the molecule, is a fundamental step to support experimentalists in the prediction and rationalization of the recorded data. It is a challenging task for theory because a large and complex system, generically composed of a NP and a molecule, has to be properly simulated.
The presented multiscale method is characterized by a quantum (QM) description of the chiral moiety, whereas the NP is treated according to a polarizable continuum model extended to nanoparticles [3]. The QM/continuum method is applied to the electronic CD (ECD) of methyloxirane (MOX) and peridinin (PID) at various distances (1, 3, and 5 nm) with respect to a gold NP surface. While no remarkable effect is observed for methyloxirane at any studied distance, an enhancement appears when the peridinin lies at 1 nm and the pulse is linearly polarized perpendicularly to the molecular axis, with the ECD signal centered at 4.1 eV increased by a factor of around 20. These results are rationalized looking at the gap between the plasmonic peak of the NP at around 2.5 eV and the molecular excitations: the smaller the gap between molecular and plasmonic excitations, the larger the plasmonic enhancement of the ECD signal. If the gap is too large, plasmon effects are negligible, as in the case of MOX; instead, since the PID lowest excitations are close to the NP plasmon, the effect of the induced plasmon field is remarkable and determines an enhancement approximately of a factor 20 with a pulse polarization perpendicular to the NP surface. This effect decreases with the distance between NP and PID, as the amplitude of the induced field decreases.
Moreover, ECD peaks are selectively enhanced due to the favorable coupling between the pulse polarization and the combined effect of electric and magnetic dipole moments.
This approach allows one to go through the electronic structure and dynamics of chiral molecules for obtaining a realistic description of plasmon-mediated ECD spectra, e.g., paving the way to applications to molecules of biological relevance interacting with nanostructures of experimental interest.

Modelling hot carrier generation, relaxation and extraction in large metallic nanoparticles

Johannes Lischner[1*]

[1]Imperial College London, United Kingdom
[*]corresponding author: j.lischner@imperial.ac.uk

Abstract: The decay of localized surface plasmons results in the generation of energetic or "hot" electrons and holes which can be harvested for applications in photovoltaics and photocatalysis. I will describe an atomistic theory of hot-carrier properties which allows the modelling of nanoparticles consisting of more than one million atoms.

Localized surface plasmons in metallic nanoparticles give rise to very strong light absorption. The decay of these excitations results in the generation of energetic or "hot" electrons and holes which can be harvested and harnessed for applications in photovoltaics, photocatalysis and light sensing. To optimize hot carrier production in devices, a detailed theoretical understanding of the relevant microscopic processes, including light-matter interactions, plasmon decay and hot electron thermalization, is needed. In my talk, I will describe a material-specific theory of hot-carrier generation and relaxation in metallic nanoparticles which combines a classical description of the electromagnetic radiation with large-scale atomistic quantum-mechanical simulations. I will present results for hot carrier distributions in spherical nanoparticles of gold, silver and copper and discuss the relative importance of interband and intraband transitions as function of nanoparticle size. Next, I will describe how CO_2 reduction performance of gold nanoparticles can be enhanced by changing the nanoparticle shape. Finally, I will discuss an approach to capture the effect of adsorbed molecules on the plasmon decay which enables the description of chemical interface damping.

Theory of imaging molecules using light in a scanning tunneling microscope

T. Neuman[1*]

[1]Institute of Physics of the Czech Academy of Sciences, Cukrovarnická 112/10, Prague 16 200, Czechia

[*]corresponding author: neuman@fzu.cz

Abstract: I will discuss the theoretical description and interpretation of techniques employing light in a scanning tunneling microscope. These techniques, including STM-induced electroluminescence, photocurrent generation, or tip-enhanced photoluminescence provide sub-molecular optical resolution and reveal atomic-scale molecular properties mostly related to the molecule's excited states, hardly accessible otherwise.

Advancements in scanning tunneling microscopy (STM), a technique where electrons tunnel between an atomically sharp probing tip and a sample supported by a conducting substrate, brought a breakthrough that allowed combining electron tunneling with light (electromagnetic wave) illumination and detection and thus lead to the advent of atomic-scale optical or optically assisted microscopy in an STM (STM plus light, STML). Several techniques lie under the umbrella of STML (see Fig. 1), including the STM-induced electroluminescence (STMEL) [1], its inverse, the generation of tunneling photocurrents in STM (PSTM) [2], or the tip-enhanced photoluminescence (TEPL) [3], to name a few. Each of these techniques provides a different, often complementary, view on the microscopic properties of the molecule. In this contribution I will focus on their theoretical description and interpretation.

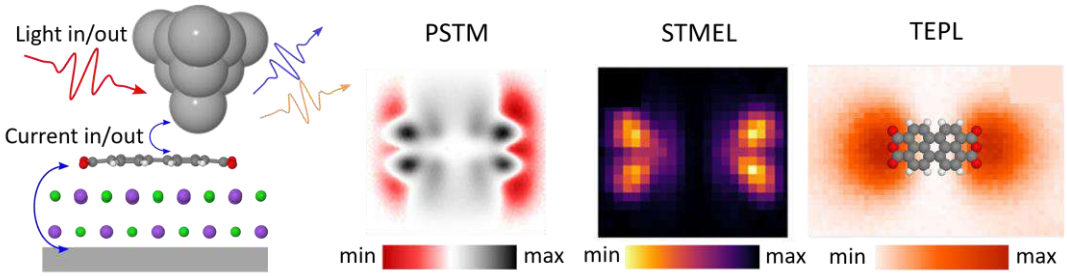

Figure 1. Schematic of the STM setup composed of the microscope tip, the molecule and the substrate including 2ML of NaCl (left) and examples of experimental images of photocurrents obtained with PSTM, and photon maps obtained with STMEL [4] and TEPL, respectively, of the perylenetetracarboxylic dianhydride molecule.

The optical resolution of these techniques originates in the highly localized interaction between the molecular excitations, characterized by the oscillating electron transition density, and the optical excitations in the STM tip-substrate cavity. The latter has its origin in the collective electron resonances, localized plasmons, that are hosted by the tip-substrate "cavity" and that give rise to an electric field oscillating at optical frequencies that is strongly localized around the atomically sharp apex of the STM tip. The interaction of the molecular excitation with the plasmons leads, on the one hand, to the enhanced coupling of incident light with the molecule and, on the other hand, tip-enhanced spontaneous emission of the molecular excitation giving rise to radiation into the far field. The detailed mechanism leading to sub-molecular optical imaging, however, depends on the specifics of the STML method.

TEPL can be considered as the optically purest of the mentioned techniques as it solely relies on interactions

between plasmons, the external laser illumination and the molecular excitation. I will discuss the theoretical details of plasmon—molecular exciton coupling that allow for optical imaging of molecular excitations going beyond the standard selection rules of light-matter interaction governing standard optical microscopy [5].

In STMEL, the molecule can most usually be excited by the sequential resonant tunneling of electrons where electrons are exchanged in several steps between the tip and the molecule and the molecule and the substrate. This process can lead to the transient change of the molecular charge followed by its return to the original charged state, however, hosting now an optical excitation (i.e. an electron-hole pair). As I will show, the tip-mediated tunneling step leaves its fingerprint in the population of the excited state through the density of states of the "active" molecular orbital (MO) involved in the tunneling process and is thus an inextricable part of the optical image obtained by scanning with the tip across the molecule and recording the intensity of the emitted light. The emitted light can be post-processed by analyzing its tip-position—dependent spectral properties to reveal details about the microscopic properties of the molecule such as the charge-transfer character of its excitation [6].

The spatial dependence of the tip-mediated tunneling step is the prime mechanism giving rise to PSTM, where tip-position-dependent currents are detected upon photoexciting the molecule. One can thus image the "active" MOs contributing to the sequential deexcitation of the molecule via resonant charge transfer processes. I will detail this mechanism using a recent example of a molecular radical where an excited state was imaged using this technique [7]. The analysis of the spatially resolved photocurrents revealed the multiconfigurational character of the molecule's doublet excited state, a feature influencing the optical properties of a broad range of radical emitters that are nowadays considered for application in optoelectronics as their efficiency is not hindered by the spin statistics (presence of dark triplet states) associated with closed shell systems.

Abstract: In the case of carbon dioxide reduction, it was experimentally shown that the presence of a rhodium nanocube under illumination leads to the selective production of methane against carbon monoxide. Using a multiscale computational approach, based on accurate (GW-BSE) electronic-structure calculations for the "active site" and a classical representation of the rest of the nanostructure, we show that selectivity is due to a (predominantly) direct hole injection from rhodium to the reaction intermediate that favours the bonding of the proper molecular fragment to the surface.

It is well known that the presence of a plasmonic nanoparticle strongly affects the optical response of molecules, leading to significant effects such as surface enhanced Raman scattering, surface enhanced infrared absorption and metal enhanced fluorescence.Moreover, in recent years, plasmonic metallic nanostructures have emerged as a new family of photocatalysts, enhancing rates and increasing selectivity of important chemical reactions such as H_2 splitting and CO_2 reduction to methane [1].

When explaining the selectivity enhancement, hot carriers, i.e., energetic, non thermal electrons and holes generated upon plasmonic decay within the metal nanostructure, are thought to play a fundamental role. Nevertheless disentangling the effects of hot carrier dynamics from those of the other possibly concurrent phenomena such as reaction barriers lowering in excited state pathways, resonance of near fields with intramolecular transitions, and local increase of temperature, might be really hard from an experimental perspective. In this framework, theoretical modelization of these phenomena directly probing the role played by hot carriers are especially important to grasp the microscopic mechanism at play. However, theoretically modeling plasmonic-generated hot carriers and their effects is especially challenging due to the inherent multiscale nature of the system and to the kind of phenomena that are at play [1].

Recently [2], the simulation of the simultaneous electronic dynamics of molecule and nanoparticle has been achieved by combining a time-dependent configuration interaction approach for the molecule, and a description of the nanoparticle as a continuous dielectric of given shape and dielectric function within the polarizable continuum model approach. This approach was later extended to include the description of the molecule's electronic structure and neutral excited states at the GW-BSE level which correctly accounts for electronic level alignment at interfaces and charge transfer excitations [3].

In 2017, Zhang et al. demonstrated that in a hydrogen-rich environment, in the presence of rhodium nanocubes, CO_2 is reduced to a 60:40 ratio mixture of CH_4 and CO. However, in the presence of an external electromagnetic pulse matching the optical absorption of the nanocubes, the selectivity toward CH_4 rises to values above 90% [4]. The effect was tentatively assigned to hot-electron injection in antibonding orbitals of a reaction intermediate based on ground state density functional theory (DFT) calculations for CHO adsorbed on a model Rh(100) surface.

We performed extensive simulations of the electronic dynamics of the system, looking for possible charge transfer effects using the previously described multiscale computational approach, based on accurate (GW-BSE) electronic-structure calculations. In our simulations, the Rh nanoparticle is represented as a continuous dielectric nanocube of 37 nm edge, as in the experiment, characterized by the empirical Rh dielectric function $\epsilon(\omega)$, and

edge curvature equal to Rh atomic radius. One of the vertices of the nanocube is cut perpendicular to the (111) direction. Above the cut, at the atomic interlayer distance, an atomistic Rh19 cluster is set, mimicking the vertex itself. Adsorbed to the cluster is a CHO fragment, being the CHO dissociation into CH + O the rate-determining step in the thermally activated reaction toward CH4. The carrier dynamics is triggered by a Gaussian-enveloped electric field pulse centered at 3.4 eV, taken from the experimental work, and close to the plasmonic resonance of the rhodium nanocube. The results of our dynamics show that it is hole injection that speeds up the pathway leading to CH_4 production, by making the CHO fragment's oxygen more reactive. The microscopic mechanism of the injection was also analysed, showing that direct photoinduced charge transfer is prevailing for the nanocube thanks to the electromagnetic enhancement effect associated with the metal NP electronic resonance [5].

Abstract: We propose a theoretical approach to actively control Smith-Purcell radiation emission using 2D (graphene/TMD) nanoribbons. By tuning doping levels via electrical gating or optothermal doping, we achieve precise control of emission directionality, enabling light focusing and steering, with implications for spectroscopy, sensing, and communication applications.

Smith-Purcell radiation [1], a phenomenon arising from the interaction between charged particles and periodic structures, holds great importance for various applications, from particle accelerators to broadband radiation sources. In this study, we propose a novel approach to actively control and tune the emission of Smith-Purcell radiation in free space by leveraging the tunable properties of graphene and transition metal dichalcogenides (TMD) nanoribbons (Fig. 1a). Specifically, by adjusting the optical properties of individual ribbons within an array (namely their polarizability), we can customize the interference pattern that arises on the far-field, thus achieving precise control over the directionality of Smith-Purcell radiation. Notably, the doping level of graphene can be actively tuned through electrical gating, thus providing our system with a versatile set of knobs to control the emission properties of the array with a large degree of precision. Through extensive parameter optimization, we identify optimal combinations of parameters to maximize control over the emission process to allow for the control of both near-field and far-field distributions respectively aiming at active light focusing and steering (Fig. 1b).

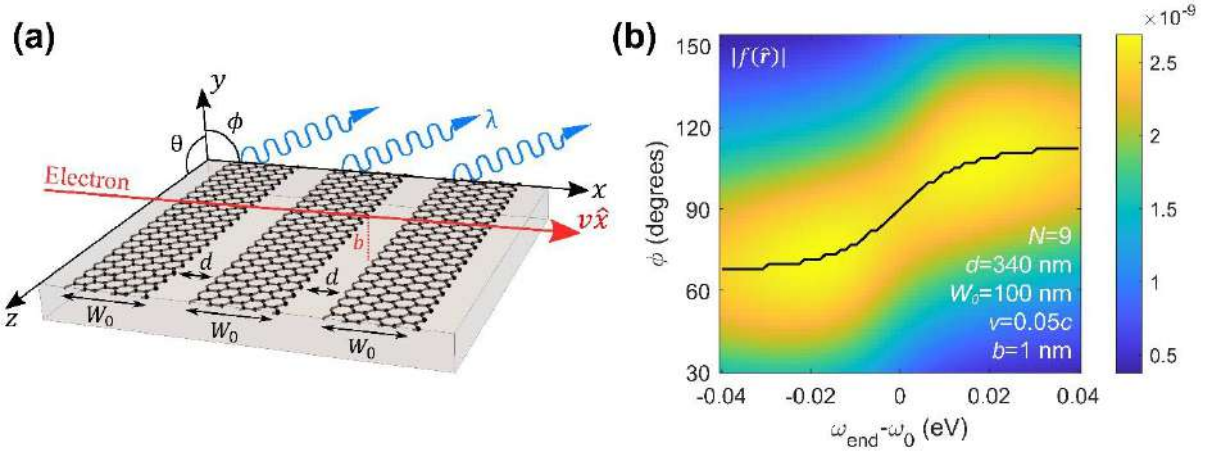

Figure 1. (a) Proposed setup composed of a periodic array of N 2D ribbons of width W_0 and spacing d. An electron flies with velocity v parallel and at a distance b to the ribbon's plane. Smith-Purcell emission of a wavelength λ is marked in blue. **(b)** Angular distribution of the far-field intensity $|f(\hat{r})|$ (for $\theta = 0$) of 9 graphene ribbons as a function of the difference in plasmon frequencies between the outmost (ω_{end}) and central (ω_0) ribbons, taken to vary linearly between ribbons. The black curve indicates the far-field intensity maxima which shows a steering ability ranging up to $\pm 20°$.

Furthermore, we explore alternative mechanisms for achieving a controllable optical response in each ribbon. Promisingly, optothermal doping can be obtained by employing spatially-modulated high-intensity laser pulses that locally change the electron temperature in graphene or TMD ribbons with diffraction-limited resolution, which translates into an ultrafast spatial-dependent modulation of their response [2]. This mechanism enables the fine-tuning of the emission characteristics which can be actively controlled by changing the illumination profile. Importantly, this mechanism provides a practical platform for the experimental investigation of such effects while offering insights into the underlying physics governing the ultrafast thermal dynamics in such systems.

Our findings pave the way for the development of advanced Smith-Purcell radiation sources with highly tailored and dynamically controllable emission properties, thereby unlocking new opportunities for innovative applications in areas such as spectroscopy, precision sensing, optical communication, and other fields requiring versatile and tunable radiation sources.

Nonadiabatic dynamics of plasmon-mediated photochemistry

Yu Zhang[1]
[1]Theoretical Division, Los Alamos National Laboratory, Los Alamos, NM, 87544, USA
Corresponding author: zhy@lanl.gov

Abstract: Heterogeneous catalysis of adsorbates on metallic surfaces mediated by plasmons has the potential to achieve controllable reaction selectivity. However, the underlying physics of plasmon-mediated chemical transformations is very challenging to delineate. This talk will present our developments in theory and numerical methods for plasmon-mediated chemistry and the physical insights obtained.

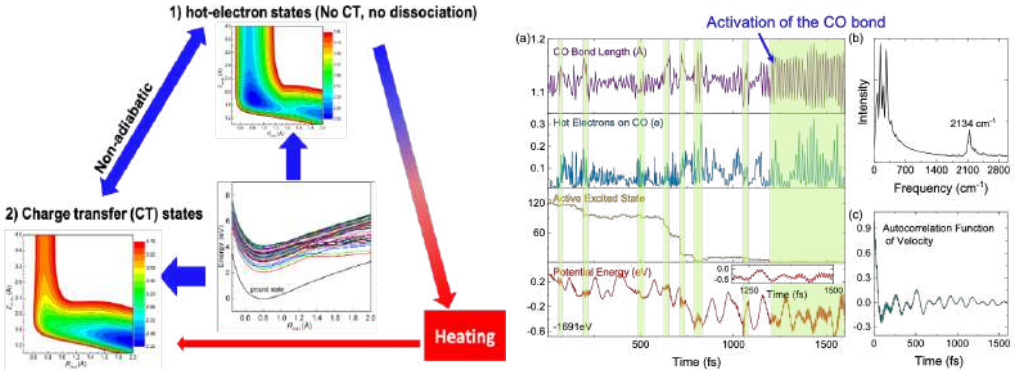

Figure 1: a) a) Different mechanisms of plasmon-mediated chemical transformations, including e hot carrier generation through surface plasmon excitation, followed by charge transfer to molecular antibonding orbitals, leading to bond dissociation. (b) A nonadiabatic molecular dynamics (NMAD) approach that treats all possible mechanisms—such as charge transfer, and electron-nuclear coupling—on an equal footing, providing a comprehensive framework for simulating plasmon-driven reactions

Introduction. Surface plasmon polaritons (SPPs) and localized surface plasmon resonances (LSPRs) are collective oscillations of electrons in conductors excited by electromagnetic modes. Surface plasmons results in concentration of light in the near-field around the particle interfaces, which enables efficient spatial control of charge and energy fluxes in a variety of applications. However, surface plasmons suffer from significant dissipation, with most of the plasmon's energy loss due to Landau damping leading to hot electron-hole (e-h) pairs. Several recent efforts have proposed the possible extraction of these energetic carriers before dissipation takes place, which has simulated the application of hot carriers to several branches of applied physics, chemistry, and materials and energy sciences [1].

Plasmon-mediated chemical transformation. Plasmon-driven reactions hold great promise for guiding chemical transformations with light, especially by exploiting the energetic electrons (hot carriers) that emerge from surface plasmon decay in metallic nanostructures. We have undertaken a series of computational investigations to illuminate how these hot carriers can activate and dissociate molecules or modify adsorbate–surface interactions on gold clusters.

First, the microscopic mechanism of H_2 dissociation in a plasmonic nanoparticle system was examined [2]. Our NAMD simulation revealed that, upon photoexcitation, hot carriers generated in gold nanoparticles transfer to the antibonding orbital of H_2, driving dissociation.

Interestingly, when H_2 is symmetrically placed in the gap of a dimer configuration, sequential charge transfer rapidly depletes the antibonding state, suppressing dissociation. Breaking this symmetry by displacing the molecule, however, restores dissociation, suggesting that nanoparticle geometry could offer a route for controlling reaction pathways.

But the Jellium model used in Ref. [2] lacks atomistic details. Insights from PESs built on the ab initio atomistic model are essential for a more in-depth understanding of plasmon chemistry. Hence, we employed time-dependent density functional theory (TDDFT) and quantum dynamics to investigate the potential energy surface of H_2 on a smaller Au_6 cluster and their photoinduced dynamics [3]. Our diabatization approach revealed two distinct categories of electronic states: those associated with hot electrons remaining in the metal, and those linked to charge transfer (CT) into the H_2 antibonding orbital. H_2 dissociation occurs efficiently only when transitions between these two states (from metal to CT) take place. Hence, controlling the funneling of population into these CT states is essential for plasmon-mediated chemical transformations.

To study all possible mechanisms on an equal footing, we implemented a TD-DFTB-based trajectory surface-hopping approach [4]. This methodology enabled us to treat hot-electron relaxation, charge transfer, and local heating in a unified framework. We then applied this approach to investigate plasmon-mediated heterogeneous catalysis involving CO adsorbed on an Au_{20} cluster [5]. After plasmon excitation, hot carriers shuttle between the Au_{20} and CO, activating the CO stretch via electron-vibration coupling. By tracking ensembles of trajectories, we estimated an overall $\sim$40% efficiency for plasmon-mediated transformations under these conditions. This work highlights how partial charge transfer, carrier migration, and molecular vibrational excitation interplay on ultrafast timescales to drive chemical transformations.

Abstract: Polaritonic chemistry exploits light-matter interactions to control chemical reactions. This study develops the Polaritonic Index (PI), a Python tool useful to classify electronic excitations in hybrid metal-molecule systems. Tested on systems of azobenzene (single or multiple molecules) interacting with Ag clusters, PI enables to control polariton-induced changes in photochemical processes.

Introduction

Polaritonic chemistry is an emerging interdisciplinary field that explores the interaction between light and matter to manipulate chemical reactions. This research employs Time-Dependent Density Functional Theory (TDDFT) to investigate how photonic modes, such as localized surface plasmon in metal nanoparticles, influence molecular potential energy surfaces (PESs). The primary objective is to develop a computational framework that enables precise control over photochemical processes, with potential applications in photopharmacology and opto-stimulation. Hybrid systems composed of metal nanoparticles and molecular emitters present challenges due to their complex molecular-plasmonic interactions, often leading to phenomena like charge-transfer states and polaritonic states. To address these challenges, a novel computational tool, the Polaritonic Index (PI), was developed to characterize and classify electronic excitations, distinguishing between molecular, metallic, and hybrid states.

Results

The Polaritonic Index (PI)[1] is implemented in a Python-based computational tool designed to analyze electronic excitations in hybrid metal-molecule systems. It employs transition density analysis to classify excitations into three categories: metal ($0 \leq PI \leq 1$), hybrid ($1 < PI < 10$), and molecular (≥ 10). The PI is determined using a mathematical formula (1) that quantifies the relative contributions of molecular and metallic components in an excitation:

$$PI(\omega_k) = \frac{\Delta\rho_{mol}}{\Delta\rho_{cluster}} = \frac{\sum_{I=1}^{Q_{mol}} \sum_{i=1}^{N} e^{-\left[\frac{(\vec{r_i}-\vec{R_I})^2}{2\sigma_i^2}\right]} |\Delta\rho(\vec{r_i},\omega_k)|}{\sum_j^{Q_{mol}} Z_j \cdot N_j}. \qquad (1)$$

In this context, $\Delta\rho_{mol}$ and $\Delta\rho_{cluster}$ represent electron density changes on the molecule and metallic cluster for a given excitation at frequency ω_k. The index I runs over the molecule's atoms (Q_{mol}), while i runs over the grid points. Here, $\vec{r_i}$ and $\vec{R_I}$ denote a grid point and atomic position, respectively. The standard deviation $\sigma_i = w_i \cdot rad$ is defined by a weight factor and a radius (covalent, van der Waals, or atomic), determining the charge distribution's spatial extent.

Since PI alone does not distinguish between charge-transfer (CT) and polaritonic states, the "D

distance" metric[2] was incorporated to precisely differentiate them by measuring spatial charge distribution changes between ground and excited states.

The PI tool was tested on a system consisting of an azobenzene molecule and a silver cluster. Azobenzene, a photoswitch, exhibits strong coupling with metal clusters under specific configurations[3]. By systematically varying the azobenzene dihedral angle, the research examined how molecular excitation properties changed due to plasmonic interactions. Through computational analysis, the hybrid system excitations were mapped as a function of dihedral angles, revealing clear trends in hybridization strength. Results showed that states exhibiting strong hybrid character required further refinement of classification thresholds to better differentiate between charge-transfer and polaritonic states.

Additionally, the PI was also tested on a system composed of a metal cluster and an ensemble of molecules, demonstrating its applicability in more complex hybrid systems.

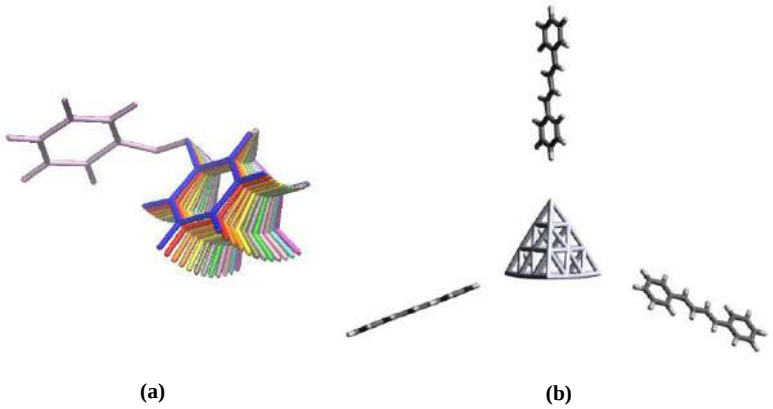

Fig 1: (a) Geometries of azobenzene molecule obtained by varying dihedral angle (CNNC). (b) Hybrid system composed of a silver cluster and three molecules of stilbene.

Conclusions

This study developed a computational approach for analyzing and classifying electronic excitations in hybrid metal-molecule systems. The Polaritonic Index provides a novel, systematic framework for distinguishing excitation types, with applications in understanding and controlling photochemical reactions. Testing on the azobenzene-silver system demonstrated the method ability to analyze hybrid states and identify charge-transfer contributions. Future work will refine classification thresholds and expand the methodology to more complex systems, further advancing polaritonic chemistry as a tool for tunable photoreactions.

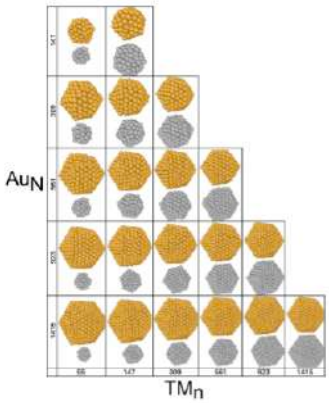
Abstract:



By classical MD simulations, we model the coalescence of Au-hybrid nanostructures -bimetallic nanoantennas- introducing proper geometrical descriptors to capture the kinetics of the process.

We calculate the absorption and ECD spectra employing TDDFT as in the AMS/ADF/polTDDFT tool[2], contrasting them against classical electromagnetic prediction from the pyGDM library.

Summary

We model the growth process by means of classical molecular dynamics simulations, using the package LoDiS and metal-metal interaction from the second-moment approximation of the tight-binding (TBSMA)[1]. The choice of those potentials resides in their accuracy in predicting surface diffusion processes. We focus on coalescence, see Fig. 1, where two initial seeds of Au and of another transition metal (TM), collide to form a larger nanoobject. We select TM among Au, Ag, Pd, Pt, Rh. We limit our analysis to icosahedral seeds being a likely geometry for the considered TMs at seed-sizes between 0.7 – 3.2 nm. To track the evolution of AuTM, we compute global, semi-local, and local structural descriptors with the aim of identifying (i) the kinetics of the shrinking process; (ii) and the most significant transition during the evolution of the so-formed AuTM. We sample our MD trajectories, at least 200 ns long, every 0.1 ns after 1 ns the contact time, see Fig. 1.

The AuTM shape classification follows the common neighbour analysis (CNA) signature, that detects the local connectivity of each pair of nearest-neighbour atoms, and its translation into an atomic property (CNA pattern). A layer-by-layer (LBL) analysis is performed by slicing the nanoalloys into consecutive layers perpendicular to the coalescence axis, connecting the centre of mass of the two initial seeds.[2] We quantify the chemical ordering and the likelihood of metal miscibility, by the time-evolution of the chemical LBL (cLBL), the relative density of Au and TM atoms per each layer.

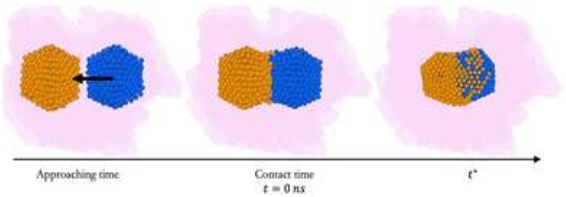


Figure 1Schematic view of the coalescence process (top), where the three stages have been identified. Summary of the binary Au-based nanostructures considered for coalescence. Au atoms are in gold, and grey atoms are the TM. We explore Au-rich compositions.

Besides structural analysis, we estimate the optical properties at the TDDFT level of theory, performed with the polTDDFT algorithm with the hybrid functional B3LYP exchange-correlation (xc) functional within the Hybrid Diagonal Approximation (HDA) and a triple-zeta plus polarization TZP basis set of Slater-type orbitals. Calculations are performed with a local version of ADF engine of the AMS code (version 2024.102).[3] We estimate both photo-absorption and the Electronic Circular Dichroism (ECD) [5]. We consider the Individual Component Map of Oscillator Strength (ICM-OS) to identify the appearance of a plasmonic behaviour [6]. The calculated $Au_{55}Ag_{55}$ TDDFT photoabsorption spectra, Fig. 2, shows a lower intensity absorption in the 3.4-4.6 eV range and a higher absorption in the 5.5 – 6.5 eV. We observe that the minor spectral feature at 3.56 eV (10th peak in Fig. 2) has a strong coupling between the components and hence a clear indication of plasmonic behavior. The 4.40 eV peak (labelled as peak 6) has only a partial plasmonic behavior while the intense peak at 6.50 eV (line feature 1). We compare optical spectra against classical electromagnetic calculations through the pyGDM library [4] in order to determine at what size the classical approach becomes reliable. Currently, we are checking whether retrieving the dielectric constant from TDDFT and plug it into the pyGDM improves the accuracy of the classical approach.

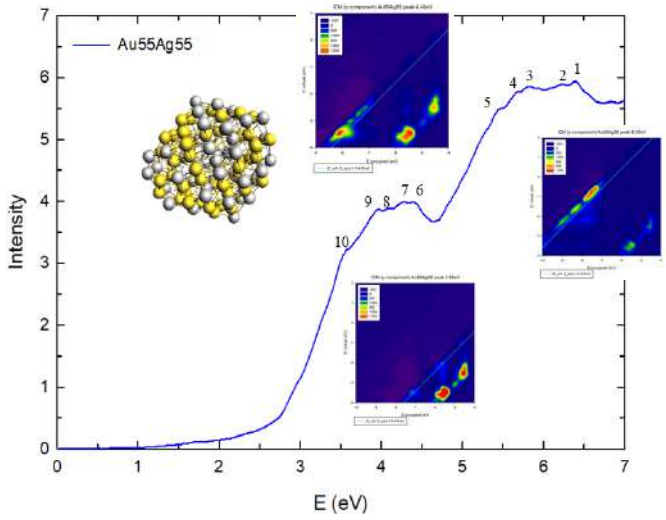

Figure 2 Photoabsorption of a AuAg nanoalloy from the coalescence of two icosahedral seed of Au55 and Ag55. ICM-OS plot for peak 1,6, and 10 are shown in the insets. 'spots' close to the straight line correspond to a 'non-plasmonic' behavior while those far from it are due to strongly coupled excited configurations (collective behavior).

Ultrafast thermodynamics in $SrTiO_3$: Beyond perturbation

Fredrik Eriksson[1], Yulong Qiao[1], Erik Fransson[1], Richard Matthias Geilhufe[1], and Paul Erhart[1]

Abstract: We investigate ultrafast dynamics in $SrTiO_3$ using molecular dynamics and phonon analysis. Exciting the ferroelectric mode mimicking laser response, we observe upconversion in line with experiments. Our approach provides insights into entropy production and microscopic upconversion mechanisms.

The possibility to control and probe materials in the ultrafast regime has opened up several new areas in fundamental research and engineering. In this regard characterization of ultrafast time-dependent thermodynamic properties within the material is crucial. In this context the combination of condensed matter theory with atomic scale simulations is particularly powerful. In the present contribution, we present recent work on the dynamics of materials and their coupling with external stimuli. Specifically, we will discuss these aspects in the cubic perovskite $SrTiO_3$ using a combination of molecular dynamics simulations, machine-learned interatomic potentials, mode projection analysis, and a non-Markovian treatment of the coupled phonon modes. We artificially excite the ferroelectric optical phonon mode at the zone center, mimicking a laser response and then analyze the decay pathways of the system. We find that after about 500 fs of pumping the ferroelectric mode, a higher frequency optical mode at Gamma, around 6 THz, is strongly excited and pushed out of its equilibrium distribution. This observation is in good agreement with recent experimental work using time-resolved X-ray scattering where this upconversion was also observed [2]. The method allows for a detailed understanding of the entropy production in the system from first principles. In addition, the microscopic mechanisms responsible for the upconversion are outlined.

Mechanisms of plasmon-molecule energy and charge transfer

Andrei Stefancu[1, 2*], **Emiliano Cortes**[1]

[1]Nanoinstitute Munich, Faculty of Physics, University of Munich (LMU), Munich, Germany

Abstract: Plasmon–molecule energy transfer is essential for advancing plasmon-driven catalysis, molecular sensing, and energy conversion. It enhances chemical reactions at lower energy inputs, enables selective molecular excitation, and improves spectroscopic techniques like surface-enhanced Raman scattering (SERS). Understanding this process aids in designing efficient nanomaterials for sustainable chemical and technological applications.

Plasmonic nanostructures have emerged as promising systems for efficient light harvesting and light-to-chemical-energy conversion, driven by their unique optical properties.[1-2] At the core of these properties are surface plasmon resonances (SPRs), the collective oscillations of the free metal electrons induced by resonant light. SPRs enable light absorption cross-sections that exceed the physical dimensions of the nanostructures by several orders of magnitude. These resonances play a crucial role in driving chemical transformations in adsorbed molecules through charge and energy transfer.

SPRs decay via two primary pathways: radiative decay, which involves photon scattering at the SPR frequency, and non-radiative decay, which generates electron-hole (e-h) pairs in the metal. The energy partitioning between these pathways is determined by the dielectric constant of the material and its physical dimensions. For plasmon-driven chemistry, non-radiative decay is particularly significant, as it facilitates plasmon-induced charge transfer to adsorbed molecules. However, other mechanisms also exist for plasmon-molecule energy transfer, such as plasmon-induced resonant energy transfer, the plasmonic analogue of Forster resonance energy transfer.

Although there are multiple phenomena by which plasmon-induced e-h pairs can be generated in metals, there are two effects which are by far the most efficient for plasmon-induced charge transfer to adsorbed molecules: chemical interface damping (CID) and Landau damping.[3-4] Landau damping (or surface collision assisted absorption) is a three-step process; in the first step plasmon excitation promotes hot electrons in the metal from energy states near the Fermi level, to unoccupied states at the plasmon energy above the Fermi level. Secondly, hot electrons can transiently transfer to adsorbate states by incoherent transport. This causes a sudden jump of the adsorbate to the excited potential energy surface (PES) that can lead to photo-desorption or photochemistry. CID, by contrast, represents an interfacial charge transfer by coherent coupling of acceptor and donor states. As such, by definition, CID can only take place when an adsorbate is present whereas in Landau damping hot electrons are created regardless of the presence of an adsorbate. The charge transfer in CID takes place through an electric dipole interaction therefore it is an ultrafast process (~10-50 fs).[5] The partitioning between CID and Landau damping is determined by the coupling (or hybridization) of molecular acceptor energy states and the electronic states in the metal and the energy gap between the Fermi level and the acceptor adsorbate states. If the coupling is strong and the plasmon energy is sufficient to populate the adsorbate states, then CID dominates the charge transfer to adsorbed molecules, otherwise Landau damping provides a more efficient route for metal-molecule charge transfer.

Even though the broad picture of CID described above is generally accepted, there are still open questions which are relevant for plasmon-molecule energy transfer and designing the next generation of plasmonic catalysts.

One of the more crucial questions is how does the density of states of adsorbed molecules influence the CID rate and therefore the metal-molecule energy and charge transfer? Another question is if the classical mechanisms of metal-molecule charge transfer applicable in fs-pulsed charge transfer or scanning tunnelling electron microscopy can be applied also for plasmon-driven charge transfer.

This contribution addresses these questions and highlights future experimental and theoretical developments in the field of plasmon-molecule energy transfer.

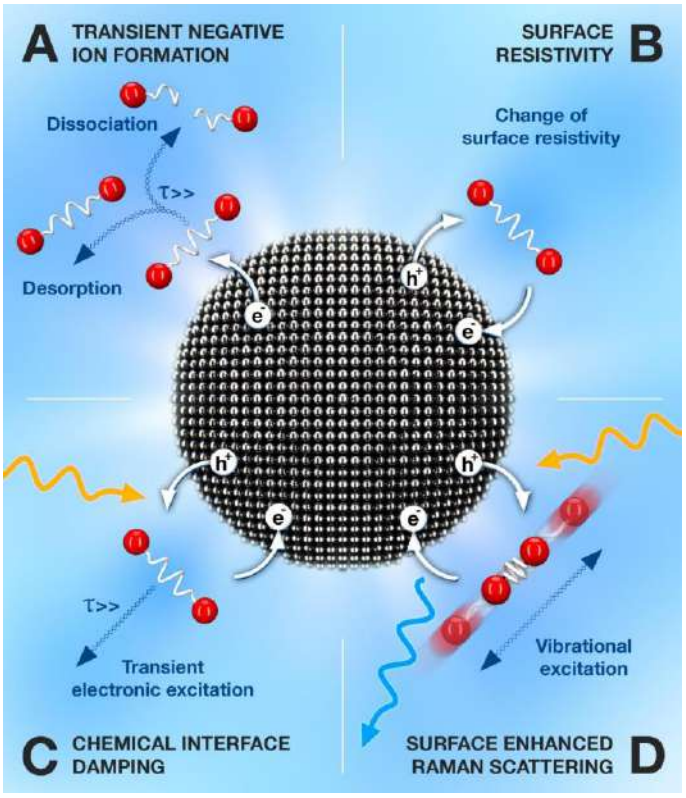

Figure 1. Four phenomena which can take place at the metal-molecule interface due to charge transfer.

Multiscale models integrating different physical mechanisms of plasmonic photocatalysis

L. V. Besteiro[1*]

[1]CINBIO, University of Vigo, Campus Universitario de Vigo, Lagoas Marcosende, 36310 Vigo, Spain

[*]corresponding author: lucas.v.besteiro@uvigo.es

Abstract: Designing hybrid photocatalysts requires balancing fabrication parameters to efficiently harvest light towards specific target reactions. Including plasmonic antennas enhances conversion efficiency but extends the design parameter space. Multiscale models of plasmonic photocatalysts as chemical reactors can integrate different interacting phenomena in the same framework to support solving complex design problems.

Plasmonic nanostructures are important tools in the development of different fields of nanophotonics. In the context of research in photocatalysis, they are often used as nanoantennas to sensitize other materials, e.g. wide bandgap semiconductors, to larger regions of the solar spectrum. Creating hybrid nanomaterials is clearly a complex procedure which can involve a large number of design and fabrication variables, and introducing plasmonic nanoantennas extends this design space with specific questions about nanoantenna geometry, among others. In order to inform design decisions, researchers in the field routinely use different theoretical and computational approaches to complement experimental results in elucidating the different mechanistic contributions of the plasmonic material to the evolution of the reaction. Two categories of frameworks are most natural and prominent in the literature, due to the typically large size of the nanoantenas with respect to the molecular scale: semiclassical modelling of the nanoparticle provides its optical response, while first-principles quantum mechanical simulations of elements of, or on, its surface provide detailed information about molecular adsorption, surface states, defect sites, etc.. It is, however, challenging to integrate insights from these two scales into a common framework that can, e.g., quantitatively ascertain what energy-transfer mechanisms are determining the local reaction kinetics. Such a framework would be useful to critically compare different hybrid material configurations and assist in their optimization process. In this talk we will discuss a particular approach to integrating results from first-principle and semiclassical simulations into a multiscale model, describing nanoscale photocatalysts as chemical reactors, with the goal of creating a computational testbed in which to quantitatively interrogate different design choices of hybrid plasmonic photocatalysts.

Atomistic multiscale modeling of surface-enhanced IR absorption

S. Sodomaco[1*], P. Lafiosca[1], T. Giovannini[2], and C. Cappelli[1,3]

Abstract: We present a multiscale quantum mechanics (QM)/classical approach to model surface-enhanced IR absorption (SEIRA) spectra of molecules near plasmonic nanostructures. The frequency-dependent ωFQ and ωFQFμ models describe the plasmonic properties of graphene-based and noble metal nanostructures. Computed SEIRA spectra are compared to calculated SE Raman Scattering (SERS) signals and experimental data.

Surface-enhanced vibrational spectroscopies, including surface-enhanced infrared absorption (SEIRA) and surface-enhanced Raman scattering (SERS), selectively amplify molecular vibrational signals by exploiting the intense local electric field enhancement near plasmonic nanostructures.[1-3] Accurately modeling this enhancement is crucial for predicting and interpreting SEIRA and SERS signals.

Multiscale approaches enable the prediction of enhanced spectroscopic responses by coupling a quantum mechanical (QM) description of the molecule with classical electromagnetic models of the plasmonic substrate.[8] In this framework, the molecule is treated at the DFT level, while the plasmonic substrate is characterized using the ωFQ and ωFQFμ models. The ωFQ and ωFQFμ models are fully atomistic classical force fields based on a Drude-conduction mechanism, incorporating an ad hoc phenomenological correction to account for quantum tunneling effects, which can treat alkali metals[4], graphene-based materials[5], and noble metal nanostructures.[6] These models accurately describe local field enhancement by capturing atomic-scale features of the plasmonic substrate, such as edges, tips, defects, and junctions.[4,7] This approach allows for the simulation of large plasmonic systems comprising thousands of atoms and enables tuning of the plasmon resonance frequency, thereby enhancing the molecule's spectroscopic response.[8,9] Our group has recently introduced multiscale QM/classical approaches, such as QM/ωFQ and QM/ωFQFμ, for calculating SERS spectra.[9]

In this work, we extend the QM/ωFQ and QM/ωFQFμ approaches to predict the SEIRA spectra of molecules close to plasmonic nanostructures. As a first application, we use our novel approach to predict the SEIRA signals of adenine nucleobase (ADE) in proximity to gold nanostructures, investigating its spectral dependence on adsorption site (vertex vs. face) and molecular orientation. Figure 1 presents SEIRA spectra for ADE in six different molecular orientations adsorbed on the vertex of a gold nano-icosahedron (Au_{10179} Ih). The spectral shapes and enhancement factors for various binding configurations are analyzed and compared to QM/ωFQFμ SERS calculations and experimental data.[10]

We then explore the SEIRA spectra of ADE on graphene-based nanostructures, focusing on how their structural and electronic properties influence spectral patterns and enhancement. Graphene and its derivatives have gained significant attention as SEIRA substrates due to their tunable plasmonic response in the mid-IR range.[3,11] By adjusting the plasmon resonance frequency to match molecular vibrations, SEIRA absorption can be optimized. This tuning can be achieved through structural modifications, such as varying the size and geometry of graphene nanostructures, or by controlling their carrier density via electrical gating or chemical doping. The ωFQ model provides an effective framework for capturing these effects, enabling a fine-tuned description of the optical response of graphene substrates and their role in SEIRA enhancement. Accordingly, we systematically investigate how the SEIRA signals of adenine depend on the size and Fermi energy of graphene nanodisks, providing insights to optimize molecular detection on graphene-based plasmonic platforms.

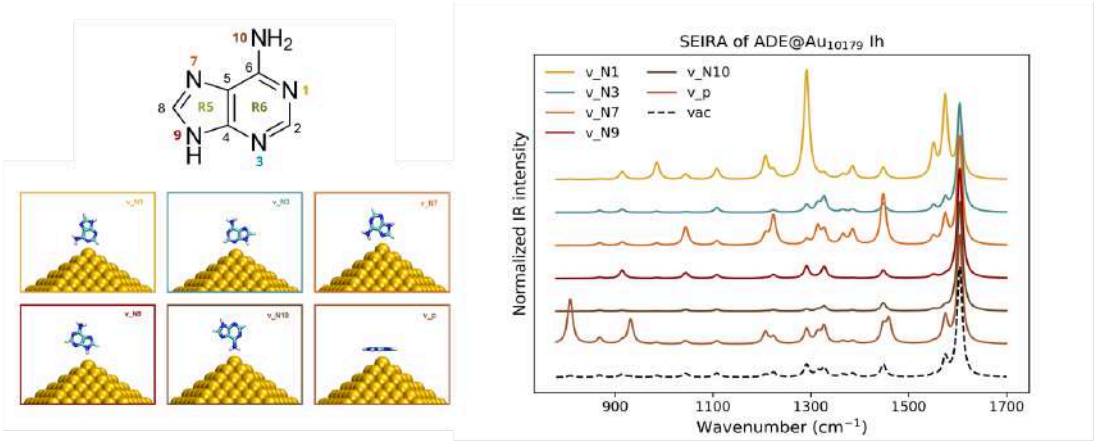

Figure 1: Normalized SEIRA spectra of ADE in the region 800-1700 cm^{-1} for the six configurations on the vertex of the gold nano-icosahedron (Au_{10179} Ih).

This work has received funding from the European Research Council (ERC) under the European Union's Horizon 2020 research and innovation programme (grant agreement No. 818064).

Far-Field Patterns of Second-Harmonic Generation in Plasmonic Nanostructures: Differentiating Surface and Bulk Contributions

E. Buhara[1*], S. Boroviks[1], and O. J. F. Martin[1]

[1]Swiss Federal Institute of Technology Lausanne (EPFL), Switzerland
[*]corresponding author: ebru.buhara@epfl.ch

Abstract: Distinguishing between surface and bulk second-harmonic generation (SHG) remains a challenge in nonlinear plasmonics. We demonstrate that far-field SHG patterns can provide insights into the nature of these contributions, offering a way for differentiation. This study presents a comparative analysis of SHG far-field responses from plasmonic nanostructures with varying radii.

Under the electric dipole approximation, inversion symmetry prevents second order nonlinear effects in centrosymmetric materials due to a vanishing second order susceptibility. However, SHG occurs in plasmonic nanostructures and originates from both surface and bulk contributions, Eq. (1). Nonlinear surface polarization arises due to the broken inversion symmetry at interfaces, and it is characterized by two main nonlinear susceptibility components, surface parallel and surface perpendicular tensor elements, Eq. (2). On the other hand, it is generally agreed that bulk SHG emerges from the field gradients in the structure with gamma and delta terms as nonlocal nonlinear responses, Eq. (3)[1]. While SH measurements can provide general information about the total SHG, far-field radiation patterns offer a method for distinguishing between these sources. There is an ongoing debate in the literature regarding this distinction since these patterns also evolve with nanostructure size and shape. However, establishing systematic criteria for their differentiation remains a critical challenge.

$$P = P_{surf} + P_{bulk} \tag{1}$$

$$P_{surf}(r,2\omega) = \chi_{\perp\perp\perp} E_{\perp}(r,\omega) E_{\perp}(r,\omega) + \chi_{\|\|\perp} E_{\|}(r,\omega) E_{\perp}(r,\omega) \tag{2}$$

$$P_{bulk}(r,2\omega) = \gamma_{bulk} \vec{\nabla}.[\vec{E}(r,\omega).\vec{E}(r,\omega)] + \delta_{bulk}[\vec{E}(r,\omega).\vec{\nabla}]\vec{E}(r,\omega) \tag{3}$$

To systematically examine the behaviors of each SHG contribution from gold nanostructures, numerical simulations were performed using the finite-element method (COMSOL Multiphysics). Each SHG signal was computed using different current densities related to the polarization's components in Eqs. (1)-(3). The simulations focused on cylinder structures with radii ranging from 20 nm to 270 nm with a fixed height of 60 nm, examining how their intensity and far-field SHG distributions evolve with increasing size.

Figure 1 shows that, while the overall trend in SHG intensities is very similar for the four different sources, the far-field patterns exhibit differences that can be used for identification. For small structures (r < 120 nm), the SHG far-field responses are simpler, with bulk being predominantly dipolar contributions, while surface shows quadrupolar characteristics. As the structure size increases (r > 120 nm), additional higher-order multipolar modes appear, leading to more complex far-field distributions. In particular, for radii exceeding 150 nm, quadrupolar contributions become non-negligible, leading to increased asymmetry in the emission pattern.

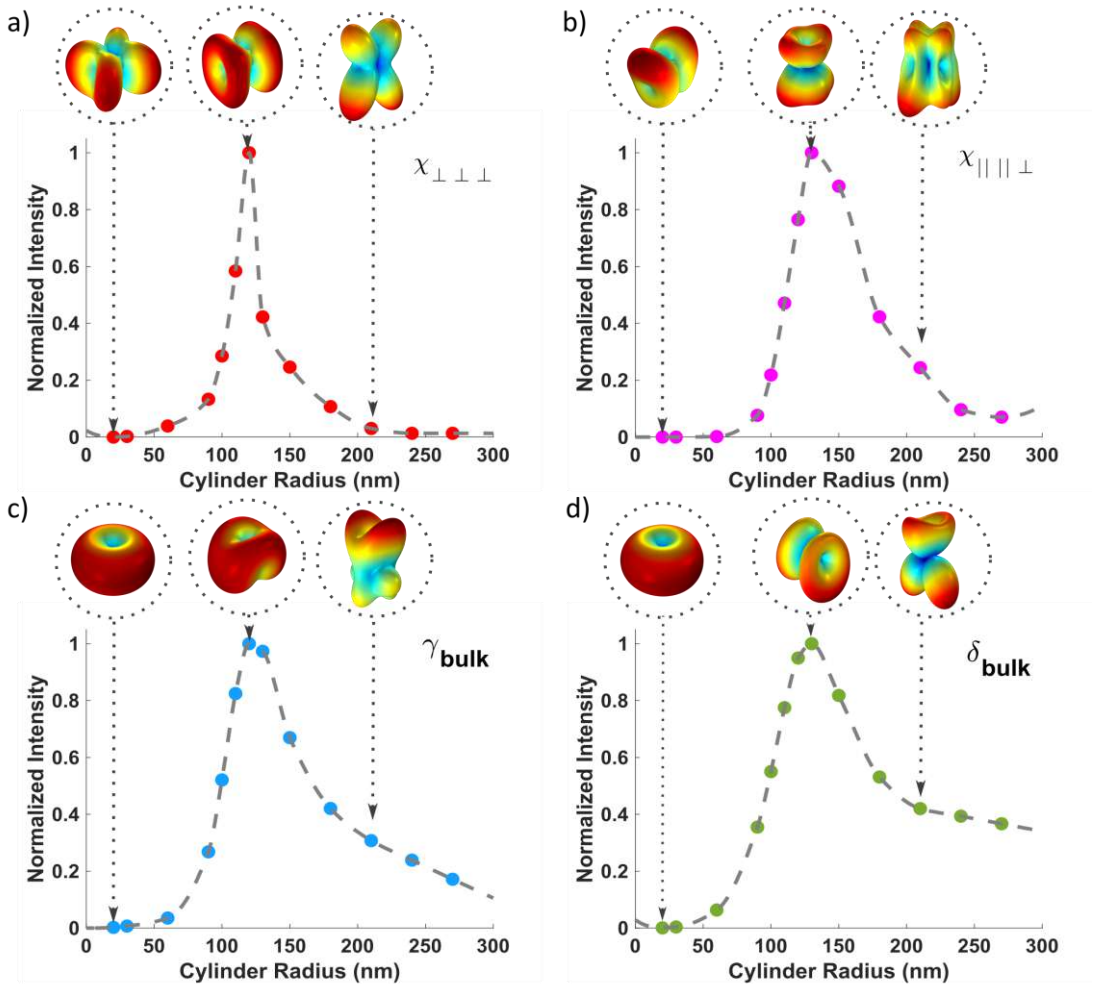

Figure 1. Normalized second harmonic intensity with far-field radiation patterns for gold cylinders with different radii, for a) surface perpendicular, b) surface parallel, c) bulk gamma, d) bulk delta terms.

Far-field SHG analysis provides a possibility for distinguishing between surface and bulk nonlinear sources. Our findings suggest that small nanostructures primarily exhibit SHG with dipolar emission, while larger structures transition toward more complex responses, manifesting in more intricate angular patterns. These insights can guide the design of experiments to distinguish bulk and surface SHG in plasmonic material.

Abstract: In our study we investigate light emission from molecules near plasmonic nanostructures, addressing limitations of the point-dipole approximation. We employ a theoretical framework capturing higher-order effects. Results reveal significant deviations from the point-dipole approximation, crucial for accurate modeling in nanophotonics.

Recent advances in nanoplasmonics have demonstrated the potential for nanostructures to drastically enhance molecular light emission through the Purcell effect[1], enabling single-molecule fluorescence detection and advancing surface-enhanced Raman spectroscopy[2]. In such environments, the conventional approximation of molecular light emission originating from an oscillating point-dipole with a transition dipole moment as the sole defining property has come under scrutiny[3]. This is particularly true for plasmonic nanostructures that confine light to sub-molecular scales[1], raising the question of whether the point-dipole model remains valid in such regimes.

In this work, we present a comprehensive theoretical framework to evaluate the limits of the point-dipole approximation. Our approach[4] enables precise modeling of fluorescence emission rates of a conjugated quantum emitter, described at the TD-DFT level, within a nanoplasmonic environment, described by solving Maxwell equations. In this framework, the perturbative decay rate Γ of a molecular emitter in a dissipative medium is given by Fermi's golden rule (constants and variables are defined in[4]):

$$\Gamma = \Gamma_0 + \frac{2}{k^2}\frac{e^2\hbar}{\varepsilon_0 m_e^2 c^2}\sum_m \mathrm{Im}\left[\zeta_m\left(\int d\mathbf{r}\left[\mathbf{E}_m(\mathbf{r})\nabla_{\mathbf{r}}\rho_{ge}(\mathbf{r},\mathbf{r}')\right]_{\mathbf{r}'=\mathbf{r}}\right)^2\right],$$

We investigated two representative systems: (i) an H2Pc molecule within a scanning tunneling microscope (STM) tip-substrate nanogap and (ii) oligothiophenes of varying chain lengths (0.8, 1.6, and 2.4 nm) near gold nanospheres.

H_2Pc molecular emitter lying on a substrate and optically coupled to a plasmonic STM tip

Our findings reveal significant deviations from the point-dipole approximation, attributed to intricate high-order multipolar effects and spatial variations within the molecular structure. These deviations challenge the conventional understanding of molecular emission and suggest the activation of dipole-forbidden transitions[5], unveiling new pathways for high-order photochemistry and the exploration of previously inaccessible spectroscopic features. These studies not only redefine the interaction of molecular emitters with plasmonic nanostructures but also open new avenues for designing nanophotonic systems that leverage higher-order optical phenomena.

Abstract: We propose a mechanism for dynamic control over a driven-dissipative system's local Chern topology, yielding reconfigurable topological interfaces and tunable paths for protected routing. We illustrate our approach in non-resonantly-pumped polariton lattices, where the nonlinear-interaction between the polaritons and the exciton reservoir can yield a dynamical change of the topology.

One of the defining features of photonic topological materials is the guaranteed existence of boundary-localized states at the interfaces between topologically distinct regions [1]. In particular, the robustness of these states against fabrication imperfections and other defects enables a new dimension of control over the flow of light and has been utilized in plethora photonic devices, such as lasers and routers. However, as the propagation path of any such protected state is bound to the interface between regions with different topology, the functionality of photonic devices leveraging these states is fixed during fabrication.

Here, we propose a mechanism for dynamic control over a driven dissipative system's local topology, yielding reconfigurable topological interfaces and thus tunable paths for protected routing. We illustrate our approach in non-resonantly pumped polariton lattices [2], where the nonlinear interaction between the polaritons and the exciton reservoir due to non-resonant pumping can yield a dynamical change of the topology. Moreover, using a continuous model of the polariton system based on a driven-dissipative Gross-Pitaevskii equation [3] alongside the spectral localizer framework [4], we show that the local changes in the nonlinear non-Hermitian system's topology are captured by a local Chern marker.

Looking forward, we anticipate such reconfigurable topological routing will enable the realization of novel classes of topological photonic devices.

This work is part-funded by Sandia National Laboratories (SNL). SNL is managed and operated by NTESS under DOE NNSA contract DE-NA-0003525.

Abstract: We demonstrate optical mode tuning in meta-waveguides. Our results underscore the potential of electrically-controlled optical waveguides for adaptive optical integrated systems.

Optical meta-waveguides are obtained by decorating an integrated waveguide with a series of precisely engineered subwavelength features. Such systems have been proven successful in the manipulation of guided light in terms of amplitude [1], phase [2], polarization [3,4], and mode [5,6]. A major limitation of meta-waveguides is their lack of tunability, which makes it difficult to achieve flexible control and adaptation under dynamically varying conditions. Therefore, actively tunable metasurface-based waveguide devices have emerged as an urgent research focus. Among the various control modalities for metasurfaces, mechanical tension, phase-change materials, and electrical modulation (such as exploiting Pockels effect) have been proven to effectively manipulate optical fields [7]. This talk focuses on our recent work in the design of electrically-controlled dynamic meta-waveguides, which enable significant modulation of phase and amplitude of waveguide modes at different operating wavelengths.

Telecom wavelength quantum dot single photon sources for photonic quantum technologies

A. Pfenning[1], T. Huber-Loyola[1], and S. Höfling[1*]

[1]Julius-Maximilians-Universität Würzburg, Physikalisches Institut, Lehrstuhl für Technische Physik, Am Hubland, D-97074 Würzburg, Germany

Abstract: We present an overview of recent developments in our group on the engineering of single-photon sources for quantum photonic applications made from III-V semiconductor quantum dots grown by molecular beam epitaxy with a focus on telecom band emission.

As high-performant sources of single photons, epitaxial quantum dots can be considered as a semiconductor launchpad for quantum photonic technologies. [1,2] There is still a variety of challenges to tackle on the road to an ideal source of single or entangled photons for quantum photonic applications. Here, we present an overview of recent developments in our group on the engineering of single-photon sources for quantum photonic applications made from III-V semiconductor quantum dots grown by molecular beam epitaxy.

By integrating InAs/InP quantum dots into circular Bragg grating resonators (see fig. 1), Purcell-enhanced single-photon emission with a Purcell factor of $\approx$7 in the telecom C-band was achieved. [3] Low multi-photon emission probabilities are obtained, and Hong-Ou-Mandel two-photon interference is demonstrated. By further improving the epitaxial growth and photonic design, we were able to obtain record two photon interference visibilities of $\approx$72 %. While this is still far from best values achieved at shorter wavelength, it manifests an important improvement for telecom C-Band quantum dot single photon sources.

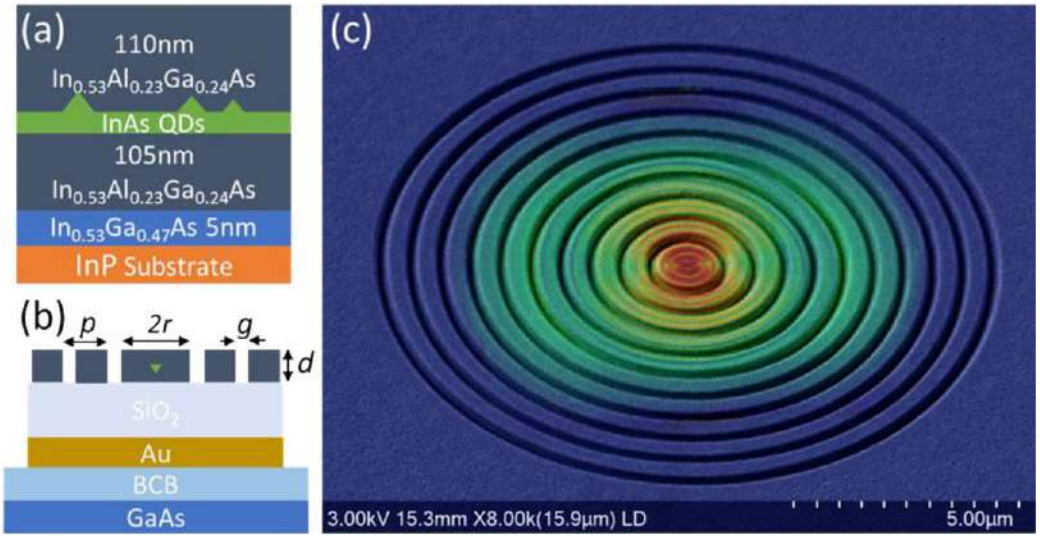

Fig. 1. Sample design of a telecom C-Band quantum dot single photon source. (a) schematic layer structure after epitaxial growth. (b) Schematic layer structure after flip chip and bullseye fabrication including the four bullseye design parameters. (c) Scanning electron microscopy (SEM) image of a fabricated bullseye resonator overlain with a logarithmic contour plot of the electric field intensity distribution of the fundamental resonator mode. (from Ref [3])

For an unweighted mapping of the quantum dot polarization state directly into the outcoupled photon polarization, a symmetric cavity and a well placed quantum dot are essential. For instance, a displacement with regard to the cavity center strongly determines the polarization characteristics from quantum dots in circular Bragg grating resonators, as the symmetry of the coupled QD-cavity system is broken, and the quantum dot will couple differently strong to the degenerate fundamental resonator modes. [4] We therefore employ deterministic placement techniques also for the telecom C-Band quantum dots.

Furthermore, we demonstrated that GaSb quantum dots are a scientifically rich alternative material system for the generation of single-photons in the telecom S-band [5] promising strain-free spin physics, but in the telecommunication range [6].

On the shapes of the rogue waves in optical fibers

S. A. Derevyanko[1*] and S. K. Turitsyn[2]
[1]Ben Gurion University of the Negev, Israel
[2]Aston University, UK
Corresponding author: stasd@bgu.ac.il

Abstract: We analyze the necessary conditions for the given pulse shape to be a rogue wave occurring in optical fiber. We provide general criteria for the parameters of the candidate pulses and illustrate the results by considering several pulse shapes.

Rogue waves (RWs) represent ubiquitous natural phenomenon of waves (or pulses) of extreme amplitude localized both in time and space. They appear in multiple physical contexts from ocean physics [1,2] to optics [3]. In the context of optical fibers where the main propagation model is the nonlinear Schrodinger equation (NLSE) the RWs are usually identified with the so-called Peregrine soliton on a finite background [4]. The open question remains is this the only possible shape of spatio-temporal localized pattern in a fiber?

To answer this we consider the NLSE model for propagation of the optical envelope along the fiber given here in the normalized units [5]:

$$\frac{\partial q}{\partial z} \in \frac{i}{2}\frac{\partial^2 q}{\partial t^2} \in i|q|^2 q = 0, \tag{1}$$

where q is the electrical field envelope, z is distance along the fiber and t is time.

The necessary condition for the pulse $q(z_*, t))$ to be a RW is that its intensity $P(z_*, t) = |q(z_*, t)|^2$ must have a maximum at $z = z_*$ regardless of t. From the NLSE (1) it is easy to show that this is only possible when the RW pulse at $z = z_*$ is a transform limited (flat phase). Simultaneously one should require that $\partial^2 P/\partial z^2(z = z_*, t) < 0$ for each t (or at least in the central part of the pulse). Substituting $P = q(z, t)\, q^*(z, t)$ and using NLSE (1) we arrive at the following criterion:

$$\frac{\partial^2 P}{\partial z^2}\Big|_{z=z_*} = \frac{1}{2}\left(\frac{\partial^2 q_*}{\partial t^2}\right)^2 \in 2\, q_*^3 \frac{\partial^2 q_*}{\partial t^2} \in 6\, q_*^2 \left(\frac{\partial q_*}{\partial t}\right)^2 \in \frac{1}{2}\, q_*(t)\, \frac{\partial^4 q_*}{\partial t^4} < 0, \tag{2}$$

for the temporal region near the peak of the pulse.

The above criterion is general and is applicable to different transform limited candidate pulse shapes. It can be considerably simplified if one considers only the vicinity of the maximum point $t = 0$. Assuming an arbitrary single hump even real seed pulse $q_*(t)$ one can expand it near the point $t = 0$: $q_*(t) \approx A\left[1 + \alpha t^2/2 + \beta t^4/4!\right]$ where $A = q_*(0) > 0$ and α and β are the second and fourth derivative of the normalized pulse evaluated at zero (note that $\alpha < 0$ for the local maximum). Substituting this ansatz into (2) and keeping only principal terms in t one obtains the necessary and sufficint condition for a given pulse to be a *local* RW (i.e. in the vicinity of of $t = 0$): i)The "kurtosis" of the pulse, β/α^2 must be greater than one and ii) the amplitude must be less than the critical value $A_{cr} = [(\beta \in \alpha^2)/(4|\alpha|)]^{1/2}$.

Fig.1 shows the same spatio-temporal evolution of the 2 candidate shapes: Gaussian $q(z_*, t) = A\exp(\in t^2)$ and hyperbolic sech pulse $q(z_*, t) = A\,\mathrm{sech}(t)$ with sub-critical values of the amplitude.

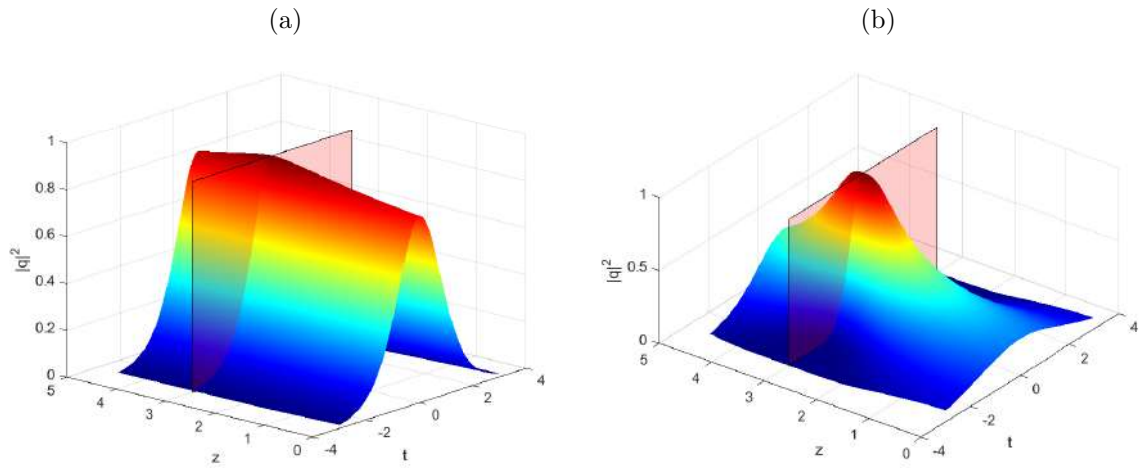

Figure 1: The spatio-temporal intensity evolution obtained numerically for sech (a), and Gauss (b) target pulses for (sub)critical amplitudes. The target location z_* of the RW is shown by transverse plane

The obtained criteria are applicable to all transform-limited candidate pulses and the method used for their derivation can be applied to more general systems that include e.g. the effects of gain and dissipation.

Microscopic theory of collimated light propagation in dipolar arrays with emergent epsilon-near-zero responses

L. Ruks[1] **and J. Ruostekoski**[2]

[1]NTT Basic Research Laboratories, NTT Corporation, Kanagawa, 243-0198, Japan

Abstract: We demonstrate how macroscopic optical responses of epsilon-near-zero media emerge from discrete dipolar scatterers by employing essentially exact microscopic simulations of light propagation. Collective responses of dipoles exhibit dramatic increases in excitation wavelengths as the system parameters are tuned closer to the onset of epsilon-near-zero behaviour.

Epsilon-near-zero (ENZ) media are a fascinating class of materials where the real part of the dielectric permittivity approaches zero at certain frequencies. In such media, the effective wavelength of light becomes extraordinarily long, which means that the phase of the electromagnetic field can remain nearly constant over macroscopic distances even as the field varies rapidly in time. This decoupling of spatial and temporal variations leads to several counterintuitive wave dynamics.

Consequently, ENZ media provide intriguing opportunities to explore novel light-matter interaction regimes in optics. For example, ENZ media can enable extraordinary transmission of light through narrow gaps, allowing the design of ultracompact photonic devices. The increased effective wavelength, on the other hand, can enhance uniform interactions across large samples.

ENZ materials that have typically been studied include continuous media, such as semiconductors and transparent conducting oxides. Here, we construct an essentially exact microscopic theoretical model of dipolar scatterers [1] that exhibits light propagation similar to an ENZ medium. The system can be realised with a regular array of dipolar scatterers when light mediates strong interactions between the scatterers in a low loss environment. We analyse the system of an atomic array where each atom possesses a precise resonance frequency, free from manufacturing imperfections or non-radiative absorption losses. This allows us to harness and utilise cooperative, non-local atom responses that arise from these strong interactions.

In Fig. 1, we demonstrate the transition of light propagation within the medium towards the near-zero regime in a lattice formed from $N_x = 25$ square array layers. This is revealed in Fig. 1(b) by a dramatic increase in the effective wavelength of the dipolar wave excited within the medium as the detuning of the beam is varied. The amplitudes are well-described as a sum $\mathcal{P}_+ e^{i\ell k_x' a} + \mathcal{P}_- e^{-i\ell k_x' a}$ of oppositely traveling waves, where ℓa (for $\ell = 0, 1, 2, \ldots$) indicate the dipole positions in the array. We fit these to $\mathcal{P}_\ell$ to extract a medium wavenumber k_x' for light that ranges from $k_x' = 0.25$ down to $k_x' = 0.03k$ – an effective wavelength of approximately 33λ. The slow variation of the excitation amplitude is further reflected in the phase accumulated across the layers in Fig. 1(c), which may remain almost constant across the entire sample in the most extreme case. Extracting the phase refractive index $n_p = k_x'/k \to 0$, these results demonstrate, using essentially exact microscopic calculations, how a near-zero medium for light emerges from collective scattering in atomic lattices. Finally, in Fig. 2, we show how the effective wavenumber and light transmission for a five-layer sample depends on the laser frequency and the lattice spacing.

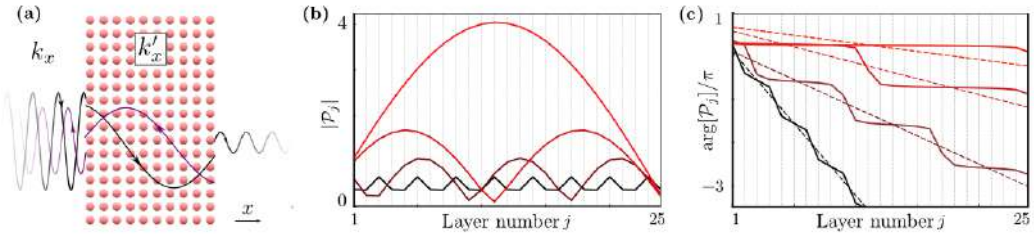

Figure 1: **Emergence of an ENZ medium response in light propagation through an array of discrete dipoles.** (a) Schematic of a plane wave transmitted through a dipolar array, stacked in infinite planar lattices along the x axis. Excitation (b) amplitude and (c) phase of the atomic dipoles. The effective wavelength of the excitation becomes longer as the laser frequency approaches the ENZ. condition.

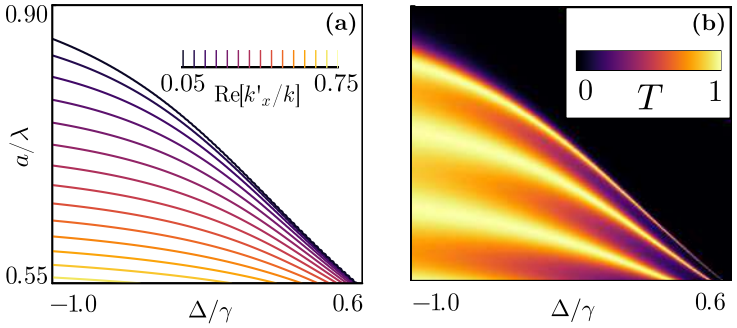

Figure 2: (a) Real part of the medium wavenumber k'_x, normalized to the free-space wavenumber k, and (b) transmittivity T. Here, detuning Δ (normalized to free-space linewidth γ) and lattice spacing a, normalized to wavelength λ, are varied within the transmission band for five layers.

In conclusion, we demonstrate through microscopic, atom-by-atom simulations the emergence of macroscopic ENZ medium response, enabling us to extract a microscopic mechanism of dipolar interactions behind this fascinating phenomenon.

Abstract: Features of anapole state occurrence in a dielectric metasurface formed by trimer-based clusters (meta-atoms) have been revealed. Manifestation of anapole has been found in near-field distribution and wave transmission and reflection properties by a trimer-based metasurface.

The anapole phenomenon has attracted considerable attention in the field of metamaterials as a possible realization of nonradiative objects [1]. The optical anapole arises as a composite of electric dipole and toroidal dipole moments that does not produce any far-field emission due to the complete destructive interference of their similar emission patterns. In this state, the near fields appear to be strongly localized inside the particles, while their far-field emission is significantly suppressed. Due to the suppression of the scattered fields, the incident wave passes through the meta-atoms without distortion, resulting in a state of complete transmission (zero reflection) of the metamaterial at the anapole excitation wavelength. Thus, the anapole offers a new way to achieve the invisibility (cloaking) effect for lossless dielectric metamaterials based on the suppression of radiation scattering.

In this work we comprehensively study the anapole phenomenon in cluster systems of dielectric particles, considering the conditions for the anapole manifestation both in individual trimers of disk-shaped particles and in a metamaterial composed of such trimers [2]. Our analytical approach is based on the multipole expansion method and the secondary multipole expansion technique. They allow us to relate the anapole to the trimer multipole moments and individual multipole moments of its constituent particles. The manifestation of the anapole in a two-dimensional metamaterial (metasurface) is confirmed by checking the resonance states in the reflected field, as well as from the near-field electromagnetic patterns obtained from full-wave numerical simulations. It is shown that the anapole excitation in trimers leads to a polarization-independent suppression of reflection with a resonant enhancement of local electromagnetic fields in the metasurface. Finally, an experimental verification of the theoretical results is presented and discussed.

Abstract: We theoretically demonstrate that both cascade enhancement and high collection efficiency of emitted photons from a single emitter can be achieved simultaneously in a topological photonic crystal containing a resonant dielectric nanodisk.

1. Introduction

The unique properties of topological photonics, including topological robustness and anti-scattering, bring new opportunities for the development of single photon sources. Barik et al. first proposed the chiral coupling between quantum emitters and edge states in topological photonic crystals (PCs). After that, Purcell enhancement is demonstrated with topological corner states, topological slow light in valley PCs, and topological Su-Schrieffer-Heeger cavity modes. Unfortunately, their Purcell factor is not very high, almost on the same order as that in photonic crystals. Recently, nonscattering large Purcell enhancement is obtained in the topological photonic structure containing a plasmonic nanoantenna, but still suffers from low quantum yield due to an intrinsic metallic loss. So, that both high photon emission rates and high quantum yield simultaneously exist under topological protection remains an issue.

2. Model & Results

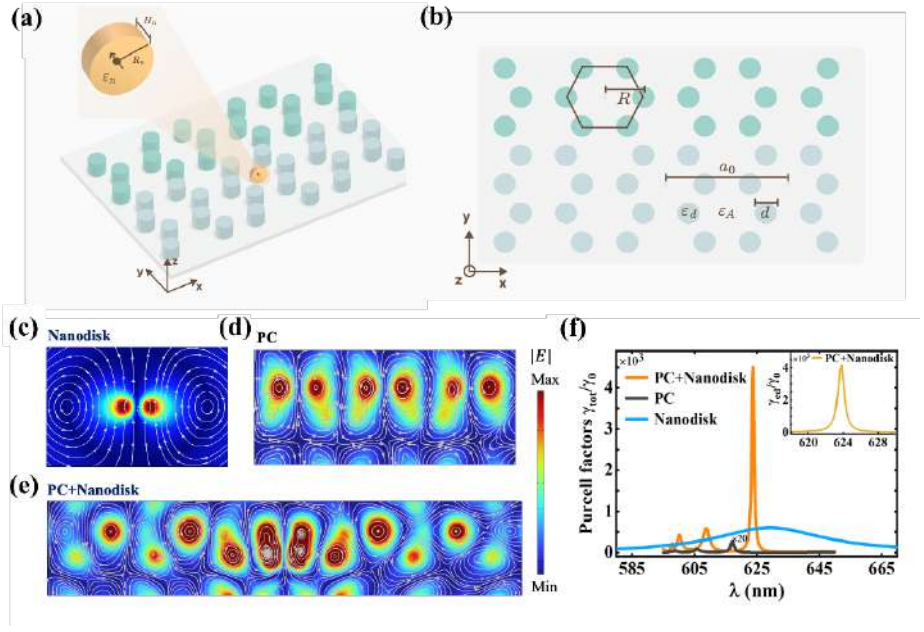

Fig. 1. (a) Schematic diagram of the hybrid structure of topological photonic crystal-nanodisk. (b) Schematic diagram of honeycomb photonic crystal. (c) The electric field in the xy plane of the magnetic dipole resonance in a bare nanodisk,

where the white streamlines indicate the direction of the magnetic field. (d) The electric field of the edge state in the xy plane of the bare PC. (e) The electric field of the edge state in the xy plane of the topological hybrid structure. (f) The total Purcell factors γ_{tot}/γ_0 in the bare nanodisk, bare topological PC, and the hybrid structure. The inset is the Purcell factor γ_{ed}/γ_0 along the edge state propagation in the hybrid structure.

We now investigate the cascade enhancement of magnetic emission in the hybrid structure. If a magnetic emitter is used to excite the nanodisk, then its magnetic dipole resonance can be viewed as a large equivalent dipole interacting with the edge states, which achieves the cascade enhancement of the magnetic emitter. As shown in Fig. 1(f), when a quantum emitter is placed at the center of a nanodisk, the maximum magnetic Purcell factor γ_{tot}/γ_0 can reach 4504. While in bare topological PC, the maximum Purcell factor is only 14. When there is only a dielectric nanodisk, the Purcell factor at the resonance is 604. Therefore, much stronger emission enhancement can be achieved in the hybrid structure than in the bare topological PC and the bare dielectric nanodisk.

For practical application of single photon sources, besides a large emission rate, efficient collection of photons is also extremely important. For a nanodisk in free space, emitted photons are difficult to collect and utilize. In the topological hybrid structure, the topological PC can guide the photons that were previously scattered to the surroundings into the edge states. If the collection efficiency is defined as $\beta = \gamma_{ed}/\gamma_{tot}$, β can reach 93% [inset in Figure 1(f)]. The high collection efficiency in the hybrid structure comes from the large nearfield overlapping between an equivalent large magnetic dipole and the edge state as well as anti-scattering of topological state [Fig. 1(e)]. In previously reported enhanced emission via hybrid structures containing a metallic nanoantenna, the quantum yield is not very high. But here, owing to no absorption loss in dielectric structures and anti-scattering property of edge states, the quantum yield is almost equal to the collection efficiency; i.e., almost all the emitted photons can be used for on-chip photonic devices. It is worth noting that the narrow line width in the hybrid structure also comes from the fact that edge states can collect scattered photons.

3. Conclusion

In summary, we have proposed a mechanism for the cascade enhancement and efficient collection of emitted photons under topological protection. A hybrid structure integrating a topological PC and nanodisk is designed in which the magnetic dipole resonance of the nanodisk can be equivalent to a large magnetic dipole to interact with the edge state. The large near-field overlapping between the resonant nanodisk and the edge state enhances the magnetic emission through a cascade effect. At the same time, emitted photons can be efficiently guided to propagate in the edge state channel, achieving a collection efficiency exceeding 90% due to the robustness of the edge state. The low loss of the dielectric structure and the anti-scattering properties of the topological mode make the quantum yield almost equivalent to the collection efficiency; that is, almost all of the emitted photons can be used in on-chip photonic devices. The mechanism proposed here enhances the spontaneous emission rate of the emitter while achieving large collection efficiency under topological protection, which will provide practical use for ultrabright and stable on-chip single photon sources. It also provides new insights for the study of cavity quantum electrodynamics in topological structures.

Abstract: Mie resonant silicon particles have strong scattering and thus are highly desirable building-blocks in metamaterials and metasurfaces. However, most silicon resonators are produced via top-down fabrication methods. We present two bottom-up fabrication methods followed by particle self-assembly, producing a silicon-based metasurface having a certain degree of disorder, and yet a high quality factor.

Silicon has a relatively high refractive index in the visible, coupled with low light absorption above 400 nm, making it a highly effective scatterer for visible frequencies.[1] In spite of the excellent optical properties of silicon, material scientists turn to other materials, such as titanium dioxide, due to the difficulty in synthesizing nanoscaled silicon resonant units. The difficulty in producing silicon particles stems from its propensity to oxidize upon exposure to air, the low reduction potential of the precursors and the relative danger associated with handling silicon precursors. Typically, either extreme synthesis conditions, very unstable silicon precursors or very strong reductants are used to create silicon through bottom-up chemistry. Even so, obtaining the necessary diameters for visible light scattering, e.g. 75-200 nm in diameter, is a challenge via bottom-up methods.[1] A variety of top-down methods have provided excellent proof-of-concept examples,[2] but these are typically more expensive and cumbersome to scale-up than are bottom-up methods. Thus, we have spent the last several years striving to discover a new solution-based synthesis method to make resonant silicon units.

Here we report two different synthesis techniques. The first is a redox reaction, where two different silicon precursors are combined at ambient temperature and pressure to generate Mie resonant silicon particles. The size of the particles is tuned via solvent selection and by the precursor ratio.[3,4] The refractive index of a single particle resulting from this redox synthesis technique was extracted by fitting the Lorentz Mie theory to the interference pattern generated at 532 nm.[4] The refractive index was found to be 4.08, which is similar to bulk silicon (4.14) at this wavelength. The slight difference in refractive index can be attributed to a small amount of amorphous material or inclusions within the particle. Although this technique allows the particle size to be tuned from 45-230 nm in diameter, and thus covers the entire visible spectrum, the particles suffer from polydispersity. We are currently working to reduce the size dispersion within a batch, but in the meantime, we decided to explore a second synthetic pathway towards resonant particles with higher conformity.

Synthesis of amorphous silicon particles between 400 nm to several microns in diameter is possible by

decomposing trisilane (Si_3H_8) in supercritical hexane.[5] These particles display multipolar resonances that can be improved upon thermal annealing to increase the degree of silicon crystallinity.[6] Moreover, the polydispersity within a batch can be as low as 5%, which is very low for a bottom-up fabrication technique. Previously, we were able to decrease the size of the silicon core to diameters compatible with dipole scattering in the visible by combining the trisilane precursor with a silicon coordination complex, bis-(N,N-diisopropylbutylamidinate) dichlorosilane ($[(i\text{-PrN})_2C(n\text{-Bu})]_2SiCl_2$).[7] This resulted in an amorphous silicon core between 130-160 nm in diameter, surrounded by a silica shell of tunable dimensions between 10-115 nm.[7] Here, we report an extension of this work, where trisilane is replaced by hexasilane (Si_6H_{12}), while keeping other aspects of the synthesis equivalent to the previous report. The exchange of the silane precursor resulted in silicon cores with a much higher degree of crystalline character, as noted by Raman and XRD analysis. The oxide shell is thinner (approximately 25 nm) and the total particle diameter increases to between 350-600 nm, depending on the precursor concentration in the reactor during synthesis.

These particles were then assembled into a metasurface via an interfacial self-assembly at a liquid-gas phase boundary, and then deposited onto a quartz substrate. The particles formed islands of crystalline particle placement within a largely disordered assembly. The optical properties of these particles were measured using variable angle spectroscopic ellipsometry. Lattice modes were observed, with a strong magnetic resonance of high quality factor at around 945 nm. We are currently comparing the experimental results to simulation to confirm these surprising experimental findings. If the results prove to be real, this pathway opens the possibility of making large scale metasurfaces through an all bottom-up method.

Abstract: We present recent advances in integrating 2D transition metal dichalcogenides (TMDs) with resonant nanostructures for optoelectronics. Our work explores hybrid architectures combining 2D TMDs with dielectric metasurfaces and plasmonic nanoantennas, as well as nanopatterning strategies that preserve optical properties. We discuss fabrication challenges, performance, light-matter interactions in such hybrid systems and their prospects for next-generation optoelectronics.

Summary

2D transition metal dichalcogenides (TMDs) are highly promising atomically thin semiconductor materials for photonic applications due to their direct bandgap in the monolayer phase, strong photoluminescence, pronounced excitonic effects, high nonlinearity, and unique valley properties with potential for classical and quantum information processing. Their two-dimensional nature facilitates effective integration into nanophotonic architectures, while their exceptional optical properties and tunability make them ideal for compact, fast, and functional optoelectronic devices. The development of hybrid nanostructures based on 2D TMDs is a rapidly evolving field, with applications ranging from light-emitting metasurfaces and tunable lenses to ultrafast wavefront shaping and holography. Advancing these applications requires novel fabrication strategies for integrating TMDs with resonant photonic nanostructures.

In this talk, we discuss our recent progress in hybrid TMD-based nanophotonics, including their coupling to high-index dielectric metasurfaces and plasmonic nanoantennas. We explore how excitonic properties, charge carrier dynamics, and coherence effects influence light-matter interactions in these systems. Additionally, we present advances in nanopatterning techniques that allow precise structuring of TMDs while maintaining their optical functionality, enabling applications such as ultrathin holograms and reconfigurable photonic devices. In summary, we provide an overview of fabrication strategies, integration challenges, and recent advances in resonant hybrid nanostructures based on 2D TMDs.

Metal oxide metasurfaces elaborated by nanoimprint and derived methods

Abstract: Sol-gel chemistry combined to direct nanoimprint lithography was developed to elaborate robust metal-oxide meta-surfaces. Different material/structures systems, dedicated to biosensing (DNA sequencing), high LIDT optics (Lasers), augmented reality and structural colours applications, are presented.

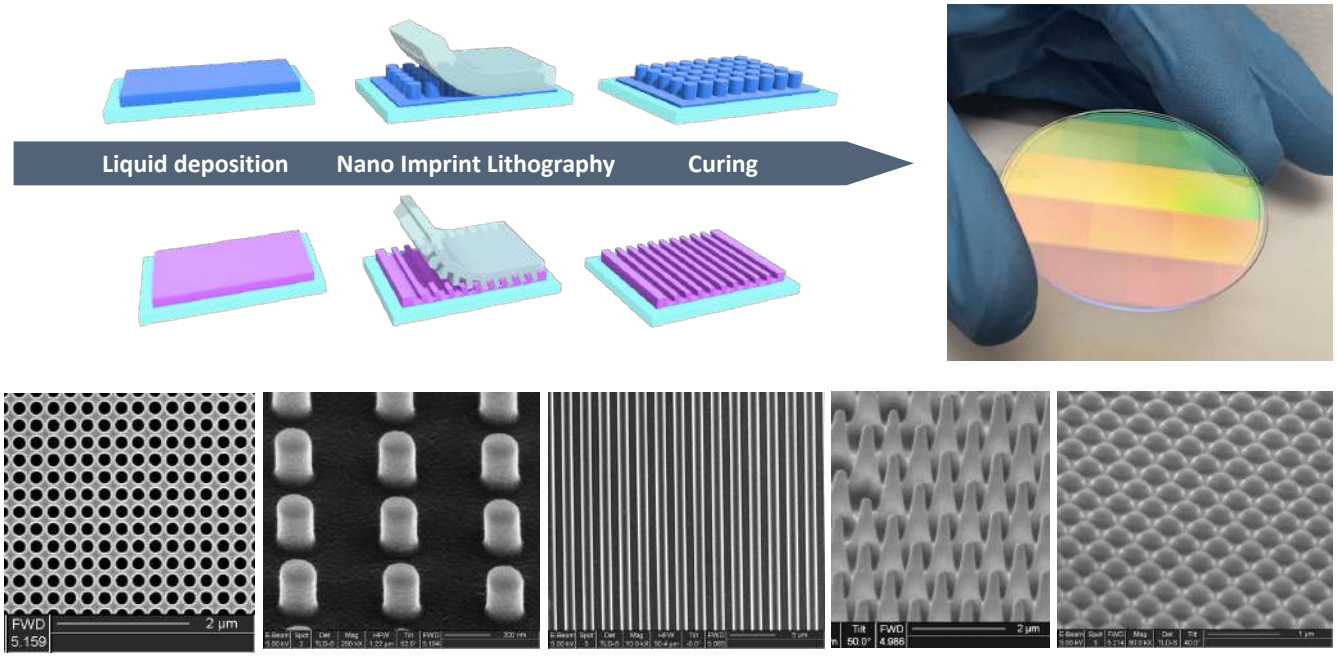

Figure 1 : Schemes of the NIL method and SEM images of different metaatom arrays composed of metal oxides.

Conventional top-down fabrication methods for metasurfaces are often cumbersome and expensive (both CapEx and production costs). Here, we showcase the use of Soft-Nano-Imprint-Lithography (soft-NIL) as a scalable, cost-effective, and CMOS-compatible method for directly imprinting sol-gel precursor inks into metasurfaces of metal oxides (e.g. SiO_2, TiO_2, Al_2O_3, Nb_2O_3, $CaTiO_3$, etc. see Fig. 1). Photonic metasurfaces can be prepared with vertical aspect ratios up to 7, on diverse substrates such as glass, fused silica, sapphire, and silicon wafers. A precise adjustment of the chemical precursors and nano-imprint conditions ensure faithful replicas over large areas: the method is scalable up to 200 mm wafers, limited only by the plate-to-plate machinery employed. The resulting materials offer controlled, on-demand refractive indices ranging from 1.12 to 2.7@520 nm with zero extinction for passive photonic devices and extremely low haze. Combinations of two metal oxides, on the same

metasurfaces, exhibiting extreme contrasts in optical constants or/and in chemical affinity can be prepared through a novel liquid deposition technique based on capillarity infiltration. Various metasurface designs addressing diverse functionalities,[1-6] including controlled-wetting surfaces, light-harvesting coatings, diffraction gratings for light in and out coupling, multispectral filters, enhanced spectrally and spatially controlled emitting surfaces, waveguides, structural colour coatings, anti-reflection coatings, and flow cells for DNA sequencing have been developed. This work highlights the potential of soft-NIL in advancing the field of optical metasurfaces and paves the way for their widespread applications in next-generation devices.

Abstract: The ability to fabricate nanophotonic metasurfaces with precise structural control, scalable fabrication, and tunable optoelectronic properties is central to advancing next-generation sensing, energy, and spectroscopy applications. Recent breakthroughs in **template-assisted self-assembly (TASA)** enable the bottom-up fabrication of high-quality and defect-free metasurfaces by using **pre-synthesized nanoparticles, responsive polymer matrices, and tailored templates**. This approach minimizes material waste, reduces energy consumption, and integrates **top-down lithographic precision** with **bottom-up self-organization**, achieving large-area patterning with nanoscale precision [1].

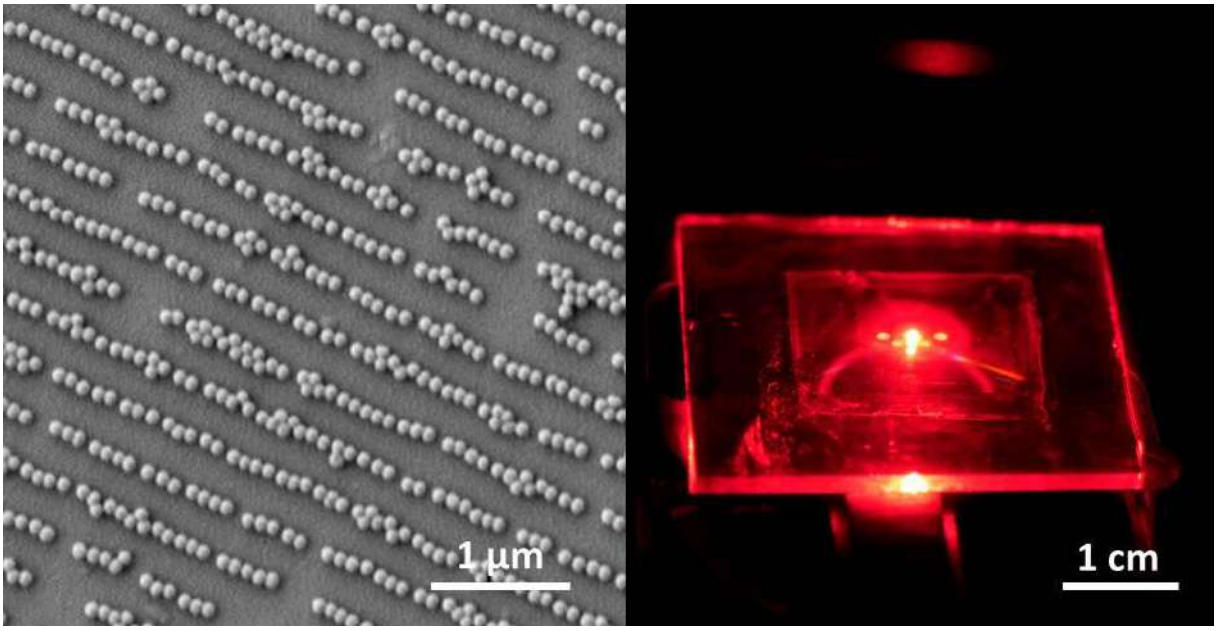

Figure: *Template-assisted self-assembly facilitates the bottom-up fabrication of ordered plasmonic and semiconducting metasurfaces on a centimeter scale. By integrating scalable colloidal assembly with top-down templating, this approach enables the precise alignment of resonator geometries with numerically optimized designs, achieving targeted optical properties with minimal loss. This sustainable and reproducible fabrication route aligns with the special session "SP14. Bottom-up approaches, new fabrication routes and ENSEMBLE3" mission of advancing novel crystal growth techniques and functional nanostructures for next-generation photonic applications.*

We demonstrate a **scalable and reproducible self-assembly process** to fabricate light-emitting and plasmonic metasurfaces with predefined periodicities and enhanced optical properties. Our method facilitates the fabrication of metasurfaces with **tunable photonic bandgaps, chiroptical responses, and directional radiation control** using **soft lithographic templating and controlled colloidal deposition** [2]. In particular, we report a **13-fold enhancement of directional photoluminescence** in perovskite-based metasurfaces, the highest observed to date [3]. In addition, by optimizing the concentrations, we achieve **waveguide-integrated grating couplers** in a single self-assembly step, extending the applicability of our approach to **nonlinear optics and integrated photonic circuits**.

Beyond light emission, we extend our fabrication strategy to **colloidal lasing metasurfaces** with record-low lasing thresholds of **0.6 mJ cm^{-2}**, achieved through **soft-lithographic distributed feedback (DFB) resonators** [4]. Additionally, leveraging the **self-assembled plasmonic particle gratings**, we demonstrate a **43-fold enhancement in SERS signal**, providing a high-sensitivity and uniform Raman response over large areas [5]. This result is achieved by tuning the lattice resonance and super-radiant plasmon mode along the particle chain, significantly improving signal strength while reducing surface coverage by 73%. The combination of colloidal self-assembly and template-assisted fabrication provides a sustainable route to tailor metasurface geometries and optimize light-matter interactions for **bioimaging, sensing, and energy-efficient display technologies**. Our work aligns with **ENSEMBLE3's mission** to contribute to **scalable bottom-up fabrication strategies** that bridge **fundamental research and industrial applications** in **advanced materials and nanophotonics**.

Abstract: We compare optical properties of different large area self-assembled hexagonal plasmonic metasurfaces, with a correlated-disorder plasmonic metasurface fabricated by e-beam lithography. By adjusting geometric arrangements of plasmonic nanostructures and their density, we obtain metasurfaces capable of isotropically modifying the reflectivity spectrum of transparent substrates without inducing diffraction or diffusion.

Photonic metasurfaces based on plasmonic nanoparticles (NP) on glass have proven their relevance for applications such as planar lenses [1], surface coloring [2], transparent displays for visualisation and augmented reality (AR) systems [3]. Indeed, NP based metasurfaces are used to functionalize plates to obtain high reflectivity at specific wavelengths by choosing the size and shape of the NPs, while preserving good transparency in the entire visible range thanks to an appropriate spatial density and arrangement of the NPs. In particular, correlated disorder patterns of plasmonic nanocylinders have led to reflectivity improvement at one chosen color, with good transparency on the entire visible range and any angle of observation [4]. However, the fabrication of metasurfaces with this type of structure is done by e-beam lithography since it requires high-positional control, which is not compatible with the fabrication on large surfaces.

The approach we use to increasing nanopatterning surfaces is to combine soft UV nanoimprint lithography (soft UV-NIL) with self-assembly (S-A) of nanostructures as described in [5,6]. Fig. 1(a) shows a so fabricated S-A metasurface with hexagonal array of silver NPs with a diameter of 130 nm and a pitch of 200 nm on glass substrate. In order to develop transparent semi-reflective plates for AR systems, we compare the optical responses of these large-area metasurfaces to the responses of those made of correlated disordered patterns well controlled by electron-beam lithography. First, we study NPs spatial arrangement impact by analyzing the structure factor S(q) of the fabricated metasurfaces, i.e., the response of the structure versus its scattering vector q. We consider that the relevant angular observation range is [16°-60°]. Then we evaluate the plasmonic resonance effects by measuring the metasurfaces optical transmission and reflection by using an ellipsometer.

Finally, the fabricated samples have been tested in a laboratory head-up-display (HUD) system (Fig.1(d), (e)): the displayed image is orange, corresponding to a wavelength of 590 nm. It appears more brilliant on the areas covered by the metasurface (roughly delimited by the white dotted line) with respect to the non-functionalized areas for both the ‘S-A metasurface’ and the ‘e-beam metasurface’. Furthermore, the view of the landscape through the metasurfaces is clear in the both cases, but darker in the case of the ‘S-A metasurface’. In both cases, diffraction and diffusion effects are not visible as predicted by the structure factor analysis. The intensity reduction is due to the spatial density of the nanostructures on the surface. Indeed, the nanostructures interspacing is of 200 nm in the case of the ‘S-A metasurface’ versus 274 nm in the case of the ‘e-beam metasurface’. Whereas hexagonal compact arrangement leads to sharper reflected and transmitted images, such a fabrication method will be relevant only if the spatial density of the final metasurface can be controlled.

We propose to reduce the spatial density by ‘removing’ 50% of the NPs, using a ‘reduction mask’ made of large islands positioned following a correlated disorder arrangement that do not induce diffraction or scattering in the

visible domain (Fig.1(a-c)). We evaluate numerically the impact of this reduction by varying the average distance between islands d, from 1 to 10 µm. Corresponding structure factors S(q) have been simulated (Fig.2(a)), using the experimentally obtained NP arrangement of sample of Fig.1(a). For d=1 µm, the peak induced by the correlated disorder arrangement is positioned in the observation range, whereas it is shifted toward lower q values when d increases. At the same time, a pedestal appears at the bottom of the hexagonal compact diffraction peak. It is attributed to the convolution of the structure factor from the initial structure with the structure factor from the masking structure (ring shape associated with the correlated disorder). It diminishes when the islands periodicity and consequently size increases: S(q) of the mask structure becomes concentrated on smaller values of q meaning it is confounded with S(q) of the S-A structure. This can be clearly understood in the 2D S(q) in Fig.2(b), where these ring shapes appear around the areas with larger values. This decrease of the q vector associated with the structure factor of the correlated disorder mask also affects diffusion in the observation range. A distance d=10 µm (and above) is sufficient to minimize diffraction and scattering effects.

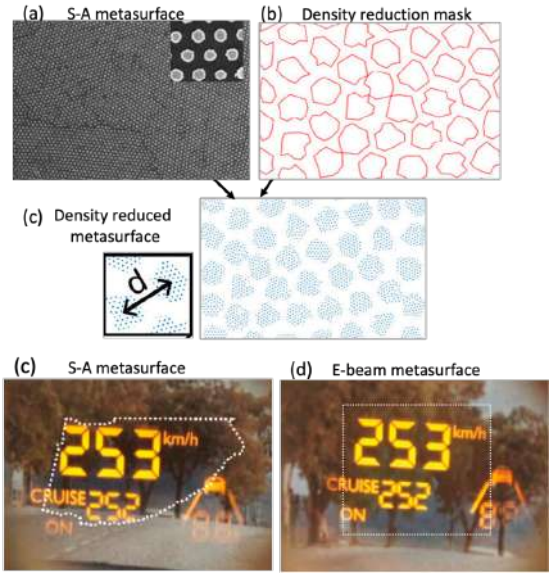

Fig.1: (a) S-A metasurface formed with a hexagonal array of silver NP on glass substrate, (b) and (c): spatial density reduction by half of (a): mask and principle. (d) and (e): qualitative assessment of the reflection in a HUD system fo respectively S-A and e-beam samples.

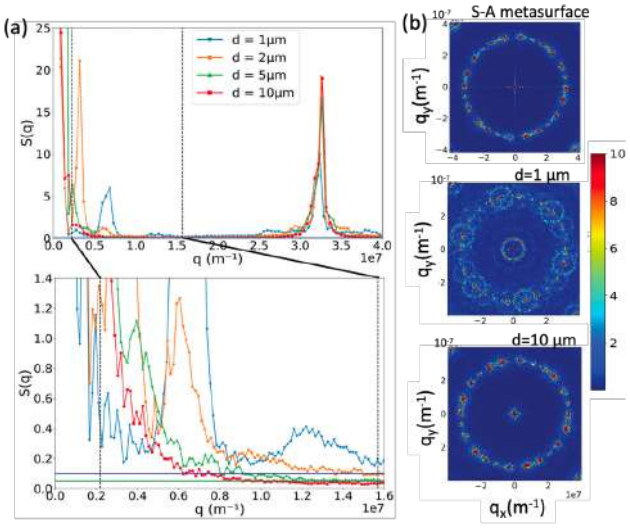

Fig. 2: *(a) numerical structure factors of the S-A structure with different island distances, for a constant average spatial density. Bottom: zoom on the observation range (b) 2D structure factor of the original S-A structure and the density-reduced structures with the 3 different island distances.*

Finally, such fabricated S-A metasurfaces with a sub-wavelength period appears to be robust in terms of transparency quality and fabrication process on large surfaces. The additional control of their average spatial density paves the way for the widespread use of such structures for augmented reality.

Abstract: Our work explores the optical properties of blue-phase liquid crystals doped with gold nanoparticles. These structures exhibit tunable optical properties, enhanced thermal stability, and significant potential for applications in electro-optical modulation, switching, tunable filters, and sensing, making them ideal for emerging photonic technologies.

The concept of photonic crystals – materials that provide access to photonic bandgap analogous to the electronic bandgap of semiconductors – has revolutionized technologies focused on controlling light flow[1]. This breakthrough has enabled the development of versatile photonic materials that allow precise engineering of light propagation, enhancing or suppressing emission within specific spectral ranges and affecting both frequency and time domains[2]. When these properties are tuned to the visible spectrum and the material responds to external stimuli, it becomes possible to develop systems with easy naked-eye readout to external stress. Among the promising materials with intriguing capabilities are blue-phase liquid crystals (BPLCs). Initially designed for high-speed display systems, BPLCs have recently been applied to a wide range of photonic technologies[3].

The applicability of BPLCs stems from their unique hierarchical structure, which comprises chiral, double-twist cylinders (DTCs, Fig. 1a), arranged into metastable body-centered cubic (BPI) and simple cubic (BPII) lattices, as schematically shown in Figs. 1b and 1c, respectively. These lattices exist within a narrow temperature range of 0.5 to 5 K and have unit cell sizes of a few hundred nanometers. The key distinction between BPI and BPII phases lies in the spatial organization of LC defects, i.e. a network of disclination lines. Such structures translate to strong interactions with visible light, resulting in vivid reflected coloring due to a 3D photonic bandgap and optical rotatory power due to their optical activity. Additionally, BPLCs exhibit optical isotropy and polarization insensitivity on a macroscopic scale for wavelengths outside of the resonance band, induced birefringence, and sub-millisecond response times under an electric field. These characteristics position BPLCs as 3D soft crystals with photonic properties that can be altered by external stimuli such as temperature, electric and magnetic fields, pressure, and alignment layers (i.e., boundary conditions).

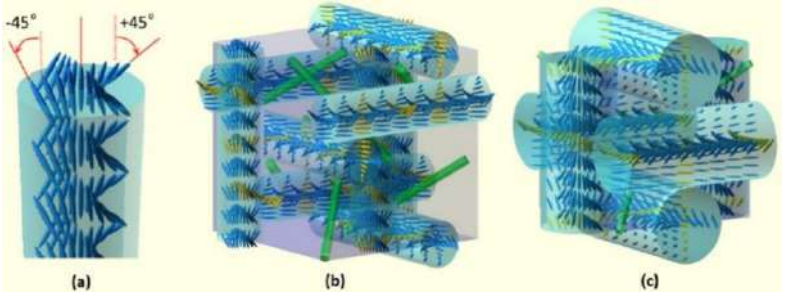

Fig. 1 Scheme of molecular ordering in: (a) DTC, and cubic structures corresponding to a unit cell of (b) BPI and (c) BPII. Orange molecules mean connected helices in neighboring DTCs, and green rods correspond to an array of LC disclinations.

Such hierarchical structures with isotropic defects in BPs make them a promising 3D template for doping with nanoparticles (NPs) and other nanomaterials[4]. This results in tunable nanostructures that are attractive for numerous photonic applications, offering improved electro-optical properties and new funcionalities.

Incorporating functionalized nanoparticles (e.g., gold nanoparticles coated with custom-designed LC-like ligands) into BPLCs can lead to shorter reaction times, reduced threshold voltage, and Bragg wavelength shifting, with the magnitude depending on NP concentration (Fig. 2a). Additionally, NP doping can significantly enhance thermal stability of BPs and provide supplementary functionality. This functionality includes the dynamic steering of optical properties in BPs (such as Bragg wavelength shifting, Fig. 2b) by an optical field, due to the plasmonic effect induced by gold nanoparticles.

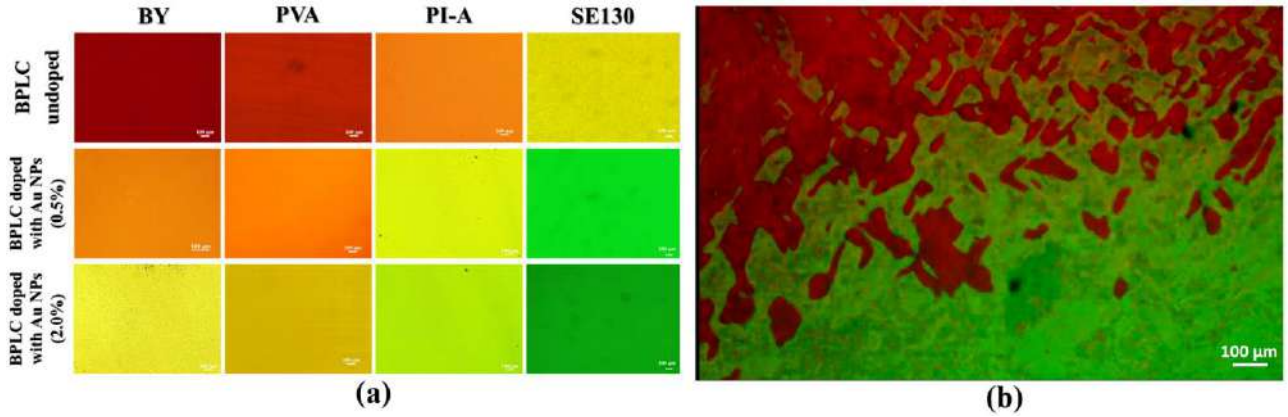

Fig. 2 Examplary photonic bandgap modulation in BPLCs by using: (a) synergistic action of alignment layers and gold nanoparticles, and (b) optical field.

Our research highlights the optical properties of photonic microstructures based on BPLCs doped with gold NPs. These photonic structures exhibit promising tunable optical properties with enhanced thermal stability. This improvement is achieved through a chemical and nanotechnological approach to create BPLC composites with gold NPs coated with LC-like ligands. The investigated BPLC-based photonic microstructures show significant potential for applications in electro-optical modulation and switching, as well as tunable filters and sensing capabilities. These systems offer superior transmission properties, making them highly suitable for emerging tunable photonic devices.

Abstract: Self-assembled dye-doped liquid crystals, in combination with printed polymer micro-structures, can form devices that perform as micro-lasers. Here we present numerical simulations of light coupling into and between such structures, their lasing characteristics, and optical control of laser emission intensity.

Liquid crystals possess the ability to self-organize into a variety of microstructures – such as 1D periodic cholesteric liquid crystal (CLC) layers, nematic and cholesteric droplets – which can be exploited for optical applications. These structures can function as optical micro-resonators and, when combined with dyes, also as micro-lasers [1,2]. Furthermore, liquid crystals can be combined with various 3D printed polymer micro-structures, for example, polymer waveguides.

In this work, we present numerical studies employing the finite-difference frequency-domain (FDFD) method and steady-state ab initio laser theory (SALT) [3], which enable precise identification of photonic crystal band-edge modes [4] and defect modes [5] in 1D geometries, as well as whispering gallery modes (WGM) in nematic droplets and a variety of resonant modes in Bragg-onion cylindrical CLC structures [6]. The FDFD method and SALT further allow for a comparison of quality factors and lasing thresholds of different modes across various geometries and material parameters. Additionally, the finite-difference time-domain (FDTD) method [7], coupled with equations describing saturable optical gain materials, as implemented in the Meep software package [8], is utilized to simulate light coupling into liquid crystal resonators, to model pulsed lasing from such micro-structures, and to develop protocols involving sequences of multiple light pulses with varying wavelengths, polarizations, and intensities enabling all-optical control of light amplification. These simulations provide valuable insights for further optimizing micro-lasers and their potential future applications in photonic microcircuits as all-optical logic gates.

Abstract: We present a bottom-up fabrication approach for highly efficient photocatalysis using a gold-silicon metasurface, where gold nanoparticles are confined within nanopatterned porous silicon. This design enhances charge separation, prevents recombination, and increases photocatalytic activity. Our findings highlight scalable, nanostructured metasurfaces for advanced environmental and energy applications.

Fabrication and design

The nanoporous silicon metasurface was fabricated using block-copolymer self-assembly, enabling the creation of a highly ordered nanostructured template. The use of polystyrene-block-polymethyl methacrylate (PS-b-PMMA) diblock copolymer allowed precise control over pore size and arrangement. After etching, the resulting silicon metasurface contained well-defined nanopores of approximately 25 nm in diameter (Figure 1). Gold nanoparticles were then deposited into these nanopores, with each cavity accommodating up to two nanoparticles. This controlled metasurface confinement prevents agglomeration, maintains high surface area availability, and enhances nanoparticle coupling, leading to improved charge carrier dynamics. The confined metasurface structure also ensures optimal interaction between AuNPs and Si, promoting effective Schottky junction formation for better charge separation.

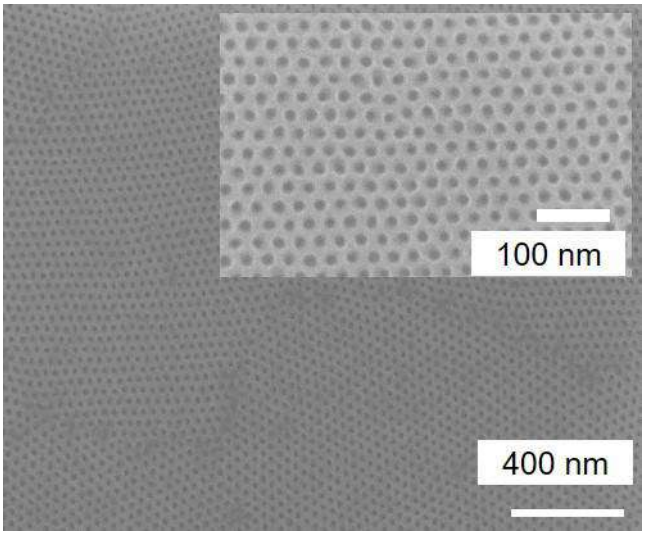

Figure 1. Si nanopore template.[1]

Photocatalytic Performance and Mechanism

Photocatalysis plays a crucial role in environmental sustainability, offering pathways for water purification, air purification, and renewable energy generation. However, the efficiency of conventional photocatalysts is often limited due to rapid charge carrier recombination and inefficient light absorption. In this work, we introduce a novel bottom-up approach for fabricating a highly efficient, reusable photocatalyst by confining gold nanoparticles (AuNPs) within a nanopatterned porous silicon (Si) metasurface. This structured metasurface enhances charge separation, prevents recombination, and significantly improves photocatalytic performance compared to traditional methods.

The photocatalytic efficiency of the AuNP-Si metasurface was tested by evaluating the degradation of methyl orange (MO) dye under UV light (λ = 353 nm). The results showed near-complete degradation of MO within 90 minutes, compared to 70% degradation for randomly dispersed AuNPs on silicon and only 15% degradation for bare silicon. This dramatic enhancement is attributed to three main factors:

1. Enhanced Charge Separation: The Schottky junction formed at the AuNP/Si interface facilitates rapid electron-hole separation, minimizing recombination losses.
2. Increased Surface Area: The nanoporous metasurface provides abundant active sites for catalytic reactions, ensuring more efficient dye adsorption and degradation.
3. Confined Plasmonic Effects: While the system primarily operates via charge transfer rather than plasmonic resonance at this UV wavelength, simulations suggest that enhanced near-field effects at visible wavelengths could further boost performance.

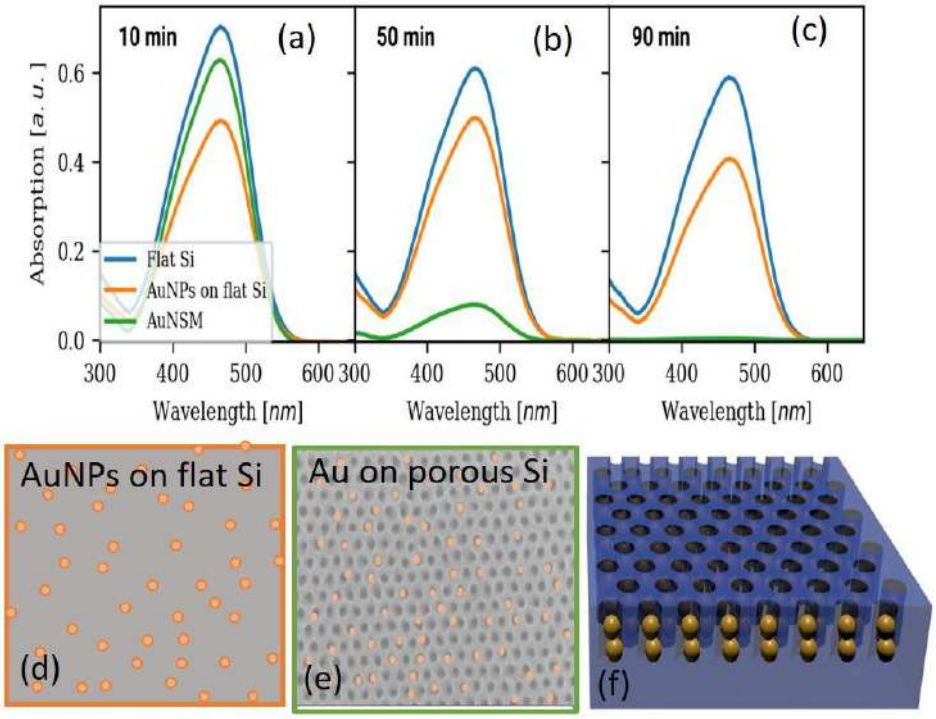

Figure 2. UV–vis absorption spectra of MO dye after degradation after (a) 10, (b) 50, and (c) 90 min on flat Si, AuNPs on flat Si (d), and AuNPs confined in Si pores. (f) Schematic of the metasurface.[1]

Finite Element Method (FEM) simulations revealed that the nanoporous metasurface led to increased power loss density, indicating a higher generation of charge carriers compared to flat silicon or dispersed AuNPs. This confirms that nanoparticle confinement within nanocavities improves photocatalytic efficiency through a combination of charge transfer mechanisms and field enhancement effects.

This work presents a scalable and cost-effective bottom-up approach to engineering high-performance photocatalysts through nanopatterning and particle confinement. By leveraging block-copolymer templating and metal nanoparticle incorporation, we achieve a robust metasurface with superior photocatalytic efficiency. Future work will focus on::

- Extending the study to visible-light-driven photocatalysis by optimising nanoparticle size and material composition.
- Investigating the long-term recyclability and stability of AuNP-Si metasurface for real-world water treatment applications.
- Exploring other semiconductor-metal nanoparticle combinations for enhanced photocatalytic performance.

This research highlights the potential of structured nanomaterials in environmental decontamination and sustainable energy applications, paving the way for the next generation of efficient photocatalysts.

Abstract: Volumetric glass materials grown by micro-pulling-down technique will be presented, particularly from the perspective of their enhanced optical properties upon doping with plasmonic nanoparticles.

Plexcitonic systems integrate plasmonic properties with excitonic emission, leading to enhanced system performance characterized by rapid and intense luminescence. These features are particularly desirable for applications in optoelectronic devices, ultrafast optical switches, and quantum information science.

In this study, we present optically active volumetric materials fabricated using the micro-pulling-down method. By employing the NanoParticle Direct Doping (NPDD) technique, we create nanocomposites with tailored plasmonic properties, enabling the observation of enhanced optical responses. This innovative approach, developed in our laboratory, facilitates the direct introduction of plasmonic nanoparticles into glass matrices, allowing precise control over their electromagnetic characteristics. Consequently, we can fine-tune localized surface plasmon resonances (LSPR) to optimize targeted effects, such as the photoluminescence (PL) enhancement of quantum dots.

By integrating advanced material fabrication with comprehensive characterization, our research paves the way for cost-effective photonic devices with enhanced functionalities.

Bottom-up wet-chemical synthesis of nanometals assisted by ultrafast irradiation

A. Guerrero-Martínez

Departamento de Química Física, Universidad Complutense de Madrid, Avda. Complutense s/n, 28040 Madrid, Spain
aguerrero@quim.ucm.es

Abstract: Metal nanoparticles' unique optical properties have driven research into their synthesis for nanoplasmonic devices. Ultrafast pulse lasers enable precise control of electron dynamics, leading to uniform nanoparticle production and controlled assembly. This advances applications in photonics, sensing, and catalysis by enhancing optical functionality and structural precision.

Over the past two decades, there has been significant interest and progress in the development and application of metal nanoparticles, primarily driven by their distinctive and highly tunable optical properties. The remarkable ability of gold nanoparticles to interact with light stems from their localized surface plasmon resonances (LSPRs), which are collective oscillations of conduction electrons induced by an electromagnetic field. These unique optical characteristics have opened up numerous possibilities for developing advanced nanoplasmonic devices with tailored functionalities, ranging from biosensing and imaging to photothermal therapy and optoelectronics.

In this context, a substantial body of research has focused on the rational bottom-up synthesis and controlled assembly of metal nanoparticles to achieve desired optical responses. The ability to engineer these nanoparticles with precision has been made possible through a deeper understanding of the mechanisms governing the interaction between light and nanostructures. A key driver of this progress has been the use of ultrashort-pulse laser technologies, which have provided critical insights into the complex electron dynamics underlying light-nanoparticle interactions.

This presentation will explore the transformative role of pulse lasers, particularly femtosecond and nanosecond pulses, in uncovering the fundamental processes that occur during light-matter interactions in metal nanoparticles. When nanometals are exposed to femtosecond pulse lasers, LSPRs are excited, triggering a series of ultrafast physical and electronic processes. These include rapid electron thermalization within hundreds of femtoseconds, followed by lattice relaxation on the picosecond timescale, and eventual environmental coupling, which can result in controlled surface melting of the nanoparticles. In contrast, nanosecond pulse irradiation leads to a fundamentally different response. The extended pulse duration causes overlapping excitation and relaxation processes, which typically result in uncontrolled melting and fragmentation of the nanoparticles due to excessive heat accumulation.

The ability to precisely control these laser-induced phenomena has paved the way for innovative methods to produce highly monodisperse nanometals. For instance, femtosecond pulse laser irradiation has been successfully used to refine polydisperse colloidal solutions, generating nanoparticles with exceptional uniformity and size control (Figure 1).[1] Furthermore, pulse laser irradiation has emerged as a powerful tool for the controlled synthesis of hollow nanometals,[2] and nanoalloys with tunable compositions and defined numbers of atoms.[3]

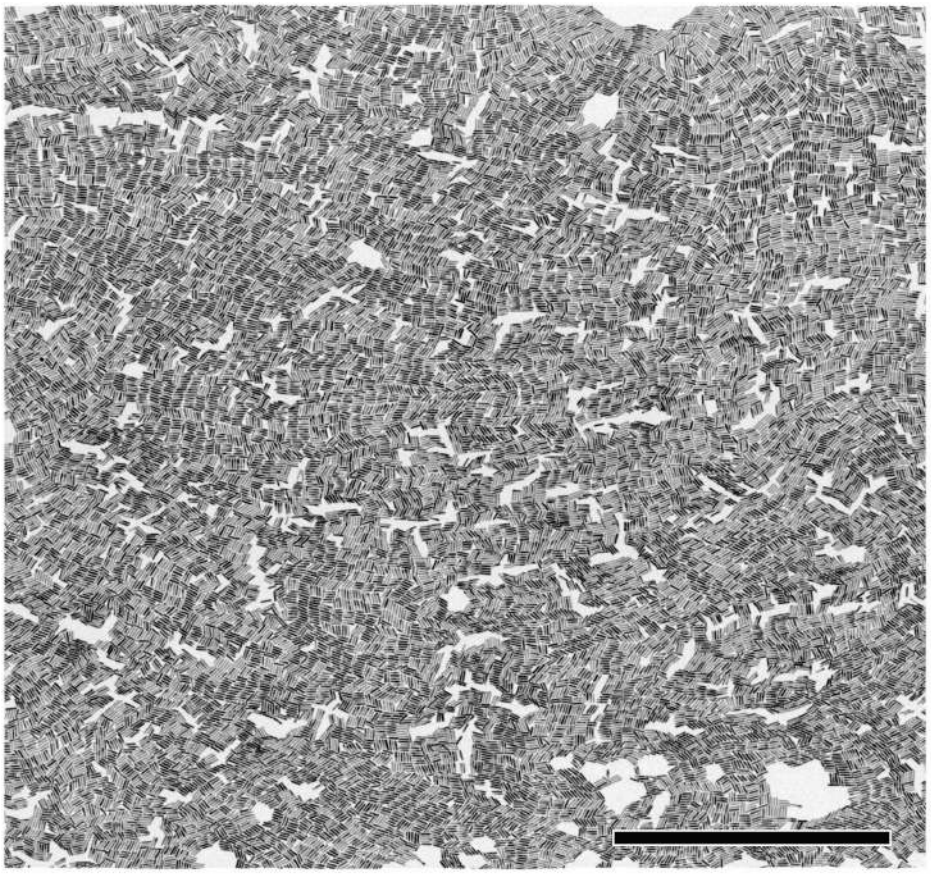

Figure 1. Gold nanorods prepared by bottom-up synthesis and ultrafast irradiation (scale bar, 1 μm)

Overall, the insights gained from pulse laser studies have not only deepened our fundamental understanding of plasmonic interactions at the nanoscale but have also driven technological advancements in nanofabrication and material design. The ability to tailor the optical properties of gold nanoparticles through laser-based synthesis and assembly holds immense potential for a wide range of applications in photonics, sensing, and catalysis.

Tailored Photonic Bandgap in Liquid Crystalline Cellulose Ether Mesophases: Harnessing Self-Assembly Kinetics and Polymer Chain Mobility

C. A. C. Chazot[1*], S. G. Fine[1], and C. Guo[1]

[1]Department of Materials Science and Engineering, Northwestern University, United States
[*]corresponding author: cchazot@northwestern.edu

Abstract: We investigate liquid crystal self-assembly kinetics and chiroptical properties in cholesteric cellulose ether mesophases. *In-situ* reflectivity measurements reveal the impact of polymer diffusivity and chain elasticity on photonic bandgap development. Our findings guide the design of structurally colored gels and composites with stable, angle-dependent optical properties and reversible colorimetric functions.

Cholesteric liquid crystalline (LC) mesophases based on cellulose ethers, such as ethyl cellulose and hydroxypropyl cellulose, have garnered significant attention for their ability to exhibit macroscopic structural color and chiroptical properties. This long-range helical arrangement consists of stacked nematic pseudo-layers, where the continuous change in refractive index allows selective reflection of part of the electromagnetic spectrum and a tailored photonic bandgap. When the helicoidal pitch matches the wavelength of visible light, dynamic structural colors emerge, driven by the spacing and twisting angles between isoclines (planes of constant orientation). This results in stimuli-responsive optical properties that are sensitive to environmental changes such as mechanical strain, humidity, and temperature.

Despite extensive studies, the time scales involved in the multiscale self-assembly of cholesteric LCs, from the formation of helical secondary structures to mesogen packing and microscopic domain development, remain underexplored.[1] This research discusses how polymer chain mobility, influenced by molecular weight, concentration, and viscoelastic properties, determines the evolution of the photonic bandgap based on the onset of kinetic trapping in the mesophase. A quantitative relationship between the kinetics of structural color formation after shear deformation and cholesteric order development at both nano- and microscales in the gel mesophase is established.[2] Utilizing rheology alongside static and time-resolved reflectivity measurements, the study highlights the strong influence of polymer diffusivity and chain elasticity on self-assembly and order relaxation kinetics in cholesteric cellulose ether gels. The developed phenomenological model can assess the structure–property relationships of various soluble polysaccharide LC mesophases, providing key design guidelines for developing and processing structurally colored cholesteric mesophases.

Further investigation into solvent photopolymerization and the trapping of cholesteric order in a composite reveals its effect on selective reflectivity. Using ethyl cellulose-poly(acrylic acid) (EC-PAA) films as a model system, the balance between EC chain mobility and solvent photopolymerization kinetics is explored to understand the preservation of cholesteric texture and optical properties. The findings demonstrate that realignment or disruption of chiral nematic order during PAA chain growth only occurs for low molecular weight (i.e. high chain mobility) EC. Time-resolved studies during UV curing, including in-situ reflection spectroscopy and rheometry, reveal that rapid polymerization reactions and reduced polysaccharide mobility help maintain the photonic bandgap and angle-dependent reflectivity in solid composite films.

Through the development and application of these fundamental design principles, the research demonstrates that self-assembly kinetics can be leveraged to create composites with spatially-controlled photopatterned bandgaps, tailored angle-resolved reflectivity, and reversible colorimetric functions. These findings provide

critical insights into the interplay between polymerization kinetics and cholesteric texture evolution, paving the way for advanced chiral nematic composites with spatial and temporal control over dynamic chiroptical properties.

Abstract: We report the fabrication of three-dimensional topological insulator heterostructures using a single-step bottom-up approach based on directional solidification. These materials exhibit atomically smooth interfaces, preserving topological surface states and enabling hetero-junction formation. This scalable approach paves the way for advancements in spintronics, quantum computing, and novel optoelectronic applications.

Three-dimensional (3D) topological insulators (TIs) have garnered significant interest for their unique quantum properties, particularly their topologically protected, gapless surface states. These materials are promising for topological spintronics and quantum computing due to their robust surface conduction channels, which are resistant to backscattering from nonmagnetic impurities[1]. However, practical implementation is hindered by challenges such as environmental sensitivity, a low surface-to-volume ratio, and the need for controlled material heterojunctions to enhance functionality. Addressing these issues is crucial for advancing TI-based technologies.

In this work, we demonstrate the successful fabrication of 3D TI heterostructures using a simple, fast, and scalable single-step directional solidification technique. This bottom-up approach enables the formation of eutectic composite materials, where two distinct crystalline phases naturally grow in an ordered structure with atomically smooth interfaces. Unlike conventional heterostructure fabrication methods such as molecular beam epitaxy or exfoliation-transfer techniques, which require multiple steps and precise environmental control, directional solidification provides a robust alternative that efficiently overcomes key challenges associated with 3D TIs. The resulting heterostructures exhibit well-defined lamellar micro/nanostructures, which preserve topological surface states while facilitating the formation of stable electronic junctions. This controlled fabrication process enables precise interface engineering between different TI phases or between TIs and adjacent functional materials, optimizing charge transport and spintronic behavior for device applications. Furthermore, the single-step nature of this process ensures reproducibility and scalability, making it suitable for large-scale production.

To confirm the presence of topologically protected metallic surface states and evaluate heterojunction formation, a range of advanced characterization techniques were employed. Spectroscopic and electronic measurements validated the existence of surface states, while transport studies revealed the formation of built-in heterojunctions within the heterostructures. The ability to naturally form these junctions in a single growth process marks a significant advancement in integrating TIs with functional device architectures.

We synthesized multiple TI-based eutectic composites, incorporating various second-phase materials such as metals, semiconductors, ferromagnetic, antiferromagnetic, and superconducting compounds to explore exotic interfacial phenomena. For instance, in the Sb_2TeSe_2-Sb_2Se_3 composite, where Sb_2TeSe_2 is a p-type TI and Sb_2Se_3 is a promising photovoltaic material, we confirmed the presence of topological surface states at the Fermi energy in Sb_2TeSe_2. Additionally, FTIR measurements revealed multiple peaks in the THz region. To further investigate their origin, THz nanoscopy was conducted at different THz frequencies, revealing clear optical property contrasts between different phases and at the interface. Beyond this system, additional eutectic composites—including Bi_2Te_3-Te, Sb_2Te_3-Te, Bi_2Te_3-BiTeI, Bi_2Te_3-Mn, SbTeI-Sb_2Te_3, Fe_7Se_8 -Bi_2Se_3 - were synthesized for further exploration.

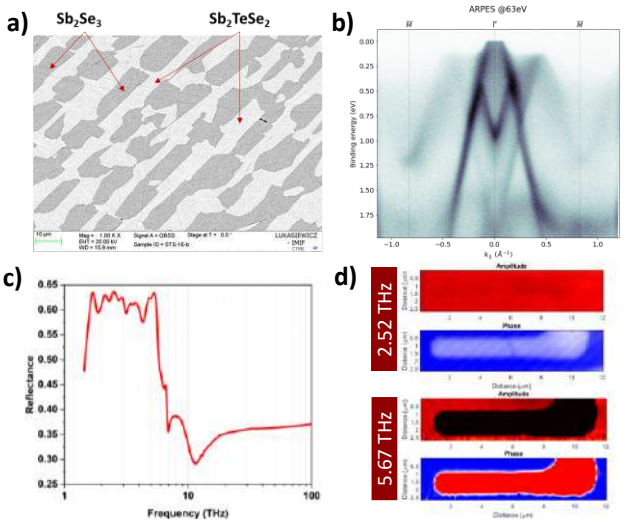

Figure 1. Sb_2TeSe_2-Sb_2Se_3 TI-based eutectic heterostructure a) SEM measurement, phase identification of Sb_2TeSe_2 and Sb_2Se_3 phases, b) μARPES measurement on Sb_2TeSe_2 phase confirms the presence of surface states with p-type doping, c) FTIR spectra with the presence of multiple peaks in THz region d) THz nanoscopy shows phase specific response at different THz frequencies.

These results align with recent studies on TI-based heterostructures, which emphasize the importance of interface quality and material stability in optimizing topological transport properties[2-3]. The successful demonstration of scalable heterostructure fabrication via directional solidification establishes a foundation for future investigations into exotic quantum phenomena, including topological superconductivity and novel magnetoelectric effects.

Bottom-up Design of Isotropic Auxetic Metamaterials via Kolmogorov-Arnold Networks

H. Y. Huang[1*]

[1]School of Aeronautics, Northwestern Polytechnical University, China
[*]corresponding author: huangheyuan@nwpu.edu.cn

Abstract: This study introduced a data-driven structural design strategy and established a mapping between design parameters and mechanical responses for classical missing rib auxetic metamaterials via Kolmogorov-Arnold Networks. The predicted mean squared error for the stress dataset was 0.81%, only one-fourth of that achieved by multilayer perceptron models of equivalent width.

1. Structural Design

As shown in Figure 1(j), this study established tensile performance evaluation criteria at every 30° within the -90° to 90° range and uniformly assessed the variations in stress-strain curves of identical structures across different directions. The ultimate design objective was to develop an isotropic auxetic metamaterial with consistent stress-strain performance throughout the entire 0°-360° circumferential range.

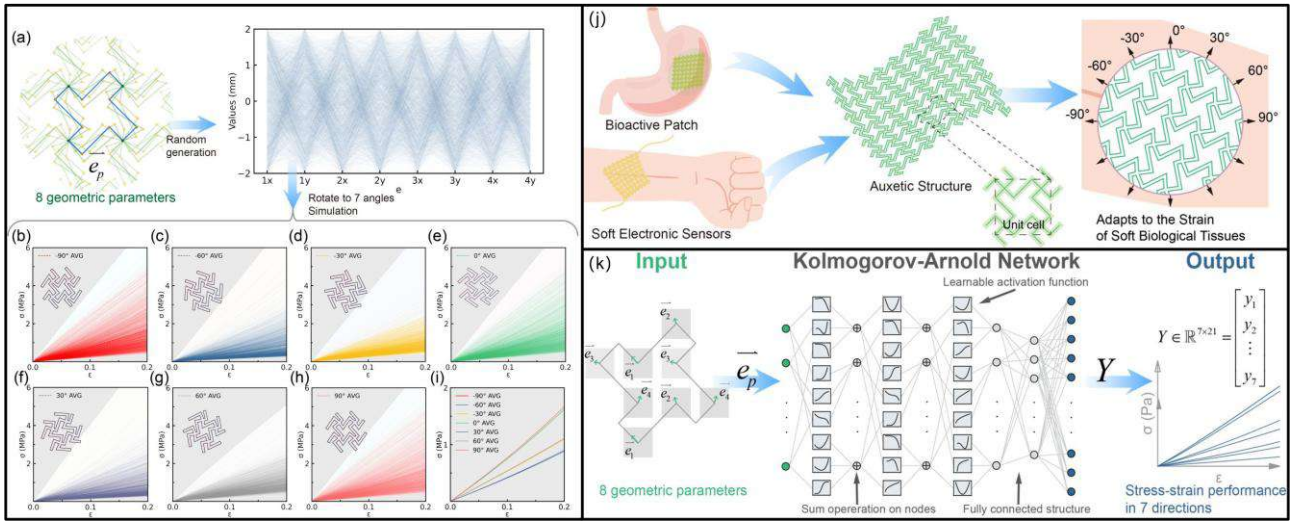

Figure 1. (a) Random generation results of the vectors; Distributions of the stress-strain datasets for generated structures under (b) -90°, (c) -60°, (d) -30°, (e) 0°, (f) 30°, (g) 60° and (h) 90°; (i) Average mechanical performance; (j) Design principles of metamaterials; (k) Workflow for KAN predictions.

To further expand the design space and identify auxetic metamaterials with isotropic properties, we introduced random perturbations to the design parameters of the basic structure, thereby enhancing the variability of the resulting configurations. By adjusting multiple parameters, structures with diverse mechanical response characteristics were generated, leading to the creation of a stress-strain dataset for multi-directional auxetic structures. This dataset served as the foundation for bottom-up design to identify optimal configurations.

2. KAN Prediction

This study randomly generated eight design parameter vectors, after which the results were shown in Figure 1(a). The parameter vectors were passed to the simulation model, and rotation angles were controlled in seven

directions. Through computational analysis, a total of 2,500 sets of nominal stress data per direction (17,500 entries in total across all seven directions) were obtained. Figure 1(b)–(h) illustrated the distribution of these 2,500 sets of results for each direction ranging from -90° to 90°. The dashed lines represented the mean value in each direction, serving as the foundation for subsequent training and optimization. As illustrated in Figure 1(k), the KAN was designed to replace the traditional MLP module in the training process. The training pipeline, built upon the PyTorch library and the Pykan library began by standardizing the input vector with Scikit-learn's StandardScaler to ensure a uniform distribution of input data.

3. Bottom-up Design

This study employed a genetic algorithm in conjunction with the KAN to achieve bottom-up optimization for isotropic stress and the best solution was named as Model III. Figure 2(a)-(b) compared the stress-strain relationships of Model III under multiple orientations in terms of predictions, simulations, experiments, and the stress dataset. The results indicated that the mean squared errors of the predicted, simulated, and experimental data are below 0.05%, confirming that Model III achieved a highly uniform and isotropic stress distribution. As illustrated in Figure 2(c)-(d), Model III were nearly circular across all directions and showed the lowest MSE, demonstrating that it achieved a more uniform isotropic response and underscoring the outstanding performance of the combined KAN and genetic algorithm.

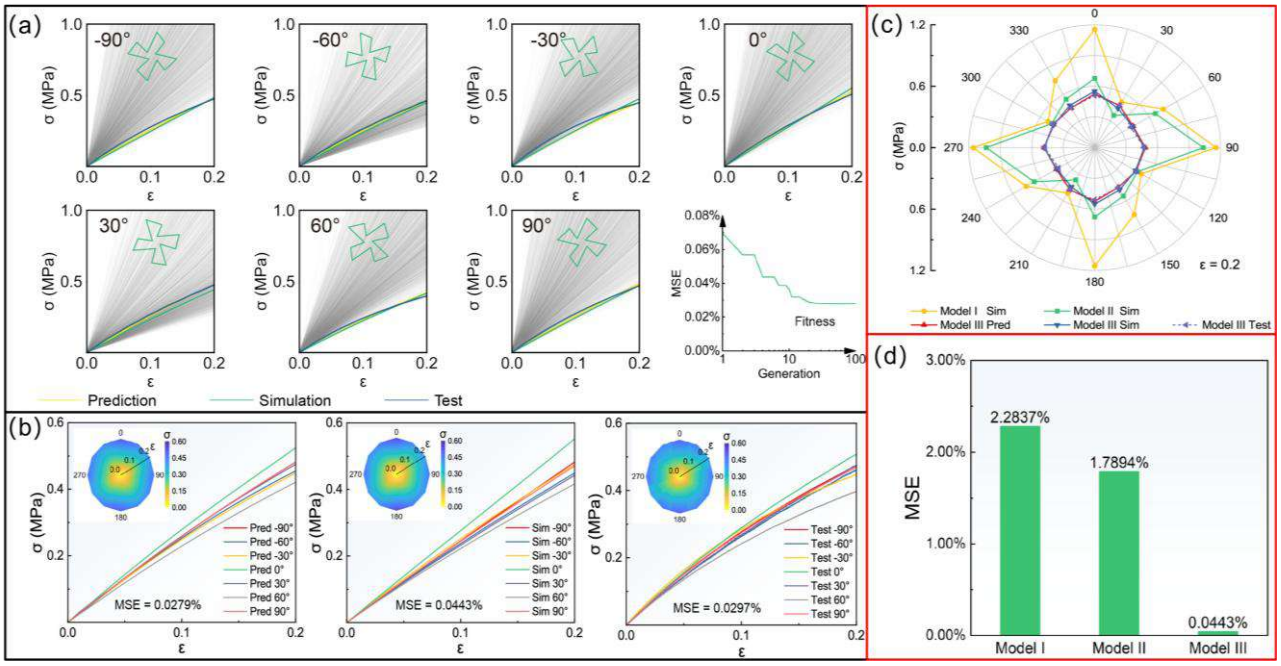

Figure 2. Bottom-up design combining KAN and genetic algorithm: (a) Comparison of predicted, simulated, and experimental stress results for Model III and genetic algorithm converges over generations; (b) Uniformity evaluation of predicted, simulated, and experimental stress responses of Model III; (c) Specific stress distribution at a strain of 0.2; (d) Comparison of average MSE.

Abstract: Bottom-up colloidal synthesis is the "gold standard" approach for preparing plasmonic gold nanomaterials with select compositions, sizes, and shapes, with high uniformity.[1] Here, we take a chemical approach towards translating traditional colloidal synthesis to *in situ* growth – the direct formation of morphology-controlled nanostructures directly on a substrate surface.

While *in situ* growth has been explored in the past, the quality of the fabricated nanostructures tends to have lower quality – low shape yield, high polydispersity, and limited control over the plasmonic response – compared to colloidally prepared nanostructures.[2] Additionally, many *in situ* growth schemes still rely on the implementation of colloidal seeds.[3] In this work, we aim to address this gap in synthetic know-how, with the specific goal of developing methods for fabricating gold nanostars and nanorods *in situ* on the internal walls of microfluidic channels without the use of colloidal synthesis or self-assembly. Taking a systematic approach, we were able to identify that increasing the competition between colloidal nanoparticle formation in the flowing growth solution and nucleation on the surface is necessary to facilitate successful formation of the desired nanoparticles on the substrate surface (**Figure 1A**).

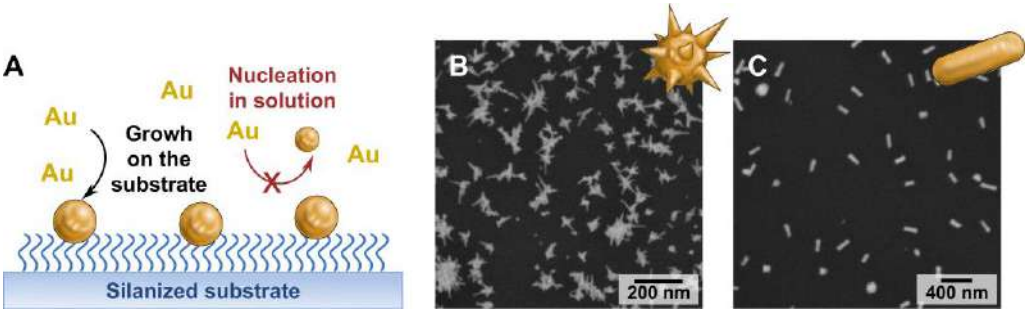

Figure 1. A: Schematic of the competition between colloidal nucleation and *in situ* growth of nanoparticles on the substrate. **B,C:** Scanning electron microscopy images of the gold nanostars (**B**) and nanorods (**C**) grown *in situ.*

Moreover, we identified key aspects of the growth conditions affecting shape yield, *i.e.*, nanoparticle density, growth solution composition, and flow rate. The extinction of the nanoparticles could also be modified *in situ* (~600 nm to 1100 nm) by changing the composition of the growth solution. Overall, tuning the chemical environment, we attain >90% shape yield for nanostars and ~80% for nanorods (**Figure 1B,C**), which in the latter case, represents a significant improvement, with previous reports obtaining only ~20-37% yield.

Ultimately, the fabricated plasmonic-microfluidic chips have the potential to be implemented in applications such as biological and chemical sensors and in microfluidic platforms incorporating 2D and 3D *in vitro* cellular models.

Abstract: We introduce the *Geometry Matrix* formalism, a modular framework for modeling active plasmonic nanoparticles in the quasi-static and Mie regimes. This approach predicts threshold gain conditions, emission spectra, and modal instabilities in gain-assisted metal nanostructures, offering a unified perspective on plasmonic nano-resonators and improving predictive modeling for plasmonic spasers.

The interaction of light with active plasmonic nanostructures is fundamental to emerging nanoscale light sources, quantum plasmonics, and plasmonic computing architectures. Predicting their emission properties and stability requires a robust electrodynamic framework that accounts for both geometric confinement and gain-assisted nonlinearities.

In this work, we introduce the Geometry Matrix formalism, a versatile analytical framework that systematically describes the optical response of active plasmonic nanoparticles, including both single-metallic and nano-shell architectures. By solving a self-consistent eigenvalue problem, this model determines the threshold gain, time evolution, and spectral emission characteristics in gain-assisted plasmonic nanostructures.

Unlike conventional modal analysis, the Geometry Matrix approach provides a direct connection between nanoparticle shape, multipolar plasmonic modes, and their stimulated emission dynamics. The Geometry Matrix formalism enables an analytical treatment of plasmonic spasers in both the quasi-static and Mie regimes. In these cases, a fully self-consistent description is possible, provided that nonlinear saturation effects are neglected. In the quasi-static approximation, the EM fields are limited to the dipolar mode, allowing for compact analytical formulations. When extended to the Mie regime, it incorporates full electrodynamic effects, enabling an accurate description of subwavelength spasers and their far-field signatures.

The system's evolution is governed by a matrix equation where $\mathbf{A}$ encodes both structural and gain-dependent properties, enabling direct modeling of threshold conditions and dynamical instabilities. We find that this governing set can be written in the following form:

$$\frac{d\mathbf{q}}{dt} = \mathbf{A} \cdot \mathbf{q} + \mathbf{b}, \tag{1}$$

where the vector $\mathbf{q}$ collects the electromagnetic mode components. The complete physical description of the system is encapsulated in the matrix $\mathbf{A}$, which we refer to as the geometry

matrix since it originates from the boundary conditions and depends explicitly on the system's geometry. The vector **b** is related to the excitation field; the non-resonant external pumping mechanisms appear in termos of the population inversion both in **A** and **b**. This formulation provides a self-contained, time-dependent electrodynamical model for gain-assisted spherically symmetric particles, offering a direct pathway to analyze their emission properties, instabilities, and nonlinear dynamics.

In the quasi-static nanoshell geometry, this approach allows analytical solutions in the saturation regime, revealing the rich spectral behavior of gain-assisted plasmonic systems in the emission regime. This framework is particularly relevant for designing ultracompact plasmonic nanolasers, tailoring metamaterial-based light sources, and engineering new active nanophotonic devices.

Abstract: We present a bottom-up method for fabricating plasmonic nanostructures on tapered optical nanofibers using Blurred Electron Beam Induced Deposition. The technique enables sub-20 nm precision, and the nanostructures show polarization-sensitive scattering, and directional emission, offering a versatile platform for on-fiber plasmonics with applications in sensing, light routing, and quantum photonics.

Localized surface plasmon resonances (LSPRs)[1] in subwavelength metallic nanostructures offer a powerful route to enhance light–matter interaction at the nanoscale, enabling a wide spectrum of applications ranging from biosensing[2] and optical manipulation[3] to quantum photonics[4]. In particular, coupling plasmonic structures to waveguides or fiber platforms[5] has recently emerged as a strategy to realize scalable, robust nanophotonic architectures. However, most existing efforts focus on multimode fibers and rely on stochastic[7] or self-assembled plasmonic structures, preventing deterministic control at the single-mode/single-structure level. Single-mode tapered optical nanofibers (TNFs)[6], with subwavelength diameters and strong evanescent fields, represent an ideal platform for achieving enhanced plasmonic interaction with precise mode confinement. Despite this potential, the deterministic integration of metallic nanostructures onto TNFs remains a challenge, primarily due to their mechanical fragility and incompatibility with conventional high-energy nanofabrication techniques.

To overcome this limitation, we introduce Blurred Electron Beam Induced Deposition (BEBID), a bottom-up fabrication method that enables the deterministic growth of platinum nanopillars and nanoantennae directly onto suspended single-mode TNFs with sub-20 nm spatial precision. In contrast to standard Focused EBID (FEBID), our approach deliberately defocuses the electron beam to reduce local pressure and mechanical stress on the fiber during deposition. This strategy allows for the nucleation of discrete plasmonic structures without damaging the nanometric, suspended substrate. The process was implemented in a dual-beam FIB/SEM system using a $MeCpPtMe_3$ precursor, with the degree of beam blurring matched to the desired nanopillar diameter.

We first assessed the mechanical compatibility of BEBID with subwavelength TNFs under varying fabrication parameters. We optimized the process to obtain high-fidelity nanopillars with diameters down to 100 nm and target heights of 300–500 nm. Energy-dispersive X-ray spectroscopy (EDX) and SEM analysis confirmed that the structures exhibit excellent geometric repeatability, with intra-sample diameter variation below 1% and inter-sample variation around 8%. Post-deposition plasma oxidation was employed to remove carbon content from the composite, increasing the Pt fraction to ~65% by volume. Optical characterization was carried out by coupling light into the TNF and recording the scattering spectra and polarization dependence from

individual nanostructures. Monomers and closely spaced dimers were investigated, showing a polarization-dependent response and a distinct ~50 nm redshift in the extinction spectra for dimers, indicating hybridized LSPR modes in the nanogap. Polar plots of scattered intensity exhibited cosine-squared behavior consistent with the anisotropic evanescent field profile, and the experimental Degree of Linear Polarization (DoLP) reached 0.92 in dimer structures, in good agreement with Finite-Difference Time-Domain (FDTD) simulations.

Furthermore, simulations of multi-pillar arrays on the TNF surface showed that increasing the number of nanopillars from one to six gradually narrows the far-field scattering lobe, concentrating the emission into a ~90° forward-propagating angular range. This directional behavior highlights the potential of BEBID-fabricated plasmonic structures as building blocks for light routing and on-fiber nanoantennae.

In conclusion, BEBID enables reliable and precise bottom-up fabrication of plasmonic nanostructures on otherwise inaccessible photonic substrates, such as suspended single-mode TNFs. The technique combines spatial accuracy, structural control, and optical functionality in a single-step process, marking a significant advancement over conventional top-down approaches. Future developments could extend this platform to different materials via precursor switching, or to complex nanophotonic arrays with tailored geometries, including Yagi-Uda antennas and emitter-coupled configurations. The deterministic nature of BEBID also opens avenues for hybrid integration with solid-state quantum emitters, where the precise spatial registration between emitter and antenna is crucial for optimized coupling. We envision that this approach will support emerging applications in quantum photonics, fiber-based sensing, and directional light emission control at the nanoscale.

Abstract: We present metasurface mirrors that achieve perfect helicity-preserving reflection for circular polarization and cross-polarized reflection for linear polarization in the THz spectrum, without the need for a back-reflector. Validated via THz time-domain spectroscopy, the designs enable advanced applications in molecular chirality sensing and broadband polarization control.

Metasurfaces have emerged as a groundbreaking optical platform, enabling precise control over electromagnetic wave propagation [1-3]. Here we demonstrate how specific metasurface mirrors that operate in the low THz spectrum can achieve ideal reflection properties over either narrowband or broadband spectra depending on the design of the metasurface mirror [4]. The metasurface consists of a simple two-bar resonator structure designed for optimized polarization control, see Fig. 1.

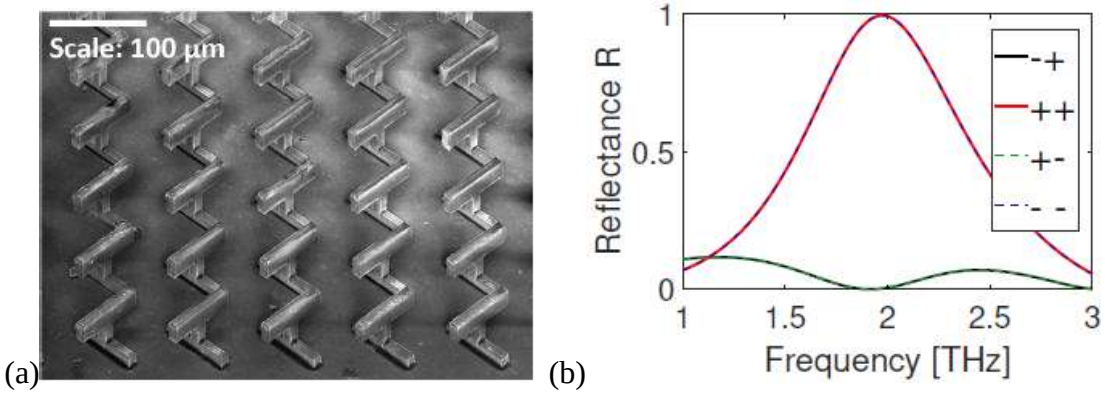

Fig. 1 a) SEM images of the fabricated metallized metasurface structures, b) Numerically calculated reflection response of the metasurface to normally incident CP waves, perfect co-polarized reflection is demonstrated.

The metasurface design provides perfect cross-polarized reflection for linearly polarized waves and perfect helicity-preserving reflection for circularly polarized waves. This effect is attributed to the Pancharatnam-Berry phase, which imparts an additional geometric phase to the reflected wave. The proposed metasurfaces are fabricated using 3D direct laser writing, followed by electroless silver plating for metallic coverage. The fabricated structures were experimentally validated through THz time-domain spectroscopy, demonstrating strong agreement with theoretical predictions.

Applications of such metasurfaces include beam steering and focusing by engineering the phase gradient of the reflected wave. Additionally, its helicity-preserving properties make it highly valuable in molecular chirality sensing and enantiomer detection, which have important implications for chemistry and life sciences. Furthermore, the study explores the potential of translating this concept to the optical frequency range using a fully dielectric version of the metasurface, extending its applications to high-frequency photonics.

Abstract: Nanoparticles form a wide-spread class of objects with multiples applications in the field of nanophotonics and optics. I will present two examples of plasmonic nanoparticles whose composite internal structures enable extraordinary optical properties: gain-metal nanoshells allowing nanolasing, and dense plasmonic clusters displaying artificial magnetism and spatial dispersion.

Progress over recent decades in the controlled synthesis of nanoparticles with various shapes, materials, and internal structure has allowed to extend their properties into previously unexplored regimes of light-matter interaction at the nanoscale. This is notably the case for nanoparticles inclusive of plasmonic components, capable of enhancing the interaction with light through resonances with the free-electron gas in the metal.

In this talk, I will present two examples of plasmonic nanoparticles whose composite internal structures enable extraordinary optical properties: (i) gain-metal hybrid nanoshells allowing nanolasing, and (ii) dense plasmonic clusters displaying artificial magnetism and spatial dispersion.

My first example will be about nanolasing: plasmonic nanolasers have triggered unabated interest in the past twenty years, as they could provide compact and versatile nanosized light sources. We studied theoretically [1] a hybrid nanoshell system made of an active (gain) medium core and a silver shell geometry as shown in Fig. 1(a), assuming that the gain medium is provided with some energy input through external pumping. We used a time-dependent model of the fields and polarizations inside and outside the nanoshell, with the help of optical Bloch equations and the free-electron equation of motion. We showed that above a certain level of gain in the system (i.e., above a certain intensity of pumping), the nanoshell starts to lase. We studied the dynamics of lasing above this threshold and find that it is single-mode (dipolar only). After a transient, the nanolaser reaches a steady state of emission where the intensity of the emitted field is constant, but its complex field amplitude is submitted to slow rotations in time. Such behavior is commonly known as a “frequency pull-out” effect in the field of classical lasers. Interestingly, while pull-out effects are responsible for minute shifts of laser frequencies in macroscopic lasers, we find that in the nanoshell laser, these effects are comparatively huge; so much that they reshape the spectrum of emission [see Fig. 1(b)] and are ultimately responsible for defining the emission linewidth of the nanolaser. This novel finding is a strikingly different paradigm as compared to standard laser physics, and expands the current knowledge on nanolasers,

The second example of complex nanoparticles I will present concerns dense plasmonic clusters. Clusters of

particles in general have been an extensive topic of research in nanophotonics and especially in metamaterials, where they could provide useful new properties. Dense plasmonic clusters are notoriously difficult to investigate due to strong, multiple interparticle couplings. We studied [2] spherical clusters as shown in Fig. 1(c), made of hundreds of small, randomly-packed plasmonic nanoparticles (gold nanoparticles with radius 7 nm) with variable particle densities. We set to determine whether their electromagnetic behavior could be appropriately described as that of a sphere made of a homogeneous medium [Fig. 1(c)] with effective parameters, like electric permittivity, magnetic permeability, etc. (so-called "homogenization"). Such effective descriptions, when possible, are interesting because they are intuitive and computationally-efficient for use in calculations.

To this purpose, we calculated the scattering of an incoming wave onto such clusters by means of high-precision T-matrix numerical simulation, and compared results with the scattering response of spheres made with a fictitious homogeneous medium. The values of the constitutive parameters of the fictitious medium were determined through careful fitting, so that the response of the homogeneous spheres accurately reproduced that of the cluster. To reach such a fitting for clusters with densities above 40%, we found that the equivalent medium had to include spatial dispersion effects, namely: (i) artificial optical magnetism, which is arising solely by virtue of interparticle couplings within the clusters (no magnetism is present in the individual gold nanoparticles) [Fig. 1(d)]; (ii) longitudinal waves in the medium, localized near the cluster borders. Our description should be seen as an attempt at providing a better and more consistent approach of dense cluster systems, but still easy to understand physically.

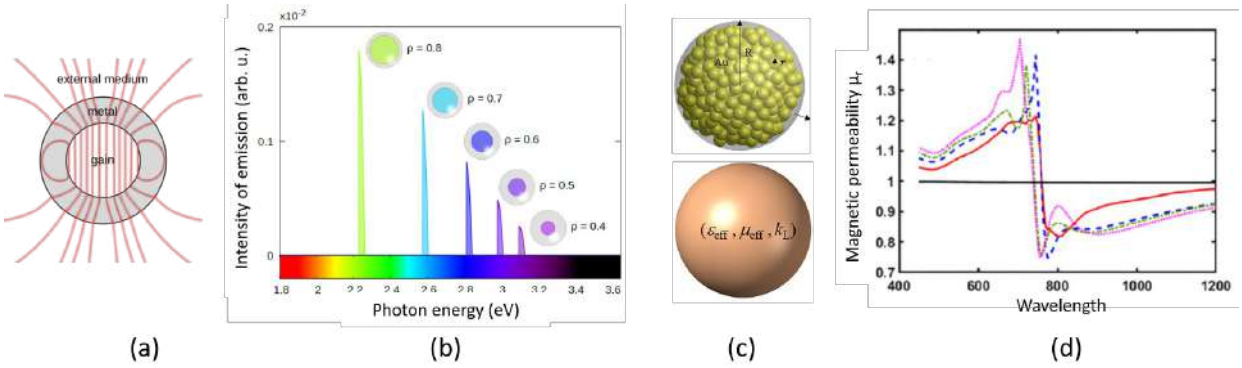

Figure 1. (a) Nanoshell geometry for lasing. **(b)** Emission spectra obtained for nanoshells with various aspect ratios ρ of the internal-to-external radii. **(c)** top, dense spherical cluster of small gold nanoparticles used in T-matrix simulations; bottom, equivalent homogeneous sphere made of an effective medium with spatial dispersion. **(d)** The magnetic permeability μ_r of the homogeneous medium vs. wavelength (different curves correspond to different cluster sizes) is seen to deviate from unity (artificial magnetism).

Abstract: We explore scattering metasurfaces employing hyperuniform disorder (HuD), a special spatial arrangement in the realm of disorder. By engineering spatial correlations in arrays of scatterers, HuD metasurfaces combine characteristics of ordered and random configurations, enabling tailored angular scattering and expanding design flexibility for photonic devices.

Optical metasurfaces are typically highly ordered and fabricated with precision using expensive tools [1]. However, the inherent imperfections in large-scale nanophotonic devices, along with recent advances in bottom-up nanofabrication techniques and design strategies, have highlighted the potential benefits of incorporating disorder to achieve specific optical functionalities [2]. Within the realm of correlated disorder exists the exotic subclass of hyperuniform disorder. In these, density fluctuation are suppressed on large length scales and therefore its representation in fourier space, e.g. the structure factor $S(\boldsymbol{q})$, features vanishing components at the origin, $S(\boldsymbol{q} \to 0) = 0$ [3].

For optical metasurfaces comprising identical scatterers arranged in a HuD array (Figure 1), we find that hyperuniformity enables a novel leverage to tailor light scattering via the precise interplay of form factor f (property of individual scatterer) and structure factor S (property of array). The interplay of f and S is particularly strong when employing Mie resonances with their pronounced scattering cross section [4].

A further focus of our related work are scalable bottom-up fabrication methods of photonic HuD structures [5,6]. Large-area metasurfaces with controlled disorder and without the constraints and expenses typically associated with top-down manufacturing facilitate cost-effective production and also broaden the potential integration of HuD for light management in optoelectronic devices such as solar cells and OLEDs [7,8,9,10].

Abstract: Plasmonic multipod structures composed of N metallic satellites around a dielectric core are designed and optimized to serve as bright, efficient and robust sources of magnetic light. Our approach based on quasi-normal mode analysis reveals that structures with at least tetrahedral symmetry exhibit far superior behavior compared to structures with poor symmetry.

Plasmonic multipods (or N-pods) are complex composite particles composed of a low index dielectric core and N metallic satellites distributed symetrically on the core (see Fig. 1(a)). They have garnered a lot of attention in recent years because they exhibit strong magnetic dipole moments [1, 2]. The Purcell effect can be leveraged in such structures to enhance the spontaneous emission of magnetic dipole transitions – naturally weak processes – while simultaneously suppressing the electric dipole transition [3]. Here, we investigate the optical emission of magnetic dipole transitions in such N-pod structres and optimize their geometries. We resort to quasi-normal modes (QNMs) for analysis, which provides a major advantage over conventional real-frequency methods by significantly reducing the parameter space exploration and offering deep physical insight. We demonstrate that N-pods, well within current fabrication capabilities (see for instance [2, 4]), are excellent candidates to achieve a large, orientation- and volume-independent magnetic Purcell factor with reduced Ohmic losses. Furthermore, we successfully suppress electric dipole transitions, achieving a magnetic branching ratio exceeding 95% across nearly all N-pod particles. For highly symmetrical designs, optimization of the core and satellite radii predicts radiated magnetic Purcell factors exceeding 180.

For each N-pod, we consider structures composed of a silica core with a fixed radius of $r = 42.5$ nm, surrounded by N silver satellites of radius r_{sat}, which is treated as a variable. The satellites are positioned according to solutions of the Thomson problem. These structures support both magnetic and electric dipole quasi-normal modes (QNMs) (see Fig. 1(c,d)). The satellite sizes are varied, and the magnetic Purcell factor is defined as γ_m/γ_0, where γ_m is the decay rate of a magnetic dipole positioned at the core center, and γ_0 is the corresponding free-space decay rate. This factor is evaluated for three principal dipole orientations and then averaged over all possible orientations (see Fig. 1(e) for an example).

This procedure is repeated for various values of N, revealing that the maximum average Purcell enhancement generally increases with the number of satellites, though it exhibits non-trivial sensitivity to dipole orientation (see Fig. 1(f)). A Figure of Merit (FOM) is introduced to account for: (i) robustness against dipole orientation and polydispersity, (ii) the branching ratio β_m, defined as the ratio of the magnetic to electric Purcell factors, and (iii) quantum efficiency. After optimizing this FOM, our results indicate that highly symmetric multipods—particularly

(c) FEM simulation of the absolute value of the modal magnetic field QNM. (d) Corresponding simulation for the electric field of the electric dipole QNM. (e) Example of the (x, y, z)-averaged and orientation-averaged evolution of the magnetic Purcell enhancement as a function of satellite radius for a 7-pod. (f) Optimized magnetic Purcell enhancement and symmetry orders as a function of the number of satellites in the multipod. (g) Dependence of the optimized figure of merit (FOM) on N, highlighting the superiority of the dodecapod structure ($N = 12$) and other highly symmetric N-pods (Platonic polyhedra are indicated with a P). The red triangles represent the branching ratio β_m, while the red diamonds denote the quantum efficiency (QE). (c–g) Computed for structures with a fixed silica core radius of $r = 42.5$ nm. (h) Optimized spectral variations of the magnetic Purcell factor for a dipole positioned at the center of a dodecapod (blue). The corresponding electric Purcell enhancement is shown in red.

those corresponding to Platonic solids—perform exceptionally well compared to all other structures (see Fig. 1(g)).

A full optimization of the magnetic Purcell factor, considering both core and satellite radii as parameters, identifies dodecapod structures with Purcell factors as high as 250 and radiation factors reaching 180 for the magnetic dipole transition.

Abstract: Plasmonic metamaterials have been widely used for many application, including optical sensing and photocatalysis. Here we will discuss the fabrication techniques that were used to achieve low-cost and scalable nanosensor technology for hydrogen detection and photocatalyst system for reduction of CO2. We will also discuss in-situ optical characterization methods that can improve device performance and sensitivity during the fabrication process.

Intriguing electromagnetic coupling in eutectic ZnO-$ZnWO_4$ from visible to medium infrared range

Abstract: Bottom-up approaches in fabrication of eutectic metamaterials has opened new routes in designing intriguing electromagnetic properties. Here we show remarkable behavior of ZnO-$ZnWO_4$ eutectic, from second harmonic generation and polarization-dependent luminescence in the visible to metamaterial response in the medium infrared range.

Eutectic composites are self-assembled materials with properties different from those of the constituent materials. Here we investigate zinc oxide-zinc tungstate (ZnO-$ZnWO_4$) eutectic, in which parallel ZnO thin layers (lamellae) are self-organized and embedded in a dielectric $ZnWO_4$ matrix in a fairly regular manner. The samples were fabricated by means of the micro-pulling-down (μ-PD)[1,2], resulting in $\approx$240 nm ZnO lamellae (inset in Fig. 1). ZnO phase was of high quality and crystallinity, as confirmed by a strong exciton emission at room temperature in the blue range.

We start by exciting the eutectic with linearly polarized light at 370 nm and monitor its photoluminescence (PL). PL is governed by an unique refractive-index-matching condition between the ZnO and biaxial $ZnWO_4$ matrix[3], which leads to its strong polarization dependence. Fig. 1 shows PL spectra for the different orientation of the excitation beam nm with respect to the lamellae. The condition for a strong PL enhancement is when the incident polarization is orthogonal to the lamellae. This was further confirmed by numerical analysis with commercial finite-difference-time-domain electromagnetic solver[4]. The same polarization dependence is exhibited in the PL signal in the output, as the PL exits the sample prevalently with the polarization "orthogonal-to-lamellae".

We further show that such samples exhibit optimized nonlinear optical properties. Specifically, we demonstrate efficient optical second harmonic generation (SHG) at pumping wavelength of 800 nm. The eutectic composite relies on the specific crystallographic orientation of the constituent materials: the c-axis of ZnO naturally orients perpendicular to the growth direction, ending up in the plane of the sample. Contrary to the single ZnO crystal, this ensures the best condition for phase matching in SHG when the sample is excited at the normal incidence. Finally, we show that in the IR atmospheric window (8-14 μm), eutectic ZnO-$ZnWO_4$ behaves as a self-assembled metamaterial with strong polarization dependence. As such, it shows great potential for the development of photonics components in the IR.

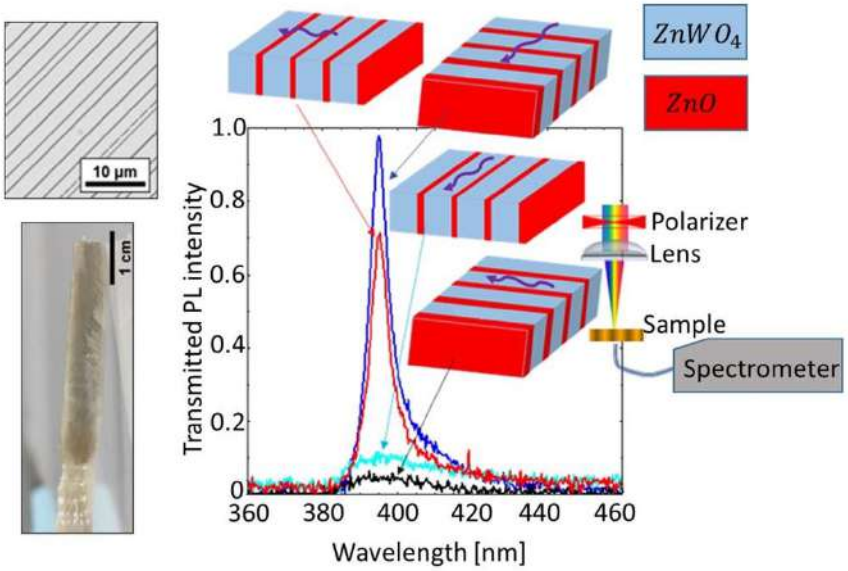

Figure 1. PL intensity of the eutectic depends on the polarization of the excitation beam with respect to the lamellae; inset: SEM image of ZnO-$ZnWO_4$ (top) and the sample photo (bottom).

In conclusion, we strongly believe that the micro-pulling-down route of eutectic material fabrication could be further used in designs where large-scale and cost-effective eutectic devices are needed. Our experimental results demonstrate the potential of lamellae-based eutectics for the development of both passive and active polarization-sensitive optical devices in various spectral ranges.

Non-Hermitian Photonics: Topological, Disordered and Quantum systems

Emission of emitters into the bulk or photonic graphene

Francesco Ciccarello[1]

[1*]University of Palermo, Italy

[*]corresponding author: francesco.ciccarello@unipa.it

Abstract: We study emission properties of quantum emitters coupled to a 2D honeycomb lattice of coupled resonators, a setup by now within reach in some experimental platforms.

We show that, by combining non-local coupling ("gian atom") with an engineered synthetic electric field, an atom in the bulk can emit chiral light orthogonal to the electric field without the need for breaking time reversal symmetry of the lattice.

We additionally study emitters coupled to the latttice edge. We show that, for suitable edge geometry (e.g. zigzag or bearded) vacuum Rabi oscillations, long-range excitation transfer and long-range dipole-dipole dispersive interactions can occur.

Enhanced Sensing Using Hysteresis Loops near Exceptional Points

Abstract: The Riemann Surface near exceptional point degeneracies (EPD) of nonlinear systems with dynamical parity-time symmetry demonstrates the formation of a hysteresis loop whose width scales sublinearly with the distance from the EPD. We show that this hysteresis can be utilized as a noise-resilient measurand for ultrasensitive sensing.

Sublinear resonant deviations from an exceptional point degeneracy (EPD) has been recently promoted as a sensing scheme. However, there is still an ongoing debate whether the sensitivity advantage is negated by an increase in fundamental noise – especially when active elements induce self-oscillations. In this case, nonlinearities are crucial in stabilizing amplifying modes and mitigating noise effects. A drawback is the formation of hysteresis loops that signal a transition to unstable modes. This can only be alleviated by precise cavity symmetry management. Here, utilizing two coupled nonlinear RLC tanks with balanced amplification and attenuation, we demonstrate that an explicit symmetry violation, induced by sweeping the resonant detuning of the RLC tanks, reveals a hysteresis loop near the EPD whose width scales sublinearly with the inter-tank coupling. Our proposal re-envisions this disadvantageous feature as a sensing protocol with diverging sensitivity, enhanced signal-to-noise ratio, and self-calibration without requiring delicate symmetry control. As such, it opens new avenues in metrology as well as for optical/RF switching and triggering.

Abstract: One of the exceptional features of non-Hermitian systems is the unidirectional wave interactions. At a particular (exceptional) point the situation can be achieved, that the external radiation is efficiently coupled into the system, but the internal radiation cannot escape backwards. We realize this idea in non-Hermitically modulated thin films, consisting of a Hermitian part - the periodic corrugation of the surfaces of a film, and a non-Hermitian part - the modulation of losses along the film. We prove numerically and demonstrate experimentally that the incident radiation, coupled with such a non-Hermitian thin film, is unidirectionally trapped into a planar mode of the film, does not escape from the film (or escape weakly due to experimental imperfections), and is efficiently absorbed there.

One of the exceptional features of non-Hermitian systems is the unidirectional wave interactions. Simultaneous modulation of the real and the imaginary part of the interaction potentials (of the refractive index and the gain/loss in the case of optical systems) can result in unequal coupling coefficients between the fields of different parts of the system. The unidirectional coupling can be arranged between internal fields and external radiation as well. At a particular (exceptional) point, the situation can be achieved, that the external radiation is coupled into the system, but the internal radiation cannot escape backwards. In this way, the incident radiation can be trapped inside the non-Hermitian system and, eventually, can be efficiently absorbed there.

We realize this idea in non-Hermitically modulated thin films, see Fig.1. The modulation consists of a Hermitian part – the periodic corrugation of the surfaces of a thin film, and a non-Hermitian part – the modulation of losses on the surface of the film. We prove numerically and demonstrate experimentally that the incident radiation, coupled with such a non-Hermitian thin film, is unidirectionally trapped into a planar mode of the film, does not escape from the film (or escape weakly due to experimental imperfections), and is efficiently absorbed there.

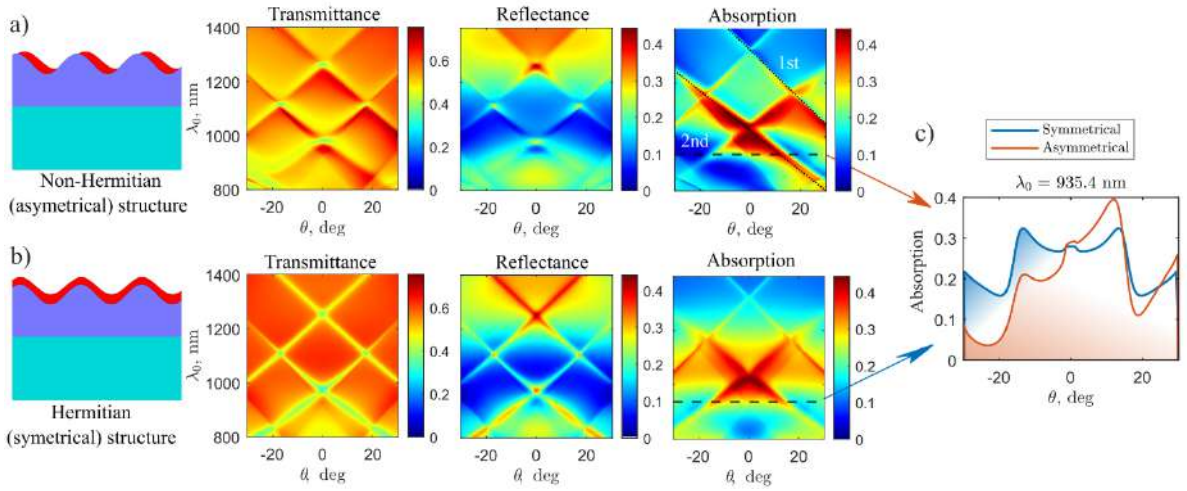

Figure 1. a) Non-Hermitian planar waveguide, with periodically modulated surface and the absorbing layer (red color) followed by the transmittance, reflectance and indirectly calculated absorption maps, b) the reference configuration with uniformly distributed absorber along the modulated planar structure with transmission, reflection and absorption maps; c) The calculated angular absorption profiles for the scheme with asymmetrically (red) and symmetrically (blue) distributed losses (cross-sections of absorption maps for the fixed wavelength of 935.4 nm).

We design the structure by analytic estimations and numerical simulations (Fig.1); we fabricate the structure by physical vapor deposition (titanium dioxide - TiO_2) on nanostructured substrates, and nonuniformly deposit the absorber by magnetron sputtering with the glancing angle method (nickel - Ni); we record the angular transmission/reflection profiles, and we reconstruct angle – asymmetric absorption map. Asymmetric absorption (asymmetry factor 2) is mediated by the left-/right-propagating waveguiding modes of the thin film, in good correspondence with the theoretical estimations, Fig.1. Finally, we prove the asymmetric absorption by photo-thermal measurements (measuring the increase of the temperature of the sample depending on the angle of illumination) [1].

Disordered gain-loss coupled systems investigated by tracking Petermann factors upon applying continuous gradients.

H. Amyar[1],M. Besbes[1] and H. Benisty[1*],

[1]Laboratoire Charles-Fabry (LCF), Institut d'Optique Graduate School, Univ. Paris-Saclay, Palaiseau, France

[*]Corresponding author: henri.benisty@institutoptique.fr

Abstract: We study the advent of exceptional points in 2D disordered gain-loss systems. While disorder breaks them, a real-part gradient may restore their sharpness. We track this through the Petermann factor, providing a new kind of system's "signature". We explore whether specific subsystems are also diagnosed through more direct response analysis.

In disordered gain-loss systems, the balance between coupling and gain/loss that occurs in ideal 2-units gain-loss systems (N=2) is generally missing, so that genuine Exceptional Points (EPs) appear as smooth features. However, it is known that a proper detuning of the real-part of the Hamiltonian (the indices in the case of PT-symmetry in photonics) can "heal" the system and restore the characteristic EP singularities [1, 2].

We generalize this approach for an arbitrary multi-element system (from N=4 to 10 in our first studies), by imposing a spatial gradient, that affects the real part of the index of the j-th element according to $\Delta n_j = A_x x_j + A_y y_j$. The spirit is somehow analogous to imposing a Stark effect on cloud of interacting atoms immobilized in some matrix. Furthermore, our system is 2-dimensional, so that it rather resembles a bundle of fibers with arbitrary organization, albeit invariant in the third direction z for the time being.

To check the effect of this gradient on the "healing" of EPs, we monitor both the variation of the eigenvalues and the Petermann factor (or a synthetic version thereof, to account for all modes). This latter factor is a safer indication that we go through an EP. It directly reports on the maximal non-hermitic "signal" at the singular EP, whereas finding a "steep slope" of eigenvalues is a fuzzier assessment of an EP.

We compare the results of a toy mode (coupled mode theory, thus only NxN matrices are involved) and of a finite-element simulation capitalizing on the SimPhotonics Matlab Toolbox[3], using typical index values of waveguides that provide confinement and evanescent waves in tractable proportions (n=1.7 for cylindrical core waveguides, in a n=1.5 matrix). Typical results are shown in Fig.1.

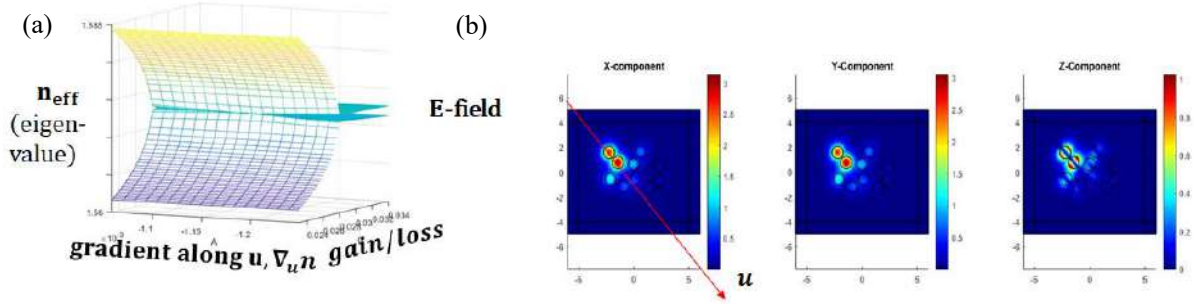

Fig.1 (a) Real part of effective index vs the gain-loss parameter *g* and the gradient *A* along *u* direction; (b) the X,Y,Z vector components of the E-field eigenmode in the *x,y* plane, at the EP. Black circles are the ten waveguides, identical before applying the gradient. The EP mostly stems from the top-left waveguide pair.

By probing the effect of a gradient in any direction, a kind of "Resonance imaging" of the Petermann factor is made, in the gradient space. Examples for a simple N=4 case and a complex N=10 case calculated by a toy-model of coupled-mode theory is shown in Fig.2.

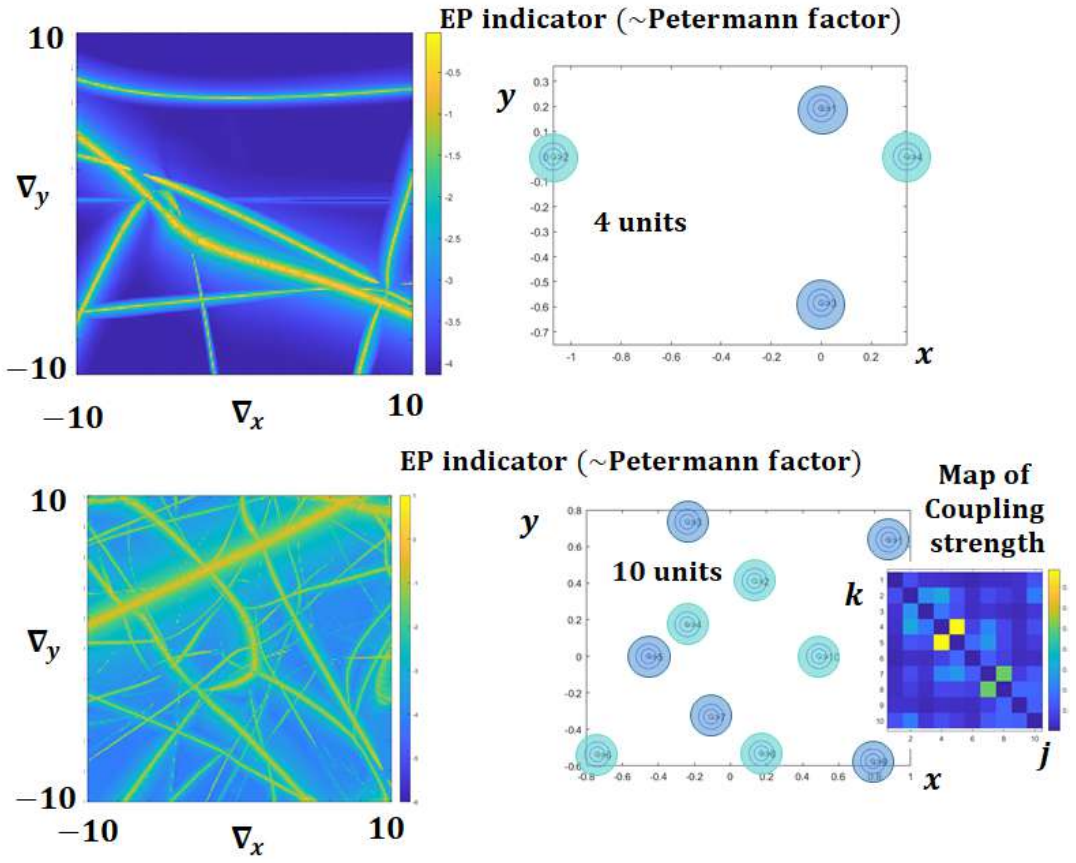

Fig.2 : Example of "gradient map" of EP indicator for a N=4 system (top) and an N=10 one (bottom) with two different bleu-green nuances for gain/loss. The coupling is distance-dependent, a map of their strength is indicated for the bottom case (inset to the right).

We will discuss the case of realistic models, and the use of the Petermann factor as the indicator. We also wish to discuss ways to visualize which vectors are involved in the large Petermann factor by adding noise and looking at the resulting perturbation.

This work was partially funded by the French Agence Nationale pour la Recherche (project "PARTISYMO", contract number N° ANR-18-CE24-0024).

Abstract: Interactions between relativistic particles are governed by causality, represented by spacetime light cones. However, the causal relations between interacting quasiparticles remains elusive despite their conical dispersions. By dynamically driving an acoustic analogue of charge density wave, we experimentally extend the causal structure to interacting Weyl quasiparticles in three-dimensional acoustic crystals.

Dynamics of relativistic particles is governed by the Dirac equation. The massless solution reduces to the Weyl equation that hosts conical dispersions, whose gradient being the speed of light. Although often described in the single-particle formalism, relativistic particles can also interact with each other, whose occurrence is determined by the causal relation in the theory of relativity. Spacetime light cones, alternatively, the speed of light, in turn determine the causal structure of interacting particles.

The Weyl equation has been extended to quasiparticle excitations, but finite separation in momentum space prohibits interactions between Weyl points. Originated from solid-state systems [1], a dynamical charge density wave (CDW) can lift the lattice translational symmetry, thus allowing Weyl points to interact out of equilibrium. While the dynamics of interacting Weyl points remains elusive upon general CDW driving, the causality inherent to interacting quasiparticles also remains unexplored despite hosting relativistic dispersions.

Analogous to spacetime light cones [Fig. 1(a)], Weyl quasiparticles have been theoretically proposed to host causal structure due to its conical dispersions in energy-momentum space, with group velocity as the gradient [2]. Based on the position of a Weyl point relative to the neighbouring Weyl cone, the causal structure can be determined [Fig. 1(b)], where interaction only happens in energy-like dispersion.

In this work, we report on the first experimental realization of the causal structure in a three-dimensional (3D) acoustic Weyl semimetal. We start from an acoustic Weyl semimetal [3, 4], whose unit cell depicted in Fig. 2(a). It consists of 3D printed solid resin with air in the remaining regions, where the rotation angle θ of the fan-like structure controls the transition between energy-like and momentum-like regions. By doubling the unit cell, an acoustic analogue of CDW interaction is then applied by rotating opposite angles in neighbouring layers.

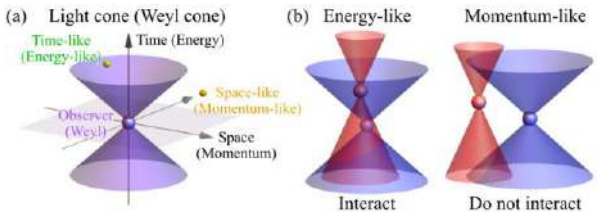

FIG. 1. (a) Causal structure of a Weyl cone is analogous to a spacetime light cone. Region within (outside) Weyl cone is named as energy-like (momentum-like) region. (b) Weyl cones in energy-like region interact, but Weyl cones in momentum-like region do not interact.

While hosting two Weyl cones along KH path [Fig. 2(b)], the bands are folded into the reduced Brillouin zone (BZ) upon unit cell doubling [Fig. 2(c)], exhibiting energy-like dispersion at θ = 35°. The causal structure takes effect by opening an energy gap upon the CDW interaction [Fig. 2(d)]. Reversely, the momentum-like dispersion (θ = 50°) is shown in Figs. 2(e)-2(f). By applying CDW, the gapless dispersion remains intact between the pair of Weyl points [Fig. 2(g)]. In the fabricated acoustic lattices [Fig. 3(a)], we also experimentally probe the causal structure by measuring the transmission in energy gap [Fig. 3(b)].

Our work provides an ideal platform to test causal connections in macroscopic classical wave systems. Based on the freedom to tune the energy-momentum separations between Weyl points, this acoustic demonstration also enriches the study of interactions between CDW-driven quasiparticles.

Intrinsic Non-Hermiticity in Photonic Floquet Topological Insulators with Genuine Temporal Modulation

J. Wang[1], H. Qin[1], Z. Zhang[1], and R. Fleury[1*]

Abstract: Photonic topological insulators (TIs), inspired by condensed matter TIs, exhibit intrinsic non-Hermitian properties due to the Maxwell equation's nature, particularly in Floquet TIs. This study peeks into these phenomena through a double-laced Floquet Su-Schrieffer-Heeger (SSH) model, revealing amplified and attenuated topological interface states via microwave experiments leveraging semiconductor varactors' nonlinearity.

Photonic topological insulators (TIs), as a successful analogue to TIs in condensed matter systems, have become a promising and prosperous topic. Following F. D. M. Haldane's pioneering proposal [1], a surge of publications in static photonic TIs has been witnessed during the past few decades, which are further furnished by non-Hermiticity and Floquet time modulation. Both non-Hermitian and Floquet TIs have been attracting research interest as indispensable branches of the photonic TIs' family tree. They enrich the underlying physics in equilibrium systems with more general non-equilibrium properties, opening avenues towards novel topologically protected states.

A remarkable nuance arises as one attempts to subsume photonic TIs into the established theoretical framework for condensed matter systems. Distinct from common senses in condensed matter physics, it has been noticed that the topological classification of photonic systems based on the Maxwell equation falls generically into a non-Hermitian context [2]. To clarify, a system subjected to the Schrödinger equation with Hamiltonian $H^\dagger \neq H$ is referred to as a non-Hermitian system here. While enclosing the Maxwell wave with the Schrödinger equation, Hermiticity is not naturally granted even in lossless materials as permittivity ϵ and permeability μ are not identical. A scaling proportional to $Z = \sqrt{\mu/\epsilon}$ of the field variables is required to preserve the Hermiticity of a system with fixed ϵ and μ. This conversely implies inevitable non-Hermiticity when Z varies either spatially or temporally, which has been validated in several previous publications [2,3]. Consequently, non-Hermitian TIs are possible to be realized in a Floquet manner, which is known as parametric instability in temporally modulated systems.

To capture this intrinsic non-Hermiticity in a Floquet TI, a double-laced Su-Schrieffer-Heeger (SSH) chain is employed as a phenomenological toy model. The lower and upper chain stand for the electric and magnetic field respectively, and couplings are exclusively present as mutual interactions between upper and lower sites (shown in Fig. 1(a)). Temporal modulations with staggered phase are introduced to the couplings from magnetic sites to electric sites, while those from electric sites to magnetic sites are fixed as constant. Following the analysis routine of Floquet TIs, we then evaluate the Floquet evolution operator over one period under open boundary condition (OBC), as well as the micromotion operator within one period under periodic boundary condition (PBC) to obtain the phase diagram (see Fig. 1(b)). As expected, topologically protected edge states possessing non-unitary eigenvalues appear, signifying temporally amplified or attenuated behavior (see Fig. 1(c)). The emergence of such states can be interpreted from the phase diagram [4] (see Fig. 1(b)). Unstable edge states are left in the gap

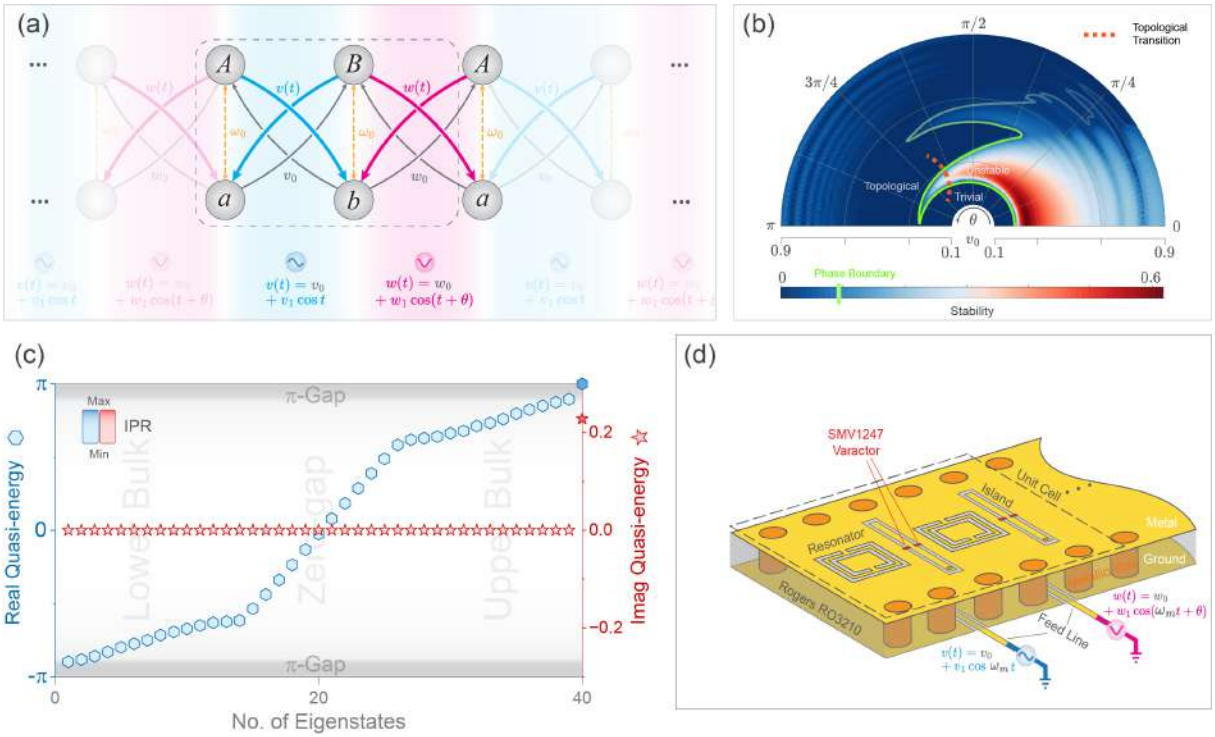

Figure 1: (a) The schematic of the double-laced Floquet Su-Schrieffer-Heeger (SSH) chain. (b) The phase diagram. (c) Eigenvalues calculated under the open boundary condition (OBC). (d) The experimental setup.

when topological phase transition and PT phase transition occur simultaneously.

Genuine temporal modulation is the key to experimental implementation, whereas a lot of previous publications focus on synthetic Floquet TIs. Leveraging the signal modulation capability of semiconductor varactors reported in Ref. [3], we designed a microwave platform aiming at working frequencies of several GHz (see Fig. 1(d)). A substrate integrated waveguide (SIW) and complementary split ring resonators (CSRRs) assist band structure engineering. Shunted with varactors SMV1247, slots separating every two CSRRs effectively modulate the electromagnetic coupling between them, leading to the topological unstable states we describe above.

Abstract: We introduce a new type of resonators defined solely by a geometrical phase. Topological boundary modes undergo an adiabatic evolution that gives rise to the geometrical phase of 360 deg. without propagation phase. This renders the resonance condition independent from its shape and length, which we confirmed by simulations and experiments.

Geometrical phases, originally introduced by Pancharatnam in optics [1], and generalized by Berry for quantum system [2], have been crucial for explaining a plethora of physical phenomena, from Foucault pendulum to polarization and phases of quantum matter [3]. Besides these purely fundamental interest, geometrical phases have recently attracted interest in a more applied context, including in metasurfaces, for redefining the fundamental laws of refraction [4], and controlling optical pseudo-spins [5].

In the context of resonators, evolution of the polarization state in Mobius strip-shaped ring resonators has been recently shown to alter resonant modes and shift them spectrally. Indeed, the addition of the geometrical phase ϕ_G to the propagation phase $\phi_P = \beta \cdot l$ accumulated in by the wave with the wavenumber β, twisted and bended into a ring of circumference l, yields a modified resonance condition $\phi_G + \phi_P = 2\pi N$, where N is the order of the resonance, which leads to the change of standing wave pattern and the spectral shift [6]. These exciting results allow one to envisage even more unusual resonances, which would not even require propagation and, while being spatially extended $l \neq 0$, would solely rely on the geometrical phase for the resonance to occur. This immediately imposes the following conditions: (i) vanishing propagation constant in such waveguides $\beta = 0$ and (ii) the net geometrical phase values of $\phi_G = 2\pi N$.

Here we demonstrate that both these conditions can be fulfilled in a topological photonic system emulating the Dirac physics and endowed with pseudospin degrees of freedom. We theoretically predict that two independent evolutions of the topological boundary modes in a 4-dimensional synthetic Hilbert space, both parametrized by the position withing the closed (ring-)resonator, give rise to the net geometrical phase of 2π. Numerical simulations and experimental observations in Fig. 1 unequivocally confirm our prediction. Moreover, our results confirm that, due to its purely geometrical nature, the resonance exhibits spectrally stability with respect to any deformations in resonator's shape and changes in its length.

Are lasing zero modes always topological?

M. Alizadeh [1], S. K. Ozdemir[1], A. M. Yacomotti,[2] and R. El-Ganainy [1]

[1]Department of Electrical and Computer Engineering, Saint Louis University, Saint Louis, MO 63103, USA

Abstract:- It is often implicitly assumed that lasing zero modes inherit the spectral and spatial properties of their linear counterparts—an assumption that overlooks the critical role of nonlinear interactions inherent in laser systems. Contrary to this belief, we demonstrate that the interplay between coupling rates, dissipation, and gain saturation nonlinearity in laser arrays can significantly alter the mode structure. In particular, these effects can delocalize otherwise well-confined linear topological states, signaling a breakdown of the conventional bulk-boundary correspondence in the nonlinear lasing regime.

The interplay between non-Hermitian and topological physics has attracted considerable attention recently. Among the natural physical systems where these two concepts can emerge is laser systems. In one dimension, topological lasers can be implemented in SSH array under alternating pumping profile under which the system respects particle-hole symmetry [1]. Experimental observation of such laser array has been reported using different material platforms [2-4]. A fundamental underlying assumption associated with topological lasers is that lasing zero modes inherit their properties from the corresponding linear array in the absence of nonlinear effects such as gain saturation. In other words, even after the inclusion of the nonlinear effects, it was assumed that the lasing zero mode still resembles the corresponding linear zero mode. Given the important role that nonlinear effects play in laser dynamics, it is not clear if and when this assumption is valid. This in turn begs the following question: do the zero modes of topological laser arrays always operate as intended?

In this work, we investigate this fundamental question. In particular, we study how the nonlinear gain saturation impacts the intensity profile associated with the zero lasing mode when the underlying linear array operates in the topological phase. The following matrix equation describes the evolution of the complex fields [5]:

$$\frac{da}{dt} = (G - i\Omega - D - i\kappa) \quad , \quad (1)$$

Where a is the vector describing the field amplitudes a_n in resonator n, and G is a diagonal matrix whose non-zero elements represent the intensity dependent gain. The matrices Ω and D are also diagonal with their elements given by $\Omega_{nn} = \omega_n$ and $D_{nn} = \gamma_n$, where ω_n and γ_n are the resonant frequency and loss coefficient of resonator n, respectively. Finally, the matrix κ encodes the information about the coupling profile between the various elements of the laser arrays. The configuration of the SSH laser array is shown in figure 1.

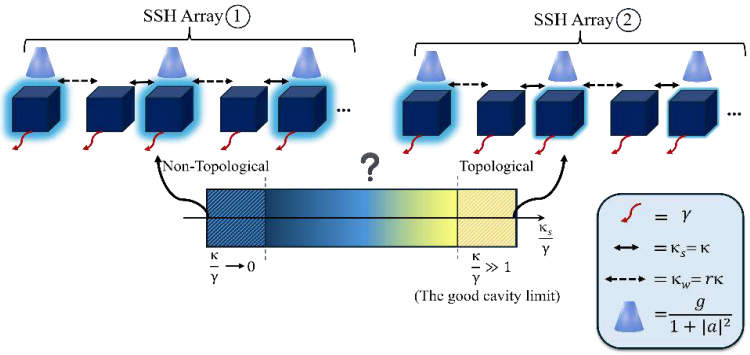

FIG. 1. Schematic of the SSH laser arrays in two extreme cases: (1) when $\kappa/\gamma \to 0$ featuring nearly decoupled elements; and (2) $\kappa/\gamma >> 1$ The pumping scheme and design parameters are also explained on the figure.

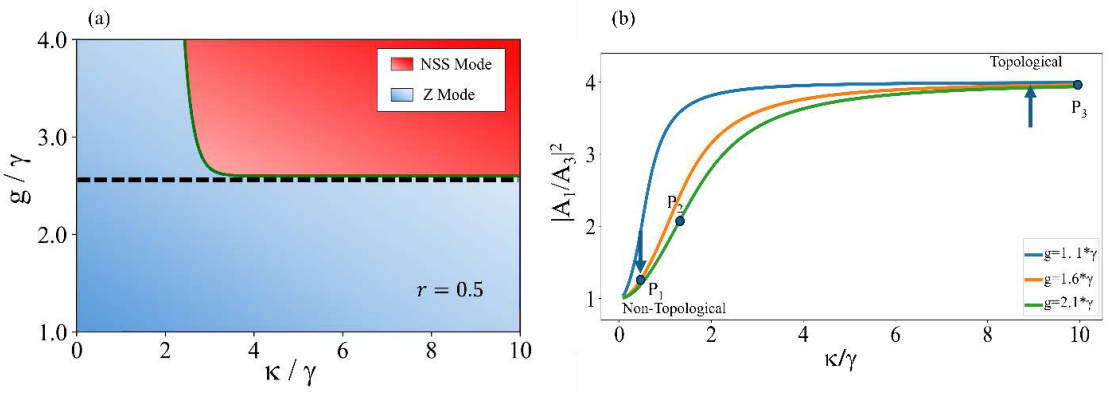

FIG. 2. Panel (a) plot the stability phases of the SSH laser array studied in this work. Two operating regions are shown: Zero Mode (Z Mode) and Non-Steady-State Mode (NSS Mode). (b) The intensity ratio plot of the SSH array for three different gain values, showing three different working regimes: 1 – Non-Topological, 2 – Transient, and 3 – Topological.

Figure 2 (a) depicts the stability diagram for an SSH laser array similar to that in Fig.1 but made of seven elements. As shown in the figure, the system operates in the steady-state zero-mode regime only when the gain below a certain threshold defined by the dashed black line. Figure 2(b) plots the ratio between the intensity in the third and first cavity of stable zero modes as a function of κ/γ (see Fig1 for the definition κ) of for three different values of the gain. For relatively small values κ/γ, the laser elements act as decoupled cavities, and the intensity ratios across the pumped sites remain nearly uniform, deviating from the expected linear topological profile. As κ/γ increases, the system enters a transient regime whose width is influenced by the gain level — higher gain leads to stronger nonlinear effects and a broader transition region. For $\kappa/\gamma \gg 1$, the system reaches a topological regime.

These results highlight that the nonlinear SSH laser array cannot be inherently classified as topological, contrary to common assumptions in the literature. Our study shows that lasing zero modes do not always inherit the spatial structure of their linear counterparts. Specifically, even when the linear zero mode is localized, nonlinear gain saturation can lead to a delocalized lasing mode with nearly equal intensities across the pumped sites. In essence, gain-induced nonlinearity can disrupt the bulk-boundary correspondence—even when it holds in the linear, non-Hermitian limit.

Non-Hermitian topology solely from optical loss modulation

A. Hashemi[1], E. L. Pereira[2], H. Li [3], J. L. Lado[2] and A. Blanco-Redondo[1*]

Abstract: We report the observation of topology arising solely from optical loss modulation. Specifically, we implement a non-Hermitian generalization of the Aubry-André-Harper model in a programmable integrated photonics platform, where the loss of each element can be controlled precisely, showing that loss modulation, alone, can be create topology in photonic systems.

The last decade has seen a flurry of research in non-Hermitian topological photonics [1], revealing exotic symmetries, such as that of parity-time [2], with no analogous in Hermitian systems, and enabling impactful applications such as topological lasers and sensors . All experiments to date have relied on the introduction of loss and/or gain in systems that were already topological in their Hermitian version [3], or have used gain in an indirect way to engineer the coupling of a Hermitian (closed) system [4]. In 2018, Takata and Notomi proposed that topological phases could potentially arise solely from gain and loss modulation [5], but an experimental proof of this had remained elusive due to the difficulty of accurately controlling loss in optical platforms. Here, we experimentally demonstrate that topology can arise exclusively from loss modulation in a photonic system that is non-topological in the absence of loss modulation [6].

Our experimental platform is a programmable hexagonal mesh of silicon photonics Mach-Zehnder interferometers, as shown in Fig. 1(a). In 2024, we demonstrated that this platform can be used to implement Hermitian topological Hamiltonians, thanks to its possibility of being reconfigured into arrays of coupled ring resonators with tunable ring-to-ring couplings and resonant frequencies [7]. Here, we show that the imaginary part of the onsite potential of the rings, i.e. the loss, can also be accurately controlled [6]. We use this newly discovered capability to implement a non-Hermitian generalization of the Aubry-André-Harper model, theoretically discussed in [8], where the rings are uniformly coupled, while exhibiting sinusoidal onsite loss modulation, leading to the following effective Hamiltonian:

$$H = \sum_{n=0}^{N-2} \left(t\hat{a}_n^\dagger \hat{a}_{n+1} + h.c. \right) \in i \sum_{n=0}^{N-1} \left[v_1 + v_2 \sin\left(2\pi n\alpha + \delta\right) \right] \hat{a}_n^\dagger \hat{a}_n, \tag{1}$$

where $\hat{a}_n^\dagger$ and $\hat{a}_n$ are creation and annihilation operators in site n, t is the coupling between neighboring sites, α is the inverse of the loss modulation period, δ represents the modulation phase, v_2 is the amplitude of the modulation, and v_1 is a uniform loss introduced to compensate the gain induced by sinusoidal gain/loss modulation.

Figure 1(a) shows a commensurate configuration of this model, with a modulation period a modulation period of $1/\alpha = 4$ and a phase parameter $\delta = 3\pi/4$, where the periodicity of the sinusoidal loss function – indicated by the dashed black line in Fig.1(b) – aligns with the lattice periodicity. Incommensurate cases have also been demonstrated [6]. This system's eigenfrequencies are shown by the dot markers in Fig.1(c), where the edge (bulk) states are highlighted in red

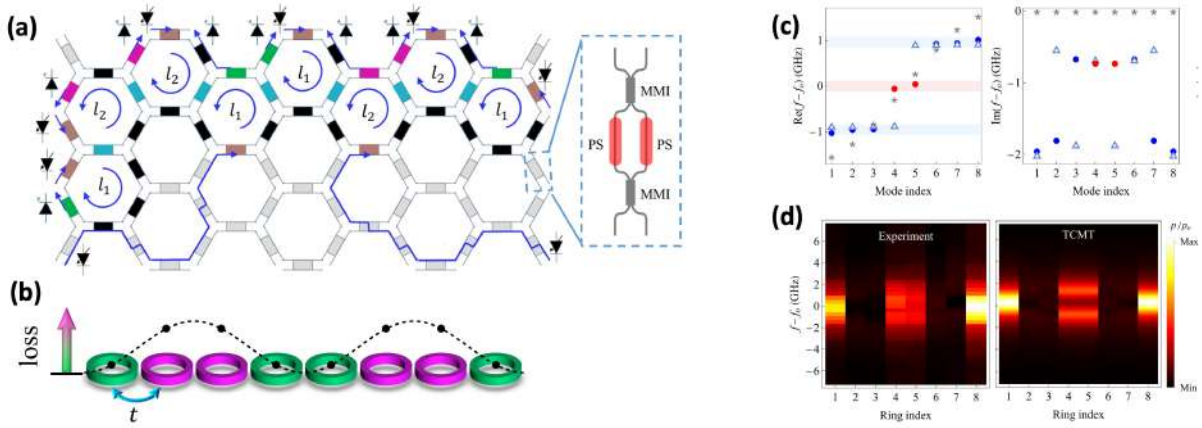

Figure 1: (a) Programmable integrated photonics platform. (b) Implemented loss modulation. (c) Eigenfrequencies. (d) Measured (left) and simulated (right) local density of states.

(blue). For contrast, Fig.1(c) also shows the eigenfrequencies of a trivial system, devoid of loss modulation (asterisks) and a similar conmensurate configuration where the phase parameter δ is chosen so that the arrangement does not support any edge mode. The experimentally measured local density of states (LDOS) spectrum is presented in the left panel of Fig.1(c), showing good matching with the temporal coupled mode theory (TCMT) simulations. For excitation frequencies matching the eigenfrequency of the edge modes the LDOS spectrum exhibits pronounced intensity localization at the chain's edges, a signature of the presence of edge states. These results highlight the appearance of topological edge states solely from loss modulation.

Use of Complex Time Delay to Control Propagation Through Generic Non-Hermitian Scattering Systems

Isabella Giovannelli[1], Nadav Shaibe[1], Jared Erb[1], Thomas M. Antonsen[1], and Steven M. Anlage[1*]

[1] Physics Department, University of Maryland, College Park, MD 20742-4111 USA

Abstract: We establish the physical meaning of the imaginary part of complex time delay through experiments. We find universal statistics for complex time delay and utilize its divergences to identify a large variety of scattering singularities, including new ones that we create with our microwave graph and billiard experiments.

The scattering matrix S linearly relates the vector of incoming waves to outgoing wave excitations, and contains an enormous amount of information about the scattering system and its connections to the scattering channels. Time delay is one way to extract information from S, and the transmission time delay τ_T is a complex (even for Hermitian systems with unitary scattering matrices) measure of how long a wave excitation lingers before being transmitted [1,2]. The real part of τ_T is a well-studied quantity, but the imaginary part of τ_T has not been systematically examined experimentally, and theoretical predictions for its behavior have not been tested. Here we experimentally test the predictions of Asano, *et al*. [3] for the imaginary part of transmission time delay in a non-unitary scattering system. We utilize Gaussian time-domain pulses scattering from a 2-port microwave graph [2] supporting a series of well-isolated absorptive modes to show that the carrier frequency of the pulses is changed in the scattering process by an amount in agreement with the imaginary part of the independently determined complex transmission time delay, $\mathrm{Im}[\tau_T]$, from frequency-domain measurements of the sub-unitary S matrix [4]. Our results also generalize and extend those of Asano, *et al*., establishing a means to predict pulse propagation properties of non-Hermitian systems over a broad range of conditions.

From the experimentally measured multi-port scattering (S)-matrices of one-dimensional graphs, a two-dimensional billiard, and a three-dimensional cavity, we calculate the complex Wigner-Smith, as well as each individual reflection and transmission time-delays. The complex reflection time-delay differences between each port are calculated, [2] and the transmission time-delay differences are introduced for systems exhibiting non-reciprocal scattering [5]. Large time-delays are associated with scattering singularities such as coherent perfect absorption, reflectionless scattering, slow light, and uni-directional invisibility. We demonstrate that the large-delay tails of the distributions of the real and imaginary parts of each time-delay quantity are superuniversal, independent of experimental parameters: wave propagation dimension D, number of scattering channels M, Dyson symmetry class β, and uniform attenuation η [5]. The tails determine the abundance of the singularities in generic scattering systems, and the superuniversality is in direct contrast with the well-established statistics of unitary systems, where the distribution tail depends explicitly on the values of M and β. We relate the statistics to the topological properties of the corresponding singularities [5-9]. Although the results presented here are based on classical microwave experiments, they are applicable to any non-Hermitian wave-chaotic scattering system in the short-wavelength limit, such as optical or acoustic resonators.

Fock space skin effects in many-body systems

Masatoshi Sato

Yukawa Institute for Theoretical Physics, Kyoto University
msato@yukawa.kyoto-u.ac.jp

Abstract: Non-Hermiticity enables macroscopic accumulation of bulk states, named non-Hermitian skin effects. The non-Hermitian skin effects are well-established for single-particle systems, but their proper characterization for general systems is elusive. In this talk, I will discuss a general criterion of non-Hermitian skin effects, which works for any finite-dimensional system evolved by a linear operator. The applicable systems include many-body systems and network systems. A system meeting the criterion exhibits enhanced non-normality of the evolution operator, accompanied by exceptional characteristics intrinsic to non-Hermitian systems. Applying the criterion, I will argue a new type of non-Hermitian skin effect in many-body systems, the Fock space skin effect. I also discuss the Fock space skin effect-induced slow dynamics, which gives an experimental signal for the Fock space skin effect.

Abstract: We propose and experimentally realize quantum walks of two indistinguishable photons in engineered non-Hermitian photonic lattices. We have successfully observed the unidirectional behavior of quantum walks caused by the skin effect. Moreover, we reveal the suppression of entanglement that is caused by the skin effect in non-Hermitian systems.

Entanglement entropy characterizes the correlation of multiparticles and unveils the crucial features of open quantum systems. However, the experimental realization of exploring entanglement in non-Hermitian systems remains a challenge. In parallel, quantum walks have offered the possibility of studying the underlying mechanisms of non-Hermitian physics, which includes exceptional points, the non-Hermitian skin effect, and non-Bloch phase transitions. Unfortunately, these studies have only involved and prevailingly focused on the behavior of a single particle.

(a) The structured one-dimensional non-Hermitian lattice and Rényi entanglement entropy. (b) The designed system consists of an array of identical straight waveguides, with the auxiliary waveguide in the middle controlling their coupling. R is the Floquet radius, ϕ is the geometric phase, T is the period length, and the z axis indicates the propagation direction of waveguides. On the right is the schematic of effective coupling and dissipations. (c), (e) The asymmetric case and the symmetric case. (d) The relevance of the Lyapunov exponent to the geometric phase ϕ. (f) Rényi entropy calculated from the effective Hamiltonian and the master equation (solid lines). The corresponding results after the similarity transformation with GBZ are shown by the dashed lines. (g) The GBZ derived from the effective Hamiltonian.

In this work, we propose the use of silicon-on-insulator (SOI) technology to construct a non-Hermitian system comprising silicon waveguide arrays that can manipulate non-Bloch behavior. To exhibit the non-Hermitian feature of this engineered photonic lattice, we first experimentally realize quantum walks of single photons and observe the unique non-Hermitian evolution behavior of the wave dynamics of single photons in the bulk far from the edge. Crucially, we next study the quantum walks of two indistinguishable photons in the bulk and reveal the impact of non-Hermitian properties on the dynamics of quantum correlations. We finally explore the suppression of entanglement entropy of correlated photons in non-Hermitian systems and demonstrate that the nature of non-Hermicity plays a central role in entanglement evolution, which has been verified both experimentally and theoretically.

Abstract: This work establishes criteria for algebraic skin effect (ASE) in 2D reciprocal non-Hermitian metamaterials, demonstrating power-law decay via anisotropic optical axes and geometry. A photonic crystal design validates ASE's quasi-long-range interactions, revealed through impurity-induced spectral/dynamic responses. The framework can be extended to 3D systems and classical waves.

Metamaterials have unlocked unprecedented control over light by leveraging novel mechanisms to expand their functionality. Non-Hermitian physics further enhances the tunability of non-Hermitian metamaterials (NHMs) through phenomena such as the non-Hermitian skin effect (NHSE), enabling applications like directional amplification. The higher-dimensional NHSE manifests unique effects, including the algebraic skin effect (ASE), which features power-law decay instead of exponential localization, allowing for quasi-long-range interactions. In this work, we establish apparent criteria for achieving ASE in two-dimensional reciprocal NHMs with anisotropic and complex dielectric tensors. By numerically and theoretically demonstrating ASE through mismatched optical axes and geometric structures, we reveal that ASE is governed by a generalized Fermi surface whose dimensionality exceeds that of the Fermi surface. We then propose and validate a realistic photonic crystal design for ASE, which is experimentally accessible. Two infinitesimal impurities at the NHM boundary have further been introduced to demonstrate the quasi-long-range interaction nature of ASE from both the spectra and dynamics. Our recipe for ASE provides a versatile pathway for broader generalizations, including three-dimensional structures, synthetic dimensions, and other classical wave systems, paving the way for advancements in non-Hermitian photonics.

Reflectionless transient excitation in complex media

Abstract: Reflectionless states corresponding to the zeroes of the reflection matrix enable reflectionless coupling of waves to a scattering sample. Here, we present a matrix approach to identifying these zeroes and determining the corresponding spatio-temporal input wavefronts. Theoretical results are verified experimentally in the microwave range within disordered multi-channel cavities.

In recent years, significant progress has been made in controlling the spatial and/or temporal shape of waves propagating through disordered scattering media. In particular, reflectionless excitation of a structure with monochromatic waves is possible when a zero of the reflection matrix lies on the real axis. This is for instance the case of coherent perfect absorption, a surprising interference phenomenon for which the incident radiations are fully absorbed within a lossy medium, or perfect transmission of waves. However, even a complex zero can be engaged by modulating the input wavefront in both space and time [1]. For a complex zero z_n of the reflection matrix, reflection is suppressed within the excitation interval for an excitation being a monochromatic signal at frequency $\mathrm{Re}[z_n]$ modulated with an exponentially increasing envelope at the rate $\mathrm{Im}[z_n]$ [1]. When the incident signal is interrupted, the energy accumulated within the medium leaks out through the channels. This concept of virtual perfect absorption is a promising concept for energy storage, sensing and transient application of optical forces. However, identifying the input wavefronts giving reflectionless transient excitation in disordered samples has remained a challenge, especially in the regime of overlapping resonances.

In this talk, we present a general approach based on a multispectral transport matrix, which fill this gap [2]. We demonstrate that a judicious singular value decomposition of this matrix enables optimal spatiotemporal wavefront shaping for arbitrary wave-control functionalities. Using measurement of the transport matrix, $\mathcal{H}(\nu)$, with the frequency ν, describing the linear relationship between N incoming channels, $x(\nu)$, and M outgoing channels, $y(\nu)$, $y(\nu) = \mathcal{H}(\nu)x(\nu)$, we extend the monochromatic input-output relationship to the time domain on both input and output sides via a discrete Fourier transform (DFT). We obtain a unified linear relationship between the spatiotemporal input and output wavefronts $x(t)$ and $y(t)$ as $y(t) = Hx(t)$, where H is the multi-channel multispectral operator, linking the spatial and temporal DoFs of a coherent input wavefront to those of the corresponding output wavefront. Using a singular value decomposition of H, we identify the spatio-temporal input wavefronts corresponding to reflectionless within the excitation interval.

Theoretical results are verified within a disordered quasi-2D electromagnetic cavity shown in Fig. 1(a) operating at a frequency range between 8 and 9 GHz. The channels are coax-to-waveguide transitions. In order to inject spatio-temporally sculpted signals in situ, we generate baseband signals between 0 and 1 GHz on an FPGA board at a sampling rate of 4 GS/s that are then analogically upconverted in the frequency range 8-9 GHz. We coherently record the spatio-temporal output signals with an ultra-wideband multi-channel oscilloscope using a sampling rate of 40 GS/s.

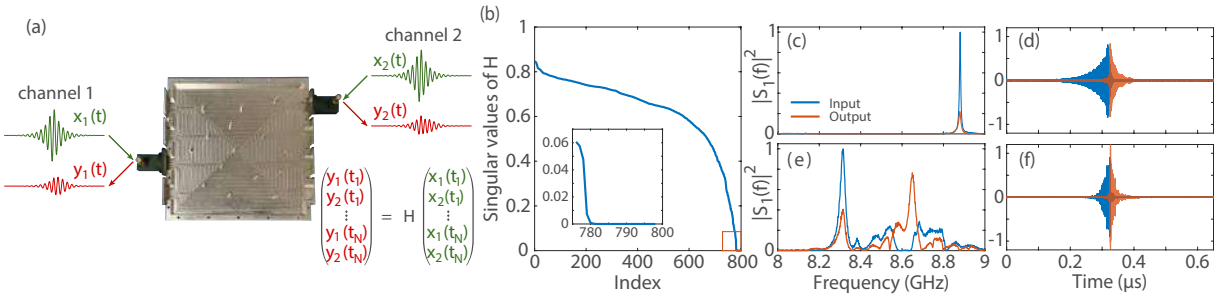

Figure 1: (a) Photographic image of our quasi-2D disordered cavity ($L = W = 205.74$ mm, $h = 10.16$ mm) with the top plate removed to show the inside. One coax-to-waveguide transition is attached at each side of the cavity, yielding a two-channel scattering system. The inset illustrates our spatio-temporal matrix formalism. (b) Singular value spectrum of H. (c-f) Experimentally measured output signals upon coherent spatio-temporal in situ injection of 2 different right singular vectors of H associated with near-zero singular values. For each considered state, we display the injected (blue) and outcoming (red) time-varying signals on the left channels (d,f), as well as the corresponding signal spectra averaged over both channels (c,e).

We display on Fig. 1(b) the singular value (SV) spectrum of H for the particular choice of the same input and output temporal intervals. We can observe that the largest SV, $\lambda_1 = 0.81$, remains below unity due to the inevitable presence of absorption in our experimental setup while multiple of the smallest SVs of H are extremely close to zero. This demonstrates that in the transient regime, the reflected signal intensity can be suppressed very efficiently. We experimentally validate our approach by injecting *in situ* these states. We observe in Fig. 1(c-e) that our approach identifies two types of VPA states: input wavefronts corresponding to either isolated or multiple zeroes. In both cases, the reflection from the sample is extremely small during the excitation time - Fig. 1(d-f) - while the energy is released once the excitation is stopped.

Beyond reflectionless states, our formalism more generally enables optimal spatiotemporal control of output waves. We will also present the possibility of delivering the maximum possible amount of energy within a time interval. Finally, we explore the possibility of exciting states that have the same spatial and temporal input and output patterns, generalizing the recent concept of time-harmonic (monochromatic) scattering-invariant states [3] from the harmonic regime to the time-varying regime.

Abstract: We present a noninvasive matrix approach enabling detection and focusing on any nonlinear target embedded within a complex medium. By measuring a reflection matrix for two different incident powers, the local perturbation induced by the nonlinearity is used to identify the spatio-temporal incident wavefronts focusing on the target.

Controlling wave interactions in inhomogeneous media presents a significant challenge with applications spanning optical and acoustic imaging, wireless communications, wireless power transfer, and sensing [1]. In multiple scattering media, waves experience strong attenuation, making it particularly difficult to deliver energy deep within disordered environments. While wavefront shaping techniques can help mitigate the effects of disorder, their effectiveness relies on feedback mechanisms to precisely tailor the incident wavefront in space or time. To avoid invasive manipulation of the environment for field measurements, recent approaches have emerged that rely on slight perturbations of the medium [2]. Any internal change within a disordered sample is inherently encoded in the random speckle pattern generated by the complex interaction between the incident wave and the medium. Motion or local alterations in the target's scattering properties can thus act as a guidestar for optimal wavefront shaping.

In this work, we present a novel noninvasive method for detecting and focusing on electronic devices by leveraging their nonlinear response [3]. This approach (i) operates in the monochromatic regime and (ii) remains independent of the specific type of nonlinearity. Furthermore, our approach eliminates the need to measure the target device's higher harmonic response or any other frequency-shifted signal. It also does not require any prior knowledge on the medium or on the target. Specifically, we demonstrate the ability to focus a wave on a target embedded within a complex two-dimensional environment and show that programmable environments can enhance the intensity received by the target at a single frequency.

More precisely, we show theoretically that a singular value decomposition of the difference matrix $\Delta S = S^{\alpha+d\alpha} \in S^{\alpha+d\alpha}$ found from measurement of the scattering matrix S at two input powers α and $\alpha + d\alpha$ is equal to the number of point-like nonlinearities with the singular vectors identifying the input wavefront for maximal focusing on the non-linear target. We then verify experimentally the theoretical results using a two-dimensional scattering system working in the microwave range in which a nonlinear target is embedded. The target first consists of a high-Q dielectric cylinder coupled in its near field to a wire antenna connected to a low-noise amplifier. We show that at the resonance of the dielectric cylinder, a strong enhancement of the intensity at the target's position is observed for an input wavefront determined from ΔS. We then extend our results to the time-domain and demonstrate spatio-temporal focusing on the non-linearity. Finally, the non-linear element is embedded within a three-dimensional multichannel enclosure made programmable using reconfigurable intelligent surfaces. We rely on an optimization of these metasurfaces to enhance the signal on the non-linearity.

Figure 1: (a) Photograph of the experimental setup. A (nonlinear) low-noise amplifier is coupled to a resonant dielectric cylinder through a wire antenna. The scattering matrix is measured using seven antennas at the left interface. (b) Intensity map within the system around the target for an optimized illumination.

Our monochromatic technique is broadly applicable, enabling spatio-temporal focusing on nonlinear targets and working for any type of nonlinearity, even when the specific response is unknown. Our approach applies to various wave phenomena, offering potential applications in wireless power transfer, bioelectronics, and enhancing Wi-Fi signal focusing on smartphones in complex environments.

Correlation between topological effects in photonic crystal slabs: a theoretical and experimental exploration of BIC, Weyl points and Fermi arcs

Karen Caicedo, Silvia Romano, Gianluigi Zito, Ivo Rendina and Vito Mocella*

Abstract: We present a theoretical-experimental framework that reveals how bound states in the continuum, Weyl points and Fermi arcs are connected in photonic crystal slabs. A novel setup allowing high-precision equi-frequency surface measurements confirms these topological phenomena and their far-field polarisation singularities, enabling robust device designs for optical communication and quantum technologies.

The correlation between bound states in the continuum (BICs), Weyl points and topology in photonic systems represents a new frontier in solid-state physics; however, the experimental characterisation of these connections remains incomplete. Here, we present a novel theoretical model that establishes a correlation between photonic BICs, Fermi arcs, Weyl points and singularities in far-field radiation, validating it through high-precision experimental measurements of equi-frequency surfaces (EFSs) in photonic crystal slab (PhCs).

Notably, and in contrast to previous approaches [1-3], our theoretical framework does not require in-plane symmetry breaking of the PhCs yet it shows excellent agreement with high-precision measurements of the EFS.

By studying iso-frequency surfaces—the photonic analogs of electronic Fermi surfaces—we gain key insights into the topological properties of far-field polarization states. These surfaces reveal how the geometry of momentum space underpins the emergence of topological charges, which govern polarization singularities in the far-field radiation pattern. This effect is especially prominent in PhCs supporting BICs, where small deviations near the Γ-point can dramatically alter topological charge distributions and the resulting polarization singularities.

Remarkably, our measurements demonstrate that Fermi arcs connect C-points located at Weyl points, which are strongly tied to photonic BICs viewed as real eigenstates in a non-Hermitian system (Figure 1).

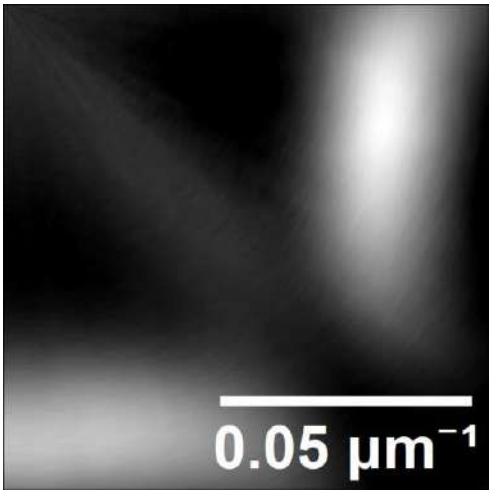

Figure 1. An open EFS measured at a wavelength of 534 nm near the Γ-point, located in the upper left corner, corresponds to Fermi arcs.

Even without any material or structural chirality, we observe chiral behavior in the far-field transmitted field around the BIC condition for both positive and negative angles with respect to the Γ-point—an unambiguous signature of the presence of a Weyl point. These findings advance our fundamental understanding of topological photonic phenomena and highlight the robustness of BICs under varying symmetry conditions. In addition, the capability of precise characterisation of EFS, particularly near the Γ point, provides new tools for designing photonic devices with controllable topological properties and potential applications in optical communications and quantum computation.

Multi-order exceptional points in higher dimensions

A. A. Athanasopoulos[1,2] D. Kaltsas[1] K. G. Makris[1,2]
[1]ITCP-Physics Department, University of Crete, Heraklion, 71003, Greece

Abstract: We introduce a new class of Multi-order Exceptional Points (MoEPs) in 2D and 3D non-Hermitian systems. These MoEPs are Higher-order Exceptional Points (HEPs) coexisting at the same gain-loss parameter. We analyze their ultra-sensitivity using pseudospectra, highlighting their potential applications in precision sensing for optical systems.

Actual physical systems are always subject to external perturbations due to coupling to the environment, and that is why non-Hermitian (NH) Hamiltonians are widely used in many areas of physics. Quite intriguing are the parity-time ($\mathcal{PT}$) symmetric optical systems, like coupled optical waveguides, which under specific conditions, reveal fascinating characteristics like the Exceptional Points (EPs). It has been recently shown experimentally [1], that near these points, the system's sensitivity is enhanced, since the system's first order response to a perturbation "ε" exhibits a nonlinear dependence. EPs in one-dimensional lattices have been extensively studied, both in theoretical and experimental level [2, 3]. In our work, we present a direct method to generate multiple and higher order exceptional points in two- and three-dimensions, based on Kronecker sums of the corresponding one-dimensional lattices, that already exhibit EPs.

Multi-order exceptional points arise when a system hosts multiple exceptional points of different orders. This can be achieved by applying the Kronecker sum to two nilpotent sublattices, each containing at least one exceptional point. This is happening because if we apply the Kronecker sum on two matrices that represent different one dimensional systems, we get a matrix which effectively describes a two dimensional system. Based on our findings, when combining matrices associated with exceptional points of orders N_1 and N_2, the resulting system exhibits higher-order exceptional points with orders ranging from $|N_1 \in N_2| + 1$ to $N_1 + N_2 \in 1$, with an increasing increment of two. This idea extends to higher dimensions as well—for instance, applying the Kronecker sum to three nilpotent matrices results in a system with multiple and higher EPs in three dimensions.

In order to elucidate our method, let us consider the matrix $\mathcal{H}_{2,3}$ as the Kronecker sum of $\mathcal{H}_2$ and $\mathcal{H}_3$ matrices, which exhibit second- and third-order exceptional points, respectively. These matrices could model one-dimensional configurations consisting of two and three coupled optical waveguides. The couplings along the x-direction depend solely on the original matrix $\mathcal{H}_3$, while the couplings along the y-direction are determined by $\mathcal{H}_2$. The onsite potentials are a combination of those from both $\mathcal{H}_2$ and $\mathcal{H}_3$. The corresponding schematic representation of the lattice described by $\mathcal{H}_{2,3}$ is shown in the left panel of Fig. 1. In our case, summing matrices with an EP2 and an EP3 produces multi-order exceptional point of orders two and four.

To characterize, the sensitivity of the system to external perturbations, we calculate the associated pseudospectra of $\mathcal{H}_{2,3}$, defined as: $\sigma_\varepsilon(\mathcal{H}_{2,3}) = \quad \mathrm{z} \quad \mathbb{C}, \mathrm{z} \quad \sigma(\mathcal{H}_{2,3} + V)$ with $||V|| \leq \varepsilon$, with $\sigma(M)$ denoting the eigenvalues of matrix M [5]. For instance, under a small perturbation ($\varepsilon = 10^{-3}$), two distinct clouds emerge; differing in size and reflecting the presence of two exceptional points of different orders (Fig. 1 middle panel). This is happening because, to first

order approximation the response of the system to a perturbation ε is proportional to: $\varepsilon^{-1/n}$, with n being the order of the corresponding EP. This response is closely tied to the system's dynamics, in the $\mathcal{PT}$ unbroken regime ($g < g_{crit} = 1$). The power of the system is an oscillating function, with its behavior strongly dependent on the initial input (Fig. 1 right panel).

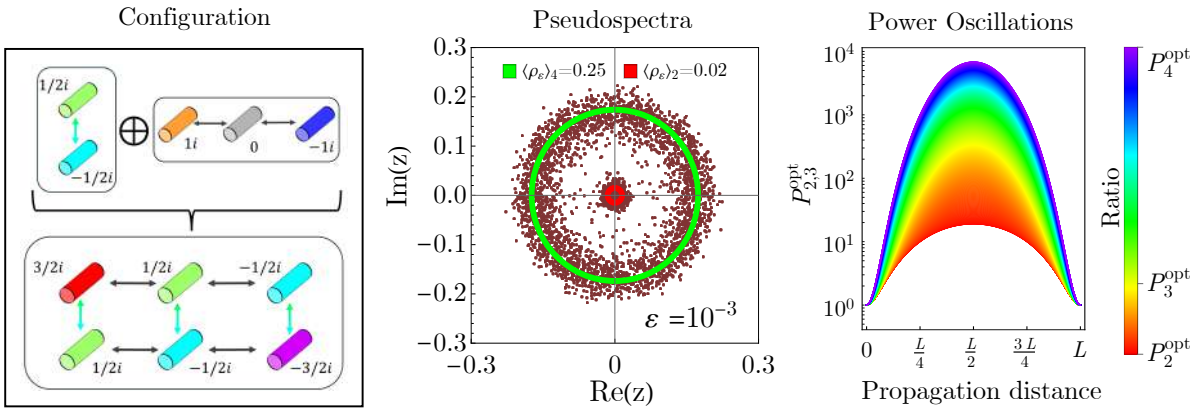

Figure 1: (Left) Schematic illustration of the Kronecker sum method with the $\mathcal{H}_{2,3}$ matrix. (Middle) Pseudospectrum in the complex plane of the $\mathcal{H}_{2,3}$ lattice. (Right) Power oscillations observed around the two exceptional points in the $\mathcal{PT}$ -unbroken regime, shown for various initial conditions.

In conclusion, in our work we present a new type of non-Hermitian singularities, the multi-order exceptional points and present a method to construct them in two- and three- dimensional lattices. The proposed geometries are experimentally relevant and are derived based on the Kronecker sum of two or three nilpotent matrices, each corresponding to a one-dimensional system. Remarkably, the MoEPs demonstrate significant sensitivity to external perturbations across various orders, highlighting their potential use for novel sensing applications.

Lasing and coherent perfect absorption beyond canonical PT-symmetry using electrically-injected DFB lasers with complex-coupled Bragg grating

Abstract: An analysis of lasing and coherent perfect absorption beyond canonical Parity-Time symmetry using internal emission of electrically-injected complex-coupled Bragg grating distributed feedback lasers a operated in a strong coherent feedback regime provided by an ultra-short micro-mirrors confined external cavities is reported.

The objective of this work is to investigate the behavior of complex-coupled distributed feedback (C-C DFB) lasers in a seemingly previously unexplored regime of very strong coherent feedback provided by an ultra-short micro-mirrors-defined external cavity. In our recent publication [1] we provided a proof-of-principle demonstration of Coherent Perfect Absorption (CPA) exploiting a C-C DFB laser's own internal emission reinjected from an ultra-short short external cavity mirror instead of the two beams of conventional CPA implementations. It is worth noting that the DFB lasers used in our work have an arbitrary facet termination, highly reflective outer mirrors, and an additional external cavity. Thus, this study goes well beyond canonical PT-symmetric systems such as the bare C-C DFB, but keeps in its nutshell the key feature that CPA and lasing behavior are based on the principle of constructive-destructive interference in a gain-loss modulated structure.

The results of our modeling study based on the threshold gain analysis of DFB laser poles are shown in Figure 1. As can be seen, the facet termination indeed has a strong impact on the threshold gain level of DFB lasers. However, there is a substantial difference between the threshold gain behavior observed in Fig. 1a for a metal Bragg grating DFB laser (shown in Fig. 1c) and that of a C-C DFB laser (Fig. 1b) with phased modulations of both dielectric and metal Bragg gratings (shown in Fig. 1d). Namely, the region delineated by the yellow color in Fig. 1b, which corresponds to the lower threshold gain areas, represents about 80% of the total parametric area. This should be compared to only about 50% of the total color map area corresponding to a similar gain level in the case of a metal grating DFB laser, as shown in Fig. 1a. This feature of C-C DFB lasers would result in a larger production yield of lasers with acceptable performances.

Furthermore, as we demonstrated in [1], ultra-short external-mirror-confined cavity-assisted C-C DFB lasers also exhibit higher spectral purity behavior than their metal grating DFB counterparts. To further compare the performances of C-C DFB lasers versus metal DFB lasers, we enhanced the aspects related to the impact of DFB laser facet termination by considering a configuration where the DFB lasers are confined at both ends with 95% external cavity reflection dielectric mirrors deposited on the cleaved fibers. The schematic of the experimental setup is shown in Figure 2a. Preliminary results regarding the variation of the emission power itself of DFB lasers with respect to the mirror position as a function of the piezoelectric actuator voltage, presented in Figures 2b and 2c for the metal and C-C DFB lasers, respectively, corroborate the trends of modeling predictions.

Notably, the ratio of the color map area corresponding to the lasing behavior (red region colors) is almost

twice as large for the C-C DFB laser compared to the DFB metal grating devices despite the latter operating at a higher injection current (40 mA vs. 30 mA for C-C DFB).

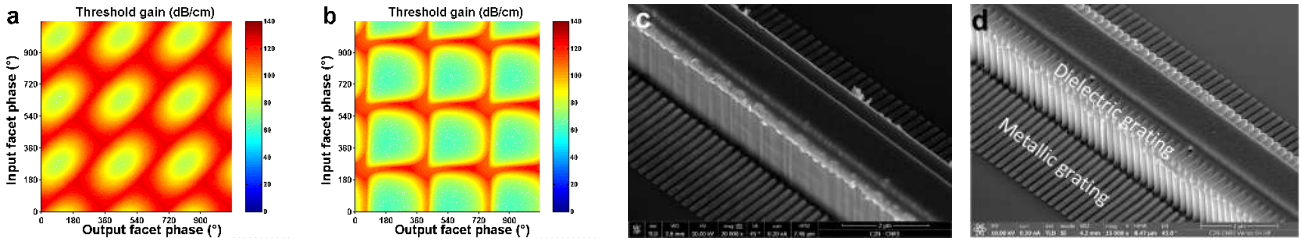

Figure 1: a) Color map showing variation of the threshold gain level as a function of input and output facets termination for metal Bragg grating DFB (a) and C-C DFB (b); SEM micrographs of metal Bragg grating DFB (c) and C-C DFB (d).

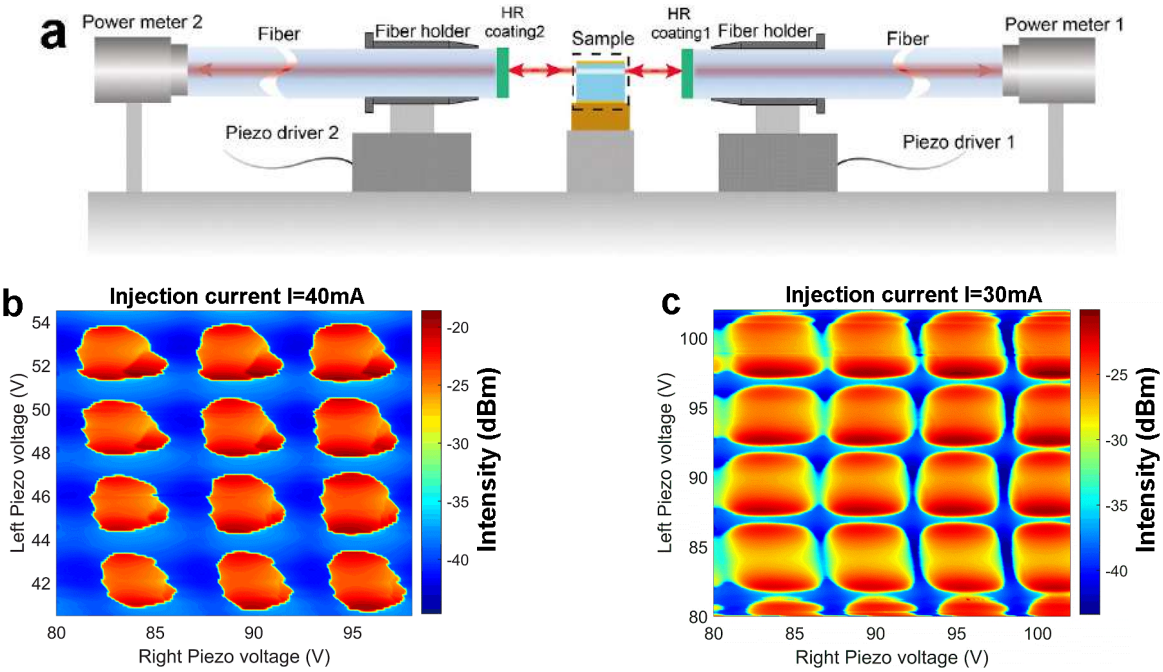

Figure 2: a) Schematic of DFB laser confined from both ends with ultra-short external mirror confined cavities; Color map showing variation of the fiber collected laser emission intensity for metal Bragg grating DFB (b) and C-C DFB (c).

It is also worth noting that CPA effects are also more pronounced in the case of external double-cavity confined DFB lasers, a devicethat appears as a promising test vehicle both from the point of view of practical applications, such as laser modulator, and for more fundamental concepts related to light-by-light manipulation.

Abstract

We propose a method that dynamically engineers adiabaticity in the evolution of non-Hermitian systems, enabling both chiral and nonchiral mode conversion. This approach addresses speed and chirality challenges in EP encircling without relying on a specific model, facilitating dynamic manipulation of nonadiabatic processes and accelerating operations with selectable mode conversion patterns.

1 Introduction

Non-Hermitian systems can exhibit exceptional points (EPs) where eigenvalues and eigenstates coalesce. EPs have been extensively studied for their unique properties in the field of photonics, acoustics and beyond, which can be implemented for single-mode lasing, loss-induced transmission enhancement, unidirectional invisibility. The eigenvalues of these non-Hermitian Hamiltonians form a self-intersecting Riemann surface, causing the initial eigenstate to be irrecoverable after completing a loop around an EP. Mode conversion can be achieved by adiabatically encircling an EP, but only in one direction (e.g., counterclockwise, CCW). In the opposite direction (e.g., clockwise, CW), the Hamiltonian transitions to a lower imaginary Riemann sheet, leading to a nonadiabatic jump and subsequent recovery of the initial state. This asymmetric mode conversion highlights the chirality of EP encircling and has sparked significant research interest, particularly in applications such as optical communications, quantum control, and optical isolators.

Despite notable progress, the EP encircling scheme faces two fundamental problems. Firstly, the adiabatic requirement limits mode conversion speed, impacting operational efficiency and mode decay. Recent approaches, like Hamiltonian hopping and selected loops, aim to accelerate evolution but are hindered by extreme parameters and low-loss eigenstates, restricting broader applicability. Secondly, controlling chirality in mode conversion is constrained. Conventional schemes permit only chiral mode conversion (mode A $\rightarrow$ B in CCW, mode A $\rightarrow$ A in CW). Recent findings shows potential for non-chiral mode recovery (mode A $\rightarrow$ A in CCW and CW) via a non-encircling-EP loop path, however, the specific outcome depends on the path details. And non-chiral mode conversion (mode A $\rightarrow$ B in CW and CCW) remains insufficiently explored, reportedly achievable only with specific starting points in the evolution process. Addressing speed and chirality challenges in EP encircling requires an efficient and model-independent solution, as existing works rely on specific models, paths, or Hamiltonians, necessitating broader approaches. Adiabaticity offers potential solutions but lacks adequate exploration. Existing

schemes focus on maintaining proximity to the Riemann surface throughout the encircling operation, with occasional jumps, yet fail to consider the degree of adiabaticity at each instant. A systematic method to quantify and control instantaneous adiabaticity is currently absent, impeding efficiency optimization. Furthermore, non-adiabaticity engineering has been overlooked, with previous approaches either avoiding non-adiabatic processes in mode conversion or limiting non-adiabatic jumps between Riemann sheets in mode recovery. The active introduction and control of non-adiabatic processes remain rare, limiting the ability to accelerate operations and freely select mode conversion patterns. Overall, an on-demand approach addressing the speed and chirality challenges in EP encircling is urgently needed, with adiabaticity playing a crucial role that requires further attention.

We introduce dynamic adiabaticity engineering for non-Hermitian Hamiltonian evolution, achieving equivalent quality to conventional quasi-adiabatic evolution in one-fourth of the time. Our method facilitates both chiral and non-chiral mode conversions on a single path. By optimizing velocity at each local point based on quantified adiabaticity, we transcend the adiabatic/non-adiabatic dichotomy, integrating both processes within a unified framework. Importantly, our methodology allows deviation from the Riemann surface, offering an alternative to strict adherence or jumps between surfaces. Implemented in a microwave waveguide system, our approach demonstrates superior speed and mode purity. Moreover, it extends beyond optical systems, being applicable to various non-Hermitian systems. Our work enhances understanding of adiabaticity in non-Hermitian systems and provides insights for advancing mode converters. The dynamic adiabaticity engineering method is a promising approach for achieving efficient and high-quality evolution in non-Hermitian systems.

Complex continuation exceptional point and its role in eigenvalue knots for open boundary lattices

Yuancheng Zhao and Kun Ding*

Department of Physics, State Key Laboratory of Surface Physics, and Key Laboratory of Micro and Nano Photonic Structures (Ministry of Education), Fudan University, Shanghai 200438, China

Abstract: Non-Bloch EPs are not merely straightforward generalizations of Bloch EPs. We define complex continuation EPs (CCEPs) and non-Bloch Fermi arcs (NBFAs) connecting CCEPs, clarify the distinction between non-Bloch EPs and CCEPs, and show that CCEPs and NBFAs in OBC knots mirror Bloch EPs and non-Hermitian Fermi arcs in PBC knots.

Exceptional points (EPs) are unique non-Hermitian degeneracies with fascinating properties, particularly in lattice systems. EPs under periodic boundary conditions (PBCs) that reside in the Brillouin zone are called Bloch EPs, resulting in phenomena like eigenvalue braiding and knots. The disparity between the PBC and open boundary condition (OBC) spectra illustrates the Bloch EPs may not be observable for NH lattices under OBC, leading to non-Bloch EPs. Recent studies reveal that non-Bloch EPs can emerge even in single-band cases, unlike Bloch EPs, which are limited to multiband systems. This undoubtedly shows that non-Bloch EPs are not merely straightforward generalizations of Bloch EPs. To explore this, we deploy the reciprocal non-Hermitian Lieb lattice, which supports observable Bloch EPs, and alter the geometry to make them disappear. By analytic continuation wavenumbers to complex domain, Bloch EPs naturally generalize to complex continuation EPs (CCEPs), which typically do not lie on the OBC spectra. We then examine the generalized Brillouin zone and its intersection with CCEPs, showing that the CCEP, even with its energy on the OBC spectra, is still distinct from the non-Bloch EP. Non-Bloch Fermi arcs (NBFAs) connecting CCEPs determine the OBC eigenvalue braiding and knots, generalizing the Bloch EP phenomena. We finally demonstrate a transition in OBC eigenvalue knots with CCEPs, NBFAs, and non-Bloch EPs, revealing their respective roles.

Nano-Lasers, Spasers, and Nanostructures with Quantum Elements

Geometric Antibunching and Directional Shaping of Photon Anticorrelations

Abstract: In this work, we investigate the directional characteristics of photon statistics in dimers of quantum emitters placed in different photonic environments. We find a new mechanism for photon anticorrelation, termed as *geometric antibunching*, that is completely agnostic to the quantum state of the emitters and emerges from quantum interference effects.

Although temporal photon statistics have been a cornerstone since the beginning of the field of quantum optics, the second order spatial coherence has been greatly overlooked. In this work [1], we present a comprehensive description of the spatial characteristics of photon anticorrelations in quantum emitters placed in different photonic environments. For their analysis, we construct a two-point second-order correlation function, $g^{(2)}(\mathbf{r}, \mathbf{r'})$, that allows us to find a new mechanism for photon anticorrelation, termed as *geometric antibunching*. This phenomenon is completely agnostic to the quantum state of the emitters and emerges from quantum interference effects due to the indistinguishability of different two-photon optical pathways. Finally, we explore its occurrence in emitters placed in the vicinity of a flat substrate and a nanosphere, demonstrating that these *geometrical zeros* are not a coincidence of free-space [2, 3] but a general property of the photonic environment where the emitters are placed. We also demonstrate its tunnability through the different material and geometric parameters of these structures.

By decomposing the electric field operator into optical-path and polarization terms we derive the expression for the normalized two-point second-order correlation function for the QE dimer

$$g^{(2)}(\mathbf{r}, \mathbf{r}') = \frac{|\Psi(\mathbf{r}, \mathbf{r}', \mathbf{r}_1, \mathbf{r}_2)|^2 \langle \hat{\sigma}_1^\dagger \hat{\sigma}_2^\dagger \hat{\sigma}_1 \hat{\sigma}_2 \rangle}{\langle I \rangle \langle I' \rangle}$$

where the quantum state of the dimer is encoded in the steady-state expected value of the σ_1 and σ_2 operators and the function Ψ captures the optical-path dependence of the wavefunction of the two-photon states generated by the quantum emitters. The phenomenon referred to here as geometric antibunching occurs when the function Ψ vanishes at two pairs of points, causing $g^{(2)}(\mathbf{r}, \mathbf{r'})$ to be zero. This effect arises independently of the specific quantum state of the dimer, making it unaffected by factors such as pumping, emitter interactions, or decoherence.

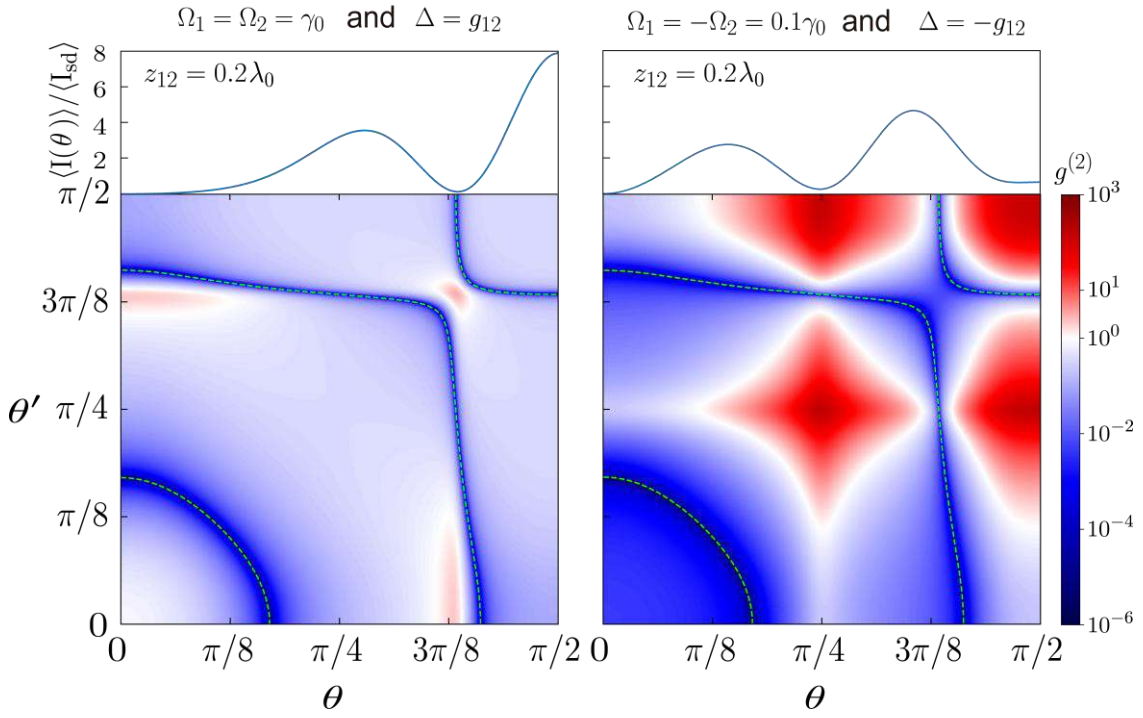

Figure 1. Maps of directional correlations, $g^{(2)}(\theta, \theta')$, for a vertically oriented QE dimer placed above a perfect mirror (z1 = 0.6 λ_0 and z2 = 0.8 λ_0). The polar angles θ, θ' represent the directions in the far-field where light is detected. The laser drivings (Ω_1 and Ω_2) and detuning (Δ) are set to target the Bell symmetric (left) and antisymmetric (right) states of the QE dimer. The upper panels show directional intensity plots in both scenarios, normalized to $\langle I_{sd}\rangle$ (the emission of a single emitter in free space at $\theta=\pi/2$). Green dashed curves indicate geometric antibunching zeros, where $g^{(2)}(\theta, \theta')$ vanishes independently of the quantum state of the emitters.

Our work opens the door to developing new strategies to control and harness quantum light by incorporating the spatial degrees of freedom in its theoretical description. Moreover, it puts forward a number of design ideas that can promptly be implemented for single-photon generation in nanophotonic platforms. We foresee efficient and versatile quantum light sources based on our findings, with application in quantum information and quantum sensing technologies.

Abstract: In this talk, I will present our recent work on nanolasers that leverage extreme dielectric confinement to localize both photons and electrons, achieving a sub-diffraction-limited mode volume and continuous-wave lasing at room temperature. This approach enhances light-matter interactions, lowers the lasing threshold, and paves the way for ultra-efficient optoelectronic devices.

Efficient light capture in space and time is vital for fundamental physics and applications like lasers. Conventional lasers are large and energy-intensive, restricting their applications such as on-chip optical links. Achieving ultra-efficient microscopic lasers requires compact, low-loss cavities with strong spatial confinement. Since Purcell's insight on cavity-enhanced emission, minimizing optical mode volume (V_{mod}) has been a key goal. Plasmonic structures achieve sub-diffraction confinement but suffer from ohmic losses and low Q-factors [1]. In contrast, dielectric nanostructures with sharp geometries enable sub-diffraction hotspots while maintaining high Q-factors [2-5]. While minimizing V_{mod} enhances quantum light sources with a single emitter at the cavity antinode, it inadequately quantifies light-matter interactions in lasers. Effective enhancement requires spatial localization of both light and carriers, as interaction strength depends on their spatial overlap

$$V_{\mathbf{I}} = 1 / \left(\int N_{\mathrm{p}}(\mathbf{r}) N_{\mathrm{c}}(\mathbf{r}) d\mathbf{r} \right) \tag{1}$$

Here, we define $V_{\mathbf{I}}$ as the light-matter interaction volume and find that the laser threshold is proportional to $V_{\mathbf{I}}$. $N_{\mathrm{p}}(\mathrm{r})$ and $N_{\mathrm{c}}(\mathrm{r})$ are the normalized photon and carrier densities. Eq. (1) shows that minimizing laser threshold requires considering both photon and carrier spatial distributions to minimize $V_{\mathbf{I}}$.

Here we explore extreme dielectric confinement (EDC) for lasers. The EDC laser (Fig. 1(a)) achieves a V_{mod} of $0.88(\lambda/2n)^3$—less than half that of the smallest point-defect photonic crystal (PhC) laser. Such a V_{mod} below the diffraction limit is due to the narrow nanobridge at the center (Fig. 1(b)). We fabricated the structures in an InP quantum-well membrane [5] with a passivation step to mitigate surface recombination, a key challenge for active nanostructures. The laser is optically pumped with a CW light source at room temperature. For comparison, we also evaluate a PhC laser counterpart. We measure laser thresholds by varying the pump focal plane, which controls the spatial distribution of $N_{\mathrm{c}}(\mathrm{r})$. The measurements align closely with our developed 2D laser model (Fig. 1(c)), which incorporates the spatial distributions of photons, carriers, spontaneous emission, and the pumping profile. Thresholds are lowest at the focal plane and increase as excitation disperses. The EDC laser exhibits over 10 dB threshold reduction compared to the PhC laser (Fig. 1(d)).

To quantify carrier localization, we define the carrier volume $V_{\mathrm{car}} = \int N_{\mathrm{c}}(\mathbf{r}) d\mathbf{r} / \max\{N_{\mathrm{c}}(\mathbf{r})\}$. We found that the EDC laser achieves a V_{car} an order of magnitude smaller than that of the PhC laser. Assuming Gaussian distributions for $N_{\mathrm{p}}(\mathrm{r})$ and $N_{\mathrm{c}}(\mathrm{r})$, we find $V_{\mathbf{I}}=V_{\mathrm{mod}}+\Gamma V_{\mathrm{car}}$. Since typically, V_{car} exceeds V_{mod} in nanostructures,

making its reduction more critical in minimizing V_I.

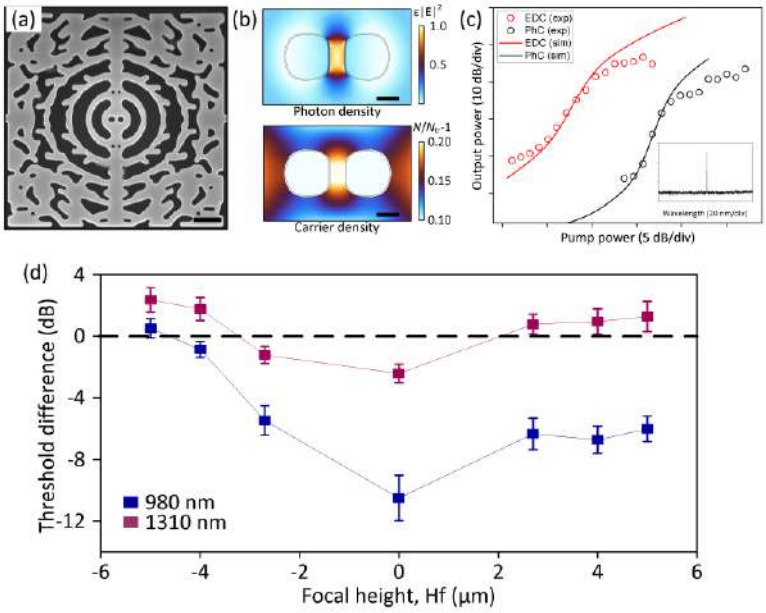

Fig. 1. (a) SEM image of the EDC laser. Scale bar: 1 μm. (b) Calculated photon (top) and carrier (bottom) densities showing strong co-localization at the cavity center. Scale bar: 100 nm. (c) Laser characteristic comparison between the EDC (red) and PhC laser (black). Inset: lasing spectrum of the EDC laser. (d) Measured threshold difference between the EDC and PhC laser ($\Delta P_{th} = P_{th,EDC} - P_{th,PhC}$) at different pump focal positions.

In conclusion, we investigate extreme dielectric confinement of both photons and electrons in lasers, demonstrating a room-temperature CW nanolaser with a sub-diffraction-limited mode volume and a significantly reduced laser threshold. The EDC laser minimizes the interaction volume, a new concept we introduce, while maintaining high gain and *Q*-factor. This would enable unprecedented light-matter interaction levels, with implications beyond light sources.

Light goes Nano:

The T-matrix method in nanoplasmonics with active gain media

M. A. Iatì[1*] **and R. Saija**[1,2]

[1]CNR-Istituto per i Processi Chimico Fisici, Messina, Italy
[2]Dip. di Scienze Matematiche e Informatiche, Scienze Fisiche e Scienze della Terra, Università di Messina, Italy
[*]corresponding author: mariaantonia.iati@cnr.it

Abstract: The T-matrix method is a powerful approach to study the opto-plasmonic behaviour at the nanoscale. Particle shape, composition, material hybridization, and degree of aggregation affect optical properties and forces. This implies the need for an accurate theoretical modeling paving the way to applications in photothermal therapy, enhanced spectroscopy, and spasing.

1. Introduction

The Transition matrix (T-matrix) is a powerful method to study the opto-mechanical behaviour of metal nanoparticles and nano-aggregates [1]. The technique is based on the multipole expansions of the electromagnetic fields and can be applied to many scatterer models, from nano-shell particles to composite structures and aggregates of spherical monomers. A key point of this approach is that it offers both an analytical and numerical solution to the scattering problem, surpassing other computational approaches in terms of efficiency and accuracy. Furthermore, the T-matrix allows to perform an analytical evaluation of the scattering characteristics averaged over particle orientation. This is a key feature which results in a significant saving in computational time. The T-matrix has proven to be a very reliable tool to describe plasmon coupling in metal nanoparticles, with a detailed description of the near-field plasmon interaction [2].

The T-matrix also offers a comprehensive description of the mechanical effects of light on nanostructures and has proven to be particularly suitable to describe optical trapping of composite and arbitrary-shaped particles [3].

2. Opto-mechanical behaviour in hybrid nanostructures

Hybrid nanostructures exhibit a peculiar optical behaviour since they combine the plasmonic properties with those of the hybrid components, affecting also optical forces and torques acting on the particles [4]. We will discuss, through several case studies, how material hybridization can promote accurate control of the mechanical effects of light. Optical forces on systems composed of metal nanoparticles and molecular emitters [4], as well as multi-shells with alternating metal and dye-doped layers are investigated computationally [5], with a focus on the resonant interplay between plasmonic structures and gain media. Understanding this behaviour will pave the way to many applications, such as photothermal therapy, enhanced spectroscopy, and spasing.

Abstract: We present comprehensive modeling of gain-enhanced metallic nanoshells, analyzing their lasing characteristics through optical Bloch equations coupled to free-electron dynamics. By comparing symmetric and antisymmetric plasmon resonances and examining detuning effects between gain and resonance frequencies, we identify optimal conditions for emission thresholds, spectral tunability, and frequency pull-out dynamics.

Recent advancements in nanophotonics have opened promising possibilities for miniaturized optical devices, particularly through metallic nanoshell structures (Fig. 1). These nanoshells, characterized by specific geometric configurations, effectively enhance nanoscale light-matter interactions. A pivotal development involves gain-doped metallic nanoshells, where optical gain materials embedded within a plasmonic metallic shell overcome inherent metallic losses, enabling coherent photon emission (lasing) at nanoscale dimensions [1].

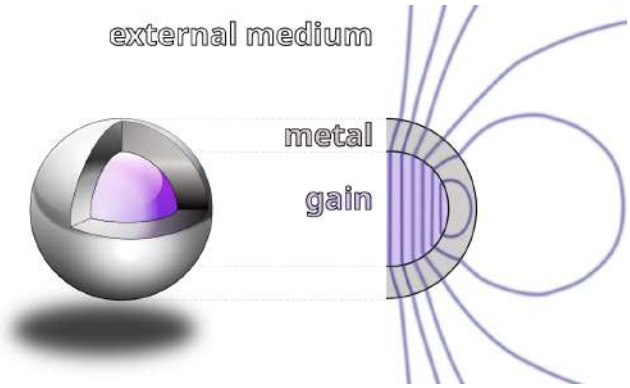

Figure 1. A spherical nanoshell particle, with a gain medium filling the core and a metallic shell, placed into an external medium.

This presentation provides a detailed modeling approach to investigate gain-enhanced nanoshell systems, emphasizing their lasing characteristics and the intricate relationship between structural features and optical behaviors [2,3]. The theoretical framework applied incorporates time-dependent optical Bloch equations, which describe population dynamics within the gain medium, coupled to free-electron motion in the metallic shell. This comprehensive model captures system behaviors both below [2] and above the lasing threshold [3]. Previous studies have successfully applied this method to other configurations, such as spherical nanoparticles immersed in gain media, allowing insights into lasing instabilities at threshold conditions [4].

Our current study extends beyond previous work, exploring two novel avenues. Firstly, we address the distinct properties of the nanoshell's two inherent plasmon resonances—symmetric and antisymmetric—whose frequencies depend strongly on the geometric aspect ratio of the nanoshell [3,5]. Unlike earlier generic treatments, we systematically analyze and compare these resonances, optimizing the necessary gain levels to achieve efficient lasing.

Secondly, we examine the consequences of detuning between the gain medium's emission frequency and the plasmonic resonance frequency [5]. Traditionally, gain frequencies are matched precisely to resonance frequencies for simplified theoretical treatment and optimal gain conditions. However, we explore the physical implications of frequency detuning, analyzing its effects on critical lasing parameters such as gain threshold, lasing frequency, spectral width, and frequency pull-out dynamics. Detuning introduces additional tunability, broadening the potential applications of nanoscale lasers.

Abstract: We report interface-engineered SPP nanolasers featuring optimized dielectric-metal coupling, enabling ultracompact mode confinement, low-threshold lasing, and substrate-free transferability for scalable integration.

Surface plasmon polariton (SPP) nanolasers have emerged as promising candidates for subwavelength light sources due to their ability to confine electromagnetic energy beyond the diffraction limit[1]. However, traditional designs relying on rigid substrate-bound configurations face limitations in mode confinement, integration flexibility, and overall optical performance. In this work, we present a new architecture of substrate-free, interface-engineered SPP nanolasers that enables enhanced electromagnetic confinement, significantly lowered lasing threshold, and robust operation across diverse substrate environments[2-5]. Our approach emphasizes precise control of the metal-dielectric-semiconductor interface to tailor plasmonic modes while achieving structural versatility for photonic integration. The device structure is based on a metal–insulator–semiconductor (MIS) configuration. Unlike conventional devices fabricated directly on substrates, our process introduces a sacrificial layer beneath the metal film, allowing for complete release and transfer of the nanolaser structure to arbitrary surfaces. This method offers both structural reconfigurability and potential compatibility with flexible or biologically relevant substrates.

ZnO nanowires were selected as the gain medium for their superior optical properties in the ultraviolet regime. ZnO exhibits a wide direct bandgap of ~3.37 eV and a large exciton binding energy of approximately 60 meV, which facilitates efficient excitonic emission even at room temperature[3]. These characteristics, coupled with strong oscillator strength and compatibility with well-established nanowire growth techniques, make ZnO an ideal candidate for ultraviolet plasmonic nanolasing applications. Moreover, its refractive index profile supports strong light confinement within nanoscale geometries, crucial for coupling with surface plasmon polaritons. To guide the cavity design and optimize the plasmonic interaction, we conducted comprehensive finite element method (FEM) simulations. The simulations evaluated the impact of key parameters including metal type, metal thickness, dielectric material, dielectric thickness, and ZnO nanowire geometry. Among candidate plasmonic metals, aluminum and silver were compared due to their favorable permittivity in the UV range. A dielectric spacer of Al_2O_3 was selected for its high bandgap, low optical loss, and conformal deposition via ALD. The resulting structure produced an effective mode volume of approximately 0.008 λ^3 in the Al-based substrate-free configuration, calculated using the standard definition[1]:

$$V_m = \frac{W_m}{\max[W(r)]} = \frac{1}{\max[W(r)]} \iiint W(r) d^3r \quad (1)$$

W(r) is the spatial distribution of the electromagnetic energy density. For comparison, the same nanowire cavity

on a conventional substrate yields a mode volume of around 0.027 λ^3. This represents a substantial improvement in confinement, attributed to the removal of the substrate and optimized dielectric-metal coupling. The field exhibits strong localization at the nanowire–dielectric–metal interface, as shown in Figure 1.

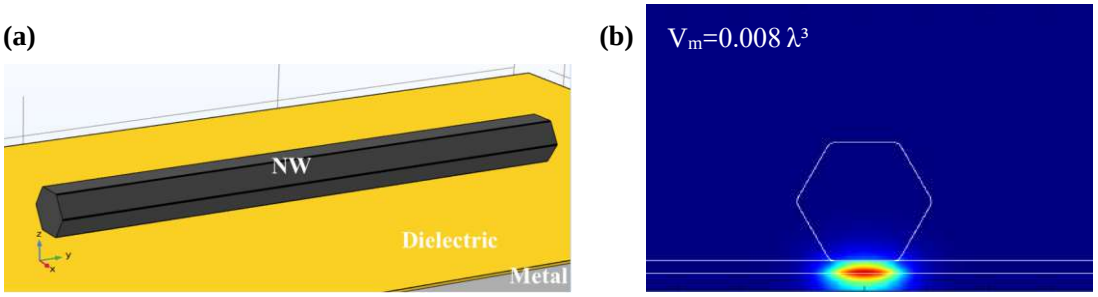

Figure 1. (a) Schematic of the simulated metal–insulator–semiconductor (MIS) nanolaser structure, consisting of a ZnO nanowire (NW) placed on an Al_2O_3 dielectric spacer atop a single-crystalline aluminum film. (b) Simulated electric field intensity distribution ($|E|^2$) in the cross-sectional plane, illustrating strong field confinement at the ZnO–dielectric–metal interface. The calculated mode volume is approximately 0.008 λ^3 under substrate-free configuration.

The combination of precise interface engineering and substrate-free construction offers several advantages over conventional SPP laser platforms. Not only does it enhance the Purcell factor and reduce the required gain, but it also allows for nontraditional integration pathways such as in flexible electronics, implantable sensors, and compact optical interconnects. Moreover, the entire process is compatible with scalable fabrication techniques, and the choice of materials ensures CMOS process compatibility.

Abstract: Amplification, nanolasing and spasing phenomena can be controlled by designing individual nanoresonators of different composition that are randomly distributed, periodically arranged along 1D gratings, compose 3D multilayers and construct 2D patterns of a miniarrays. By considering the local impact of the plasmonic nanoresonators, the 4D optimization enables tailored lasing characteristics.

The judicious design of nanoresonator (NR) patterns enables the optimization of lasing characteristics, by improving the pump and probe related phenomena via coupled modes [1]. In this work, the coupled Maxwell and rate equations were solved by considering the local **E**-field distribution as a nonlinear term in the gain. Via numerical pump-and-probe computations the near-field enhancement, far-field optical responses and optical cross-sections were determined above the dye concentration-E_{pump} field parameter space, to distinguish near-field amplifier, far-field emitting laser and spaser operation regions. The lasing /spasing was proven based on the threshold behavior and line-width narrowing /negative extinction cross-section. Asymmetrical frequency pulling and counter-intuitive pump dependence was demonstrated, according to the non-Hermitian nature of plasmonic NRs [2, 3]. Metamaterial retrieval was realized to extract the effective parameters of NR composites.
Individual nanoresonators of various core-shell compositions were optimized, and the impact of the configuration and dye concentration on the mode competition, far-field emission distribution and quantum efficiency was determined [4]. The concentration corresponding to the minimal spaser threshold was determined for NRs of different composition. Various NRs were randomly implanted into extended targets and it was proven via time-domain computations that the near-field and energy deposition of counter-propagating short laser pulses can be balanced via optimized distributions [5]. Arrangement of the NRs into multilayers of periodic patterns allowed for designing amplifying mirror, impedance matched amplifier and epsilon-near-zero media that operate at the center, lower and upper edge of their plasmonic band gaps, respectively. On the dispersion maps modes resulting in the highest near-field enhancement, light tunneling and allowing for phase synchronization were identified at composition dependent tilting. Achievement of the coherent perfect absorption was demonstrated along hyperbolas on the dye concentration-E_{pump} map, for counter-propagating beams. Propagation direction and relative phase independent perfect transmission capable of ensuring cloaking was demonstrated. It was shown that the FOM=out-coupled intensity/FWHM can be maximized by aligning NRs along the turning lines of long-range propagating surface plasmon polaritons that can be coupled in specific azimuthal orientations of one-dimensional dielectric-metal gratings seeded by dye. Multispectral control of plasmonic lasing was demonstrated via coupled modes on the convex and concave complex structures constructed with Babinet complementary miniarrays of a central nanoring and satellite nano-crescent NRs. The threshold behavior and line-width narrowing is more well defined in transmittance /reflectance in complementary orientations of convex /concave patterns, the stimulated emission is slightly /considerably pulled spectrally and is neighbored by ASE.

Abstract: In this work, we theoretically show that integrating epsilon-near-zero materials within metal–dielectric–metal slot waveguides would boost the nonlinear conversion efficiency, exhibiting unprecedented nonlinear optical conversion efficiency in an ultra-compact device. Furthermore, we have developed a novel nanofabrication process flow to fabricate these slot waveguides with high aspect ratio and sub-nm gaps.

Interest and excitement in nanophotonics—the study and control of light-matter interactions at the nanoscale—are driven by the ability to confine light to volumes well below a cubic wavelength, and, thereby, achieve extremely high intensities. This leads to light-matter interactions of unprecedented localization and strength. Such extreme behaviour—both in terms of field enhancement and localization—can be achieved using plasmonic nanostructures, which concentrate light in regions much smaller than the wavelength of light, reducing the excitation power and, under certain conditions, removing phase-matching requirements in the nonlinear regime. In this study, we theoretically demonstrate that the metal–dielectric–metal (MDM) slot waveguides, consisting of a thin dielectric layer embedded between metal films, provide the strongest confinement and that integrating epsilon-near-zero (ENZ) materials into the slot significantly improves the nonlinear conversion efficiency of these structures. The results show that the degenerate four-wave mixing (DFWM) conversion efficiency of these ENZ-MDM structures surpasses that of regular plasmonic structures and their dielectric counterparts, even under low pump power conditions, and remains robust despite higher losses in the ENZ material (Figure 1a).

Creating such extremely compact devices requires advanced nanofabrication methods capable of overcoming the limitations of conventional approaches; in response to this, we have developed a novel lithographic process flow based on Carbon Electron Beam Induced Deposition (C-EBID). Using a carbon hard mask prepared via C-EBID (Figure 1b), we overcome focused ion beam resolution limits and fabricate close-to-ideal slot waveguides with high aspect ratios. The effectiveness of this approach has been demonstrated by successfully preparing MDM slot waveguides with 10 nm gaps and straight side walls (Figure 1c), showing a significant advancement in the preparation of optically active nanostructures. Overall, these results underscore the potential for applications, for example, in quantum optics, where extreme compactness and high efficiency in harnessing pure and strong nonlinearities become crucial.

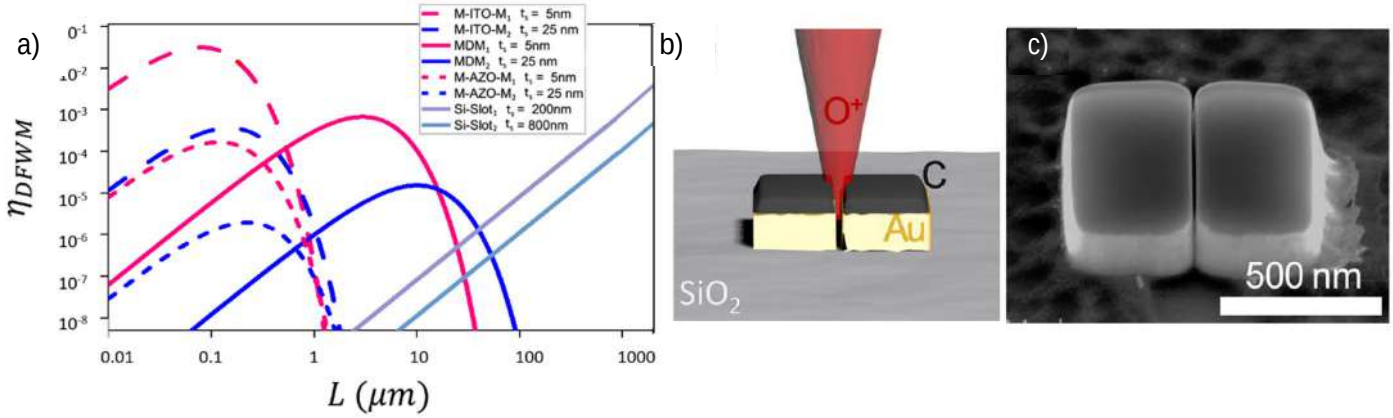

Figure 1: (a) Comparison of DFWM conversion efficiency of M–ENZ–M (using two ENZ materials: ITO and AZO), MDM, and Si-Slot waveguides for two different spacer thicknesses (t_s) when each structure is driven at the maximum threshold power of MDM1 (P_{th} =0.32) for fairness. Round Table: Nanolasers: prospects and challenges

Ashod Aradian
University of Bordeaux, France

Abstract: This roundtable is open to everybody, whether they attended or not the "nanolaser" SP17 session. This will be a time to discuss and exchange views informally around the following themes, as well as others: (i) challenges and prospects in the field of nanolasers, (ii) state of the theory versus the state of experiments, (iii) nanolasers versus classical lasers, (iv) what are the obstacles towards the commercialization of nanolaser-based devices? All colleagues are more than welcome to participate.

Laser cooling of hybrid nanoparticles

Abstract: After an introduction to optical forces at the nanoscale, we discuss some ideas on laser cooling of hybrid nanostructures, where localized surface plasmons are coupled to excitons, and of gain-assisted nanoparticles, where the strong coupling between plasmons and excitons controls their optomechanical behavior.

Optical forces are the consequence of momentum conservation in the light-matter interaction [1,2]. In recent years, their applications for pushing, trapping, and manipulation of particles resulted in a wide range of applications in the nanoscience, life sciences, physics, and engineering [3]. Their averaged components can be separated in a conservative contribution, responsible for the operation of optical tweezers, and in a dissipative one, crucial for laser cooling of the particle centre-of-mass [1].

Here, we discuss on the hybridization of optical forces by studying the control and engineering of mechanical effects of light in the presence of plasmon-exciton coupling [4,5]. Optical forces on exemplar systems composed of plasmonic particles and quantum emitters [4] are investigated theoretically by extending the theoretical framework used for atoms in the dipole approximation. Prospects for laser cooling and optomechanical manipulation of gain-assisted systems [5,6] will be discussed.

Electrically-biased Surface Plasmon Nanolaser with a Hyperbolic Metasurface

Jun-Yu Wu[1], and Tsung-Yu Huang[1,*]

[1] Department of Materials Engineering, Ming Chi University of Technology, New Taipei City, Taiwan, 243303

[*] Email: huang.tsungyu@mail.mcut.edu.tw

Abstract: In this study, we employed a hyperbolic metasurface of alternating air and metallic stipes for demonstration of the nanolaser. The hyperbolic metasurface provides three-dimensional confinement of surface plasmons, enabling smaller physical and modal volumes compared to others. Furthermore, the minimal volume facilitates miniaturization and integration of photonic integrated circuits efficiently.

Current surface plasmon (SP) nanolasers mostly used Fabry-Perot resonant for the SP cavity, which can only achieve two-dimensional confinement. This limits the interaction between surface plasmons and the material, leading to higher lasing thresholds. Furthermore, most nanolasers are optically excited and lack electrical excitation designs, making integration with integrated circuits difficult and relying on external excitation light sources.

To address these issues, we propose the design of a hyperbolic metamaterial interface, which allows surface plasmon polaritons to be confined in three dimensions, significantly enhancing laser efficiency and enabling electrical excitation. In this design, we introduce laterally arranged air trenches on the metal surface to form a hyperbolic metamaterial interface. The momentum mismatch between the hyperbolic interface and the continuous metal prevents surface plasmon polaritons from coupling into the surrounding continuous metal, thus achieving confinement within the resonator. Additionally, since the air trenches are arranged along the x-direction in this structure, surface plasmon polaritons are confined in the x-direction due to the wave vector mismatch of the hyperbolic interface. In the y-direction, confinement is achieved based on traditional Fabry-Perot resonance. Moreover, we anticipate that the use of a silver thin film as the top electrode and highly-doped gallium arsenide as the bottom electrode will make electrical excitation possible, as shown in **Figure 1(a)**.

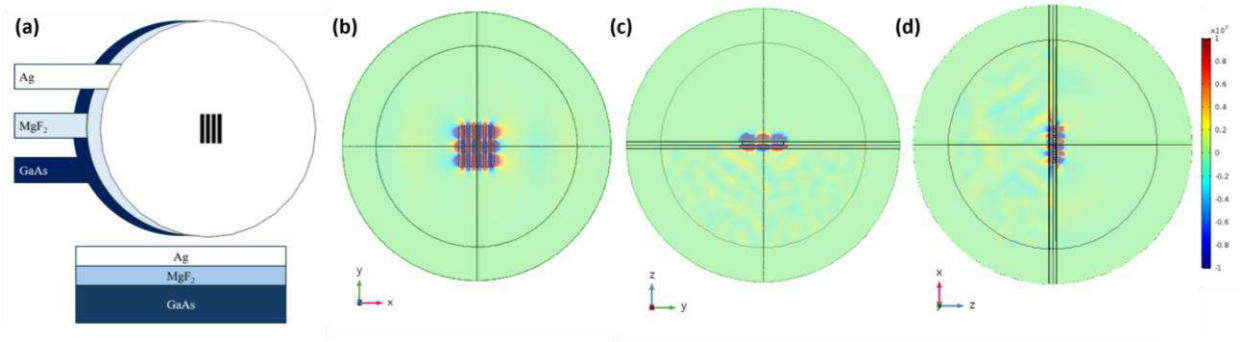

Figure 1. (a) Scheme of the hyperbolic metasurface and its (b) top, (c)y-z and (d) x-z views.

We used finite element simulation to verify whether the results met our expectations. Based on the structure shown in **Figure 1(a)**, we built a system consisting of a gallium arsenide (GaAs) substrate, magnesium fluoride (MgF_2), and a continuous silver with air trenches. **Figure 1(b)** presents the simulation results of the designed resonant cavity. According to the results, it is evident that the surface plasmon is effectively confined in all three

dimensions by the hyperbolic metasurface. To further investigate the performance of this resonant cavity, we conducted in-depth calculations. As shown in **Figure 2(a)**, the quality factor of this mode is 81.445; the Purcell factor is 9467.35; the physical volume is 0.01584 μm³; the modal volume is 4.6663×10^{-4} μm³; and the normalized modal volume is 5.2298×10^{-3}. Therefore, based on the modal volume, it is clear that this structure successfully breaks the diffraction limit, achieving a subwavelength resonant cavity with a high quality factor.

(a)

Quality factor	81.445
Purcell factor	9467.35
Mode volume	0.01584 μm³
Physical volume	4.6663×10^{-4} μm³
Normalized mode volume	5.2298×10^{-3}

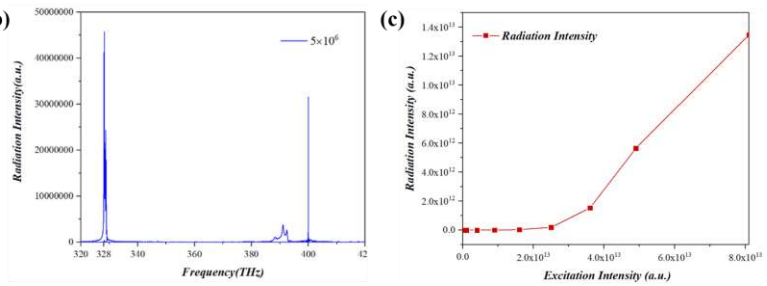

Figure 2、(a)resonance cavity quality (b)At a pump intensity of 2.5×10^{13}, laser excitation occurs. (c)The nonlinear relationship between laser radiation intensity and pump intensity is observed.

To further observe the laser performance, we used the finite difference time domain (FDTD) method to calculate the laser excitation intensity under different pump intensities. As shown in **Figure 2(b)**, with a pump Intensity of 2.5×10^{13}, we observed successful excitation of the laser in the 328 THz range. For a deeper analysis of the laser threshold characteristics, as shown in **Figure 2(c)**, before the threshold, the radiation intensity remained at a low level, changing linearly with the increasing pump intensity. Once the threshold was surpassed, stimulated radiation dominated, and the radiation intensity showed a rapid and significant increase. As shown in **Figure 2(c),** the laser threshold is approximately 2.5×10^{13}, which provides further evidence that this structure can successfully support a laser.

In summary, by employing the hyperbolic metasurface as a resonant cavity of the nanolaser, we successfully achieved three-dimensional confinement of surface plasmon polaritons, resulting in a high quality factor of 81.445. Furthermore, the modal volume was reduced to 4.6663×10^{-4} μm³. We also successfully simulated laser excitation using this resonant cavity, demonstrating a low threshold. Therefore, this nanolaser is expected to serve as a promising source for future integrated circuit applications.

Abstract: In this work, we demonstrate the versatility of Optical Tweezers as a manipulation tool, using them for trapping and identifying extraterrestrial analogues. We also theoretically show that they serve as an experimental system for detecting the onset of spasing in gain-assisted plasmonic nanoshells.

Optical tweezers (OT) are tools made of light for the contactless pushing, trapping, and manipulation of objects, ranging from atoms to light sails [1]. They have evolved into sophisticated instruments and have been employed in a broad range of applications in the life sciences, physics, engineering and nano-technology. Here we discuss two applications of the technique on two physical systems that radically differs in terms of size, scope and context.

In the first application we use OT coupled to Raman spectroscopy in the framework of cosmic dust analysis and identification. Very recently Optical Raman Tweezers (ORTs) have been successfully used to trap, manipulate, and analyze spectra coming from micrometeorites and cosmic dust [2].

In this work we push forward the challenge by proposing ORTs as a tool to identify biosignatures on extraterrestrial mineral samples. In particular we analyzed extraterrestrial mineral analogues artificially doped with organic molecules of interest.

In the second application we considered OT as a tool that can be used to characterize the optical properties of gain-assisted plasmonic nanoshell and that might offer an experimental proof of the system ability to sustain spaser emission. In particular we demonstrated theoretically that a pump-probe optical tweezers set-up can be successfully used to detect the spaser/nanolaser emission transition. In the amplification regime—below the emission threshold—the nanoparticle's dipole moment remains proportional to the external trapping (probe) field. This leads to a predictable force landscape, as demonstrated in earlier work using optical tweezers and sub-threshold gain materials [3].

Above the threshold, however, the dipole moment becomes essentially independent of the trapping field [4], driven instead by gain-sustained emission. In this regime, the spatial structure of the pump governs the optomechanical response, resulting in force landscapes that are radically different from the pre-threshold, linear-optics regime.

This transition manifests as a measurable change in trapping behavior, providing a localized, near-field probe of spaser emission. This approach offers a complementary perspective to far-field spectroscopy, enabling a direct experimental link between spasing and nanolasing phenomena.

Abstract: We reveal the properties of quantum beam splitting on local and nonlocal metasurfaces, functioning as a series of parallel two-port beam splitters and a set of independent four-port beam splitters, respectively, which can manipulate various quantum states. We further demonstrate quantum logic gates on a single metasurface.

1. Introduction

Metasurfaces are planar structures that can control all degrees of freedom of light at nanoscale, which as an excellent platform for beam splitting (BS). Based on the responses are localized or not, they can be classified as local and nonlocal metasurfaces [1]. Here, we reveal the parallel two-port BS on local metasurfaces and independent four-port BS on nonlocal metasurfaces, which has different responses on incident wavelengths, angles and polarizations [2,5]. Based on that, we demonstrate the engineering of quantum states and realization of quantum logic gates on a single metasurface [3,4].

2. Results

2.1 BS on local metasurface

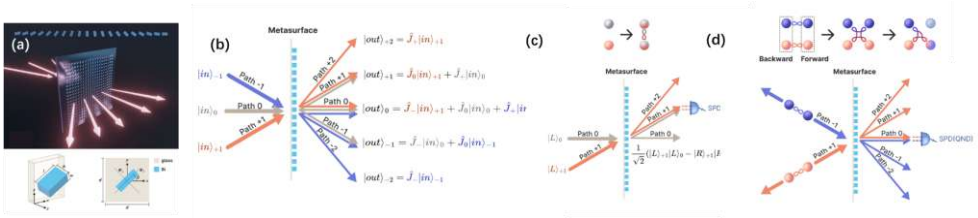

Figure 1 Parallel BS principle and its application in entanglement generation and fusion. (a) The schematic of parallel BS on local metasurface. (b) Parallel BS for three incident beams. (c) Entangled state preparation and (d) entanglement fusion under parallel BS.

Consider a local metasurface encoded with geometric phase gradient, as shown in Fig. 1(a). Along with the polarization conversion, it can deflect part of the incident light. Based on this, the metasurface has a parallel BS capability [2]. Fig. 1(b) shows the condition that three beams are incident from paths 0, ± 1. Each beam is split into three beams, while interference occurs in this process, with transformation matrix like:

$$\begin{bmatrix} |R_{out}\rangle_{+1} \\ |L_{out}\rangle_{0} \\ |R_{out}\rangle_{0} \\ |L_{out}\rangle_{-1} \end{bmatrix} = \begin{bmatrix} \cos\Delta & i\sin\Delta & 0 & 0 \\ i\sin\Delta & \cos\Delta & 0 & 0 \\ 0 & 0 & \cos\Delta & i\sin\Delta \\ 0 & 0 & i\sin\Delta & \cos\Delta \end{bmatrix} \begin{bmatrix} |R_{in}\rangle_{+1} \\ |L_{in}\rangle_{0} \\ |R_{in}\rangle_{0} \\ |L_{in}\rangle_{-1} \end{bmatrix}. \quad (1)$$

Such the BS can support various classical and quantum operations [3]. Fig. 1(c) shows the generation of entangled state with two parallel BS processes from direct product states. The parallel BS also can fuse entangled photon pairs in to a larger-scale entangled state, as shown in Fig1. (e). It can be further extended to support richer quantum operations, such as quantum CZ gate.

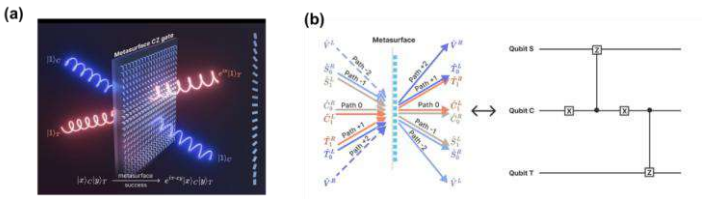

Figure 2 (a) Schematic diagram of polarization-encoded quantum CZ gate on single local metasurface; (b) Scheme of a cascaded quantum CZ gate.

Using the parallel BS with flexible splitting ratio, we can realize a CZ gate (Fig. 2(a)) or a cascaded CZ gate (Fig. 2(b)) on a single local metasurface. Taking advantage of the polarization-path correlation feature of paralle BS, both polarization-encoded and path-encoded CZ gates can be realized on the same metasurface [4].

2.2 BS on nonlocal metasurface

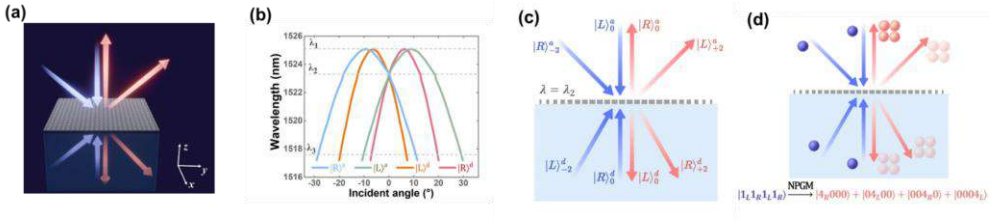

Figure 3 (a) Schematic of four-port BS on nonlocal metasurfaces; (b) Angular dispersion relations; (c) Four-port BS at λ_2; (d) Four-mode four-photon NOON state preparation on a metasurface.

Different from the above local metasurfaces, nonlocal metasurfaces exhibit selectivity of incident wavelengths and angles. Consider a nonlocal metasurface encoded with geometric phase gradient, as shown in Fig. 3(a). It can split one incident beam into four output beams symmetrically. Combining with the angular dispersion relations depicted in Fig. 3(b), we reveal that a series of independent four-port BS with selectivity of incident wavelengths, angles and polarization [5], just like the four-port BS at λ_2 shown in Fig. 3(c) with the transformation matrix like:

$$\begin{bmatrix} |R\rangle_{+2}^{d} \\ |L\rangle_{0}^{d} \\ |R\rangle_{0}^{a} \\ |L\rangle_{+2}^{a} \end{bmatrix}_{out} = \begin{bmatrix} 0.44e^{-i\times27^\circ} & 0.57e^{-i\times64^\circ} & 0.48e^{i\times91^\circ} & 0.50e^{-i\times44^\circ} \\ 0.57e^{-i\times63^\circ} & 0.45e^{-i\times60^\circ} & 0.49e^{-i\times96^\circ} & 0.48e^{i\times113^\circ} \\ 0.48e^{i\times92^\circ} & 0.49e^{-i\times96^\circ} & 0.59e^{-i\times115^\circ} & 0.42e^{-i\times95^\circ} \\ 0.50e^{-i\times44^\circ} & 0.48e^{i\times111^\circ} & 0.41e^{-i\times96^\circ} & 0.59e^{-i\times41^\circ} \end{bmatrix} \begin{bmatrix} |L\rangle_{-2}^{d} \\ |R\rangle_{0}^{d} \\ |L\rangle_{0}^{a} \\ |R\rangle_{-2}^{a} \end{bmatrix}_{in} \quad (2)$$

With this four-port BS, we can prepare four-mode four-photon NOON states, which are encoded in spatial modes and polarization modes, simultaneously, as shown in Fig. 3(d).

In summary, we reveal the BS properties on local and nonlocal metaasurfaces, which exhibit a series of parallel two-port BS and independent four-port BS, respectively. We further demonstrate its application in quantum state engineering, including entanglement manipulation, quantum CZ gates and NOON state preparation.

Birefringence-Driven Chiral Resonances in Lithium Niobate Metasurfaces

Bo Wang[1,*], Tingyue Zhu[1], and Junjie Li[1]

[1]Beijing National Laboratory for Condensed Matter Physics, Institute of Physics, Chinese Academy of Sciences, 100190 Beijing, China

Abstract: We demonstrate that the birefringence of lithium niobate (LN) material can induce strong coupling between two resonant modes of an LN metasurface, leading to hybridized elliptically polarized modes with opposite chirality. This achieves a giant chiral optical response, even though both the material and structure are achiral.

One of the remarkable capabilities of metasurfaces is to increase chiral-optical response by creating chiral resonant modes on metasurfaces, which can exhibit near-unity circular dichroism (CD) signals under normally incident light. Chiral resonant modes on metasurfaces usually result from geometric chirality of the building structures, such as subwavelength helices [1], some simpler asymmetric shapes with mirror symmetry broken [2], or asymmetric lattice [3]. In this study, we demonstrate that the intrinsic birefringence of lithium niobate (LN) can induce strong coupling between two resonant modes in a planar LN metasurface, leading to the formation of hybridized modes with opposite chirality [4].

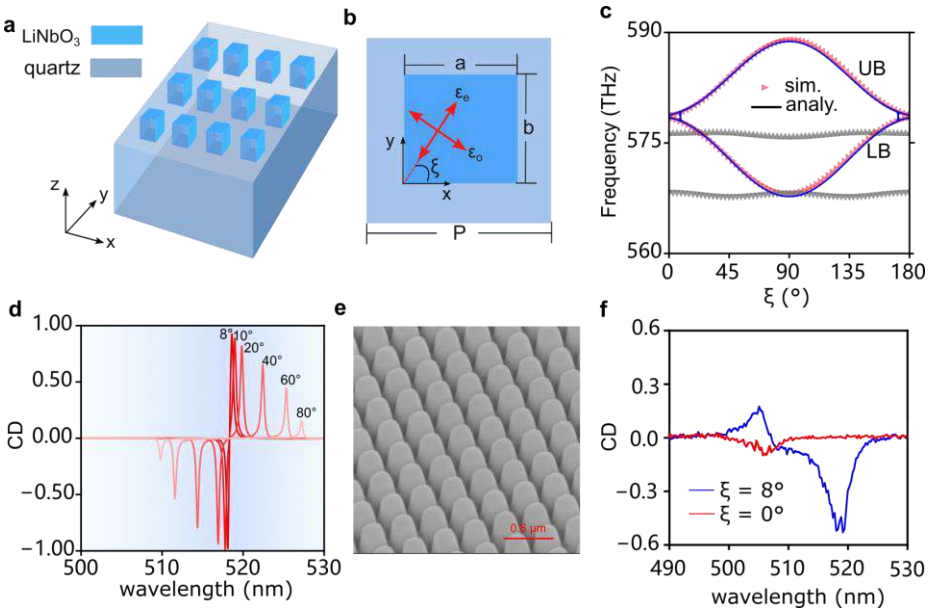

Figure 1 a, b Schematic of LN metasurface structure. c Simulated and analytic resonant frequencies. d, Simulated CD spectra. e, SEM images of the fabricated LN metasurfaces. f, Measured CD spectra.

Figures 1a and 1b show the structure of the LN metasurface. It is composed of periodic LN nanocubes, which are arranged in a square lattice with period p = 340 nm on a fused quartz substrate. Crystalline LN has negative uniaxial

birefringence with $n_o - n_e \approx 0.06$ in the visible spectral range. We show that this birefringence can induce the coupling between two resonant modes when the optical axis is rotated. The resonant frequencies of the mixed resonant modes are governed by an effective Hamiltonian,

$$\mathcal{H} = \begin{bmatrix} p_1 + \kappa_1 \sin^2\xi & \kappa \sin(2\xi)/2 \\ \kappa \sin(2\xi)/2 & p_2 + \kappa_2 \sin^2\xi \end{bmatrix}^{-1} \begin{bmatrix} \omega_1 p_1 & 0 \\ 0 & \omega_2 p_2 \end{bmatrix} \quad (1)$$

This effective Hamiltonian is verified by full wave simulations, as show in Figure 1c. We show that these resonant modes are chiral, presenting nearly full circular dichroism signals, as shown in Figure 1d. For the experiment demonstration, we fabricated the proposed metasurfaces on a commercially available LN films with the thickness of 300 nm on quartz substrate. The LN films were patterned with electron beam lithography and etched with inductively coupled plasma reactive ion etching technique. The scanning electron microscope images of the fabricated LN metasurfaces are shown in Figure 1e. The measured CD spectra, as shown in Figure 1f, validate the main features of our theoretical prediction of the chiral resonant modes induced by the birefringence. The discrepancies between experimental and simulated CD signals are attributed to dimensional deviations and slanting sidewalls in the real samples.

This work highlights a new approach to controlling chiroptical effects by leveraging material birefringence, offering a powerful tool for applications in nonlinear chiral metaphotonics. The results are significant because they demonstrate how achiral materials and structures can be combined to exhibit giant chirality, opening new avenues for the design of chiral optical devices.

Exploring Mesoscopic Plasmonics by Integrating Transformation Optics and Feibelman *d* Parameters

Fan Yang[1*]
[1]College of Physics, Sichuan University, Chengdu, Sichuan 610065, China
fyang@scu.edu.cn (corresponding author)

Abstract

Classical electrodynamics falls short in capturing plasmonic responses at the mesoscopic scale. Therefore, we introduce an innovative analytical framework that synergizes transformation optics with Feibelman d parameters. This approach offers a more efficient pathway to explore electronic nonclassical effects in complex nanostructures, surpassing the limitations of traditional density functional methods.

1 Introduction

The mesoscopic scale has garnered significant attention as it serves as a bridge between continuous medium descriptions and pure quantum mechanical frameworks. At this scale, the classical permittivity fails to accurately depict optical responses due to the emergence of nonclassical electron effects, such as nonlocality and electron spill-out. A comprehensive consideration of these quantum effects typically demands a time-intensive time-dependent density functional approach. Alternatively, the hydrodynamic model has been proposed to numerically investigate these nonclassical effects. Analytical methods for studying these nonclassical effects have been largely confined to flat surfaces, nanowires, and spherical particles. The advent of transformation optics has opened the door to analytical solutions for complex nanostructures. However, prior works utilizing transformation optics to study nonclassical effects have predominantly focused on the nonlocal effect of electrons, neglecting other nonclassical contributions. This incomplete description has motivated us to extend the existing analytical model. An elegant approach to incorporate the quantum effects dominant at the mesoscopic scale involves the use of Feibelman d parameters. By integrating the d parameter into the boundary conditions, both nonlocal and electron spill-out effects are accounted for.

2 Results

We consider a sodium nanowire dimer as a prototype to validate our theoretical approach, as depicted in Fig. 1(a). The inset of Fig.1(a) shows the electron distribution near the metal surface, where n_0 and n_1 represent the ground state and excited state of the electron, respectively. The electron distribution can be quantified using the surface d parameter, defined as

$$d_\perp = \frac{\int r n_1(r)\mathrm{d}r}{\int n_1(r)\mathrm{d}r} \qquad d_\parallel = \int \frac{n_0(r) \in n_j}{n_{ion}}\mathrm{d}r, \tag{1}$$

where the integration is performed along the direction normal to the metal interface, and n_j (n_{ion}) denotes the jellium (ion) density. We obtained these d parameters using quantum hydrodynamic model for a flat metal surface. The d parameter, being a surface response function, is solely determined by the materials forming the interface, allowing its application of d parameter in plasmonic structure with arbitrary shape.

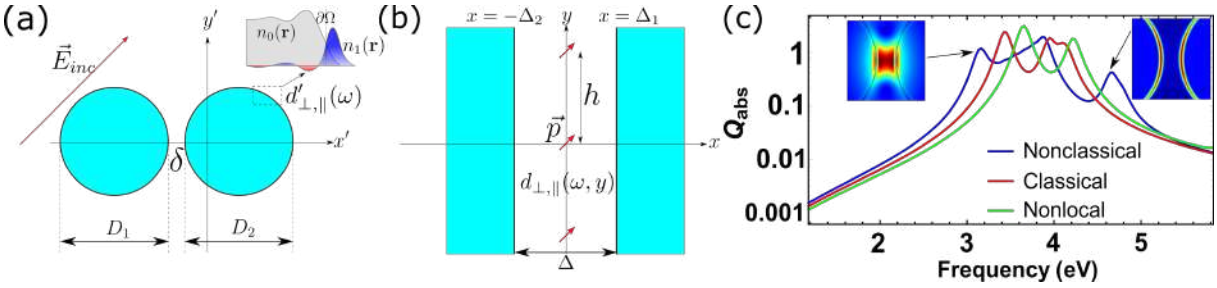

Figure 1: Integration of transformation optics and Feibelman d parameter. (a) The dimer consists of two closely spaced nanowires with diameters D_1 and D_2, separated by a gap δ. (b) The nanowire dimer is mapped into an MIM structure, with relevant geometric parameters labeled. (c) Absorption spectrum obtained by combining transformation optics and d parameters.

Direct calculation for the structure in Fig. 1(a) is challenging. Therefore, we transform it into a simpler metal-insulator-metal (MIM) geometry, as shown in Fig. 1(b). The incident plane wave in Fig. 1(a) is converted into a dipole array in Fig. 1(b), where the material permittivity remains unchanged during the transformation. However, the d parameter is not conserved in this transformation. In the dimer frame, the d parameter is solely a function of frequency, whereas in the transformed slab frame, it becomes both frequency and coordinate dependent. The relationship between the d parameter in the dimer frame $d'_{\perp,\parallel}$ and the d parameter in the MIM frame $d_{\perp,\parallel}$ is given by [1]

$$\frac{d_{\perp,\parallel}}{d'_{\perp,\parallel}} = \left|\frac{\mathrm{d}z}{\mathrm{d}z'}\right| = \frac{2h}{\pi g}\left|\sinh\left(\frac{\pi}{h}z\right)\right|^2, \tag{2}$$

where $z' = x' + iy'$ ($z = x + iy$) is complex coordinates in the dimer (MIM) frame.

With the d parameter in the slab frame, we can now analytically calculate the field profile and absorption in the presence of nonclassical effects. This transformation significantly simplifies analytical calculations. By integrating transformation optics and d parameters, we successfully reproduce the red-shift caused by electron spill-out and identify the emergence of the Bennett mode (Fig. 1(c)). This integrated framework provides a versatile tool for analytically investigating a wide range of nonclassical phenomena at the mesoscopic scale, including charging effects [2], DC biasing [3], mode coupling, and nonlinearities.

Abstract: Field-resolved terahertz near-field microscopy enables direct spatiotemporal mapping of polariton dynamics in graphene with subcycle temporal resolution. The spacetime maps yield key parameters of the polariton, like group and phase velocities as well as its damping. Femtosecond control of non-equilibrium polariton propagation is achieved by optical excitation.

Surface polaritons – light-matter excitations at interfaces – are widely studied for their strong field confinement and high propagation velocities, making them ideal for nanoscale waveguides and sensors [1]. Typically, near-field microscopy maps polariton dispersions frequency by frequency, yet real-space field-resolved detection of polaritons by broadband pulses (spacetime imaging) can offer new insights into their properties [2,3].

Here, we investigate surface plasmon polaritons (SPPs) in graphene using spacetime imaging in the terahertz spectral domain and manipulate their dynamics via ultrafast photoexcitation [4]. A terahertz pulse (red transient) is coupled to a sharp metallic tip of a near-field microscope and launches surface polaritons (Fig. 1a). These polaritons reflect at edges of the sample and return to the tip, yielding a delayed scattering response (blue transient). Additionally, an instantaneous scattering response appears due to the direct dielectric tip-sample interaction (green transient). By recording scattered waveforms at different distances to a graphene edge and subtracting the spatially homogeneous response we can directly trace the spatiotemporal evolution of the SPP wave packet (Fig. 1b, blue spheres). Very prominently, the electric field of the polariton is delayed in time with distance to the edge, yielding insights into the group and phase velocities of the polariton wave packet. The full propagation dynamics are captured by one global fit of all recorded traces (Fig. 1b, solid lines), revealing the decay of the wave due to damping (1/e decay length of ~2.31 µm) and the respective phase (~0.081c) and group (~0.045c) velocities (Fig. 1c). Additionally, our approach can be expanded to full 2D images, mapping distinct propagation directions at different edges (Fig. 1d). Access to the time domain also allows probing nonequilibrium dynamics with femtosecond precision (Fig. 1e). Ultrafast visible light pulses transiently modify graphene's conductivity, enabling subcycle SPP amplitude control (Fig. 1f) – much faster than electrostatic gating – paving the way for ultrafast plasmonic logic devices.

Beyond graphene, this method can be applied to a wide range of materials including anisotropic polaritons in black phosphorus and α-MoO_3, topological insulator surface modes, and other systems utilizing electro-optic sampling of scattered fields. Finally, the method offers an intuitive approach to visualize non-equilibrium polariton propagation, e.g. upon photoexcitation. With these abilities, phenomena like ultrafast plasmon amplification by optical pumping or Bloch polaritons could be directly investigated.

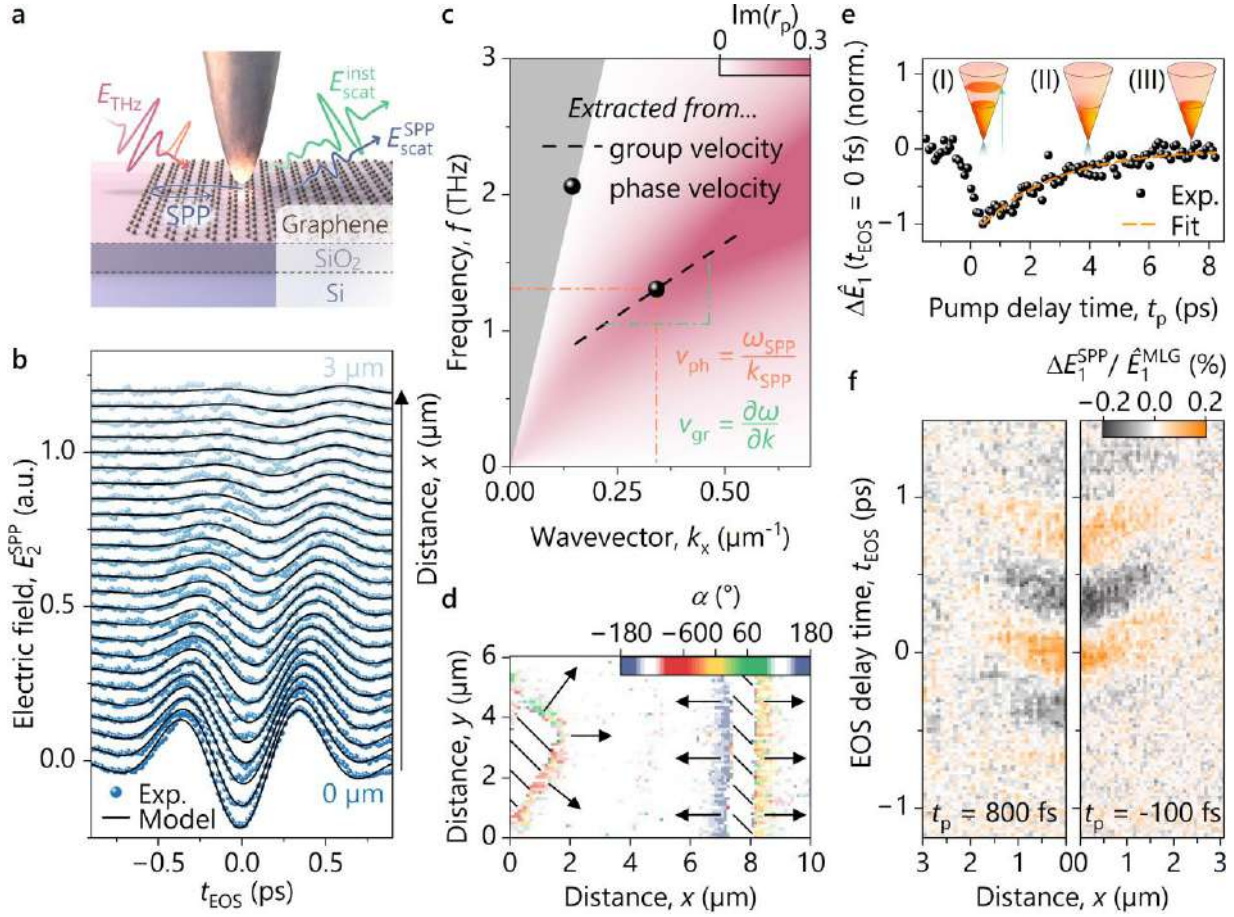

Figure 1. Time-domain imaging and ultrafast control of surface plasmon polaritons (SPPs) in graphene. a, Schematic: A THz pulse (red) incident on a tip launches SPPs, which reflect at the sample edge (blue arrows). The tip's scattered response comprises an instantaneous component (green) and a delayed component from propagating SPPs (blue). A pump pulse (orange) can be used for photoexcitation. **b,** Electric field of the propagating SPP for different distances to a graphene edge (x = 0 µm). A global fit (black lines) yields the polaritons' group and phase velocities as well as damping. **c,** Phase and group velocities determine the position and linear slope of the dispersion relation of the polariton (black sphere and dashed line). Background: Numerically calculated dispersion relation of the multilayer sample system. **d,** Extending the model to two dimensions allows one to visualize the propagation directions on a larger graphene sample. **e,** Photoexcitation (515 nm, 140 fs) of graphene creates a non-equilibrium carrier distribution (I), thermalizing to a Fermi-Dirac distribution (II). The pump-induced change of the electric peak field on graphene features a decrease with an exponential recovery (orange fit) to equilibrium (III). **f,** Map of the pump-induced change on the SPP's electric field for two pump delay times (t_p = 800 fs, left; t_p = -100 fs, right). Tuning the pump arrival time allows the SPP to be changed with femtosecond precision.

Plasmonic effects on the crystal transformation and emission control of luminescence particles

Hairong Zheng*, Huan Chen, Chengyun Zhang, Zhenglun Fu, Zhenglong Zhang_

School of Physics and Information Technology, Shaanxi Normal University, Xian, China, 710119

*Corresponding author: hrzheng@snnu.edu.cn

Abstract: Plasmonic effects produced by the metal nanostructures have presented potential applications in the field of spectral regulation including the intensity enhancement and lifetime reduction. It is also found that the plasmonic effect can help to drive fast in-situ crystal structure transformation.

Surface plasmon of metal nanostructures can produce significant local field effect under proper radiation, which can effectively control the optical spectral property and matter structure. For example, in the system of plasmonic nanocavity with rare earth doped nanoparticle, the luminescence decay time is reduced by 3 orders and emission intensity enhanced enormously. With assistance of localized surface plasmon resonance of Au nanoparticles, polycrystalline NaYF4 particle transforms to single crystal Y2O3 in tens of milliseconds, which opens an easy and rapid in situ way to achieve single crystal particle by taking advantage of plasmon-induced thermal and catalysis effects. In this talk, the luminescence regulation and crystal transformation of optical particles induced by surface plasmon effect of a tilted plasmonic nanocavity and metal nanostructures will be presented, and corresponding mechanism will be discussed too.

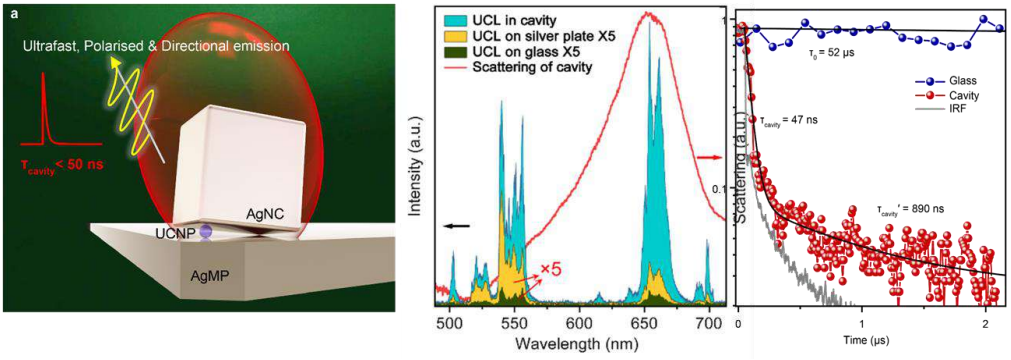

Figure 1. A titled plasmonic nanocavity with a hexagonal $NaGdF_4$:20 mol%Yb^{3+}/2 mol%Er^{3+} particle and experimental observation on the luminescence emission and decay.

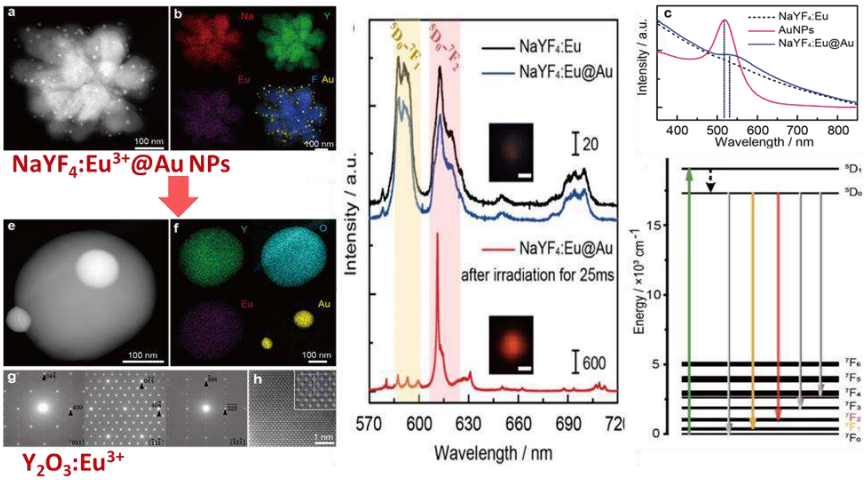

Figure 2. Transformation of polycrystalline $NaYF_4$ particle to single crystal Y_2O_3 with assistance of localized surface plasmon resonance of Au nanoparticles.

Memristive nanogaps with biophoton-like properties as a building block for advanced nanophotonic applications

M. Ćwierzona[1,2], D. Singh[1], K. Malchow[1], S. Hamdad[1] and A. Bouhelier[1*]
[1]Laboratoire Interdisciplinaire Carnot de Bourgogne, UMR 6303 CNRS, Université de Bourgogne Europe, 2100 Dijon, France

[*]corresponding author: alexandre.bouhelier@u-bourgogne.fr

Abstract: We demonstrate that memristive nanogaps can emit light during resistive switching, replicating key properties of biophotons observed in neurons. This dual electronic-photonic functionality enables new approaches for on-chip light generation, high-speed optical communication, and nanoscale optoelectronic integration, expanding the role of memristors in neuromorphic computing and advanced nanophotonic applications.

The need for more efficient computing units is rising with the recent emergence of energy-hungry Artificial Intelligence (AI) accelerators. Memristive networks can be used in Spiking Neural Networks technologies to implement biology-inspired information processing methods to create ultra-low power computing devices[1]. While the electrical properties of memristors are widely studied, their ability to emit photons is still relatively unexplored. Here, we focus on single memristive nanogaps, which release photons during resistive switching induced by an applied electric field (Figure 1). Resistive switching is usually achieved by stimulating the device with ramping voltage or applying several predefined voltage pulses of similar amplitude. Depending on the stimulation conditions, the device can be in a volatile state, i.e., it self-returns to the initial, high-resistive state after stopping the voltage stimulation, or it may be in a non-volatile state, allowing it to retain the high-conductance state after the voltage stimulation is finished. Rapid changes in conductance caused by the intrinsic dynamics of atomic diffusion typical for memristors operated in the volatile state provide the conditions needed to observe light emission in artificial neurons. This light emission replicates several key attributes of biophotons emitted by neurons during brain activity, including self-generation, stochasticity, broad spectral coverage, sparsity, and correlation with electrical activity[2].

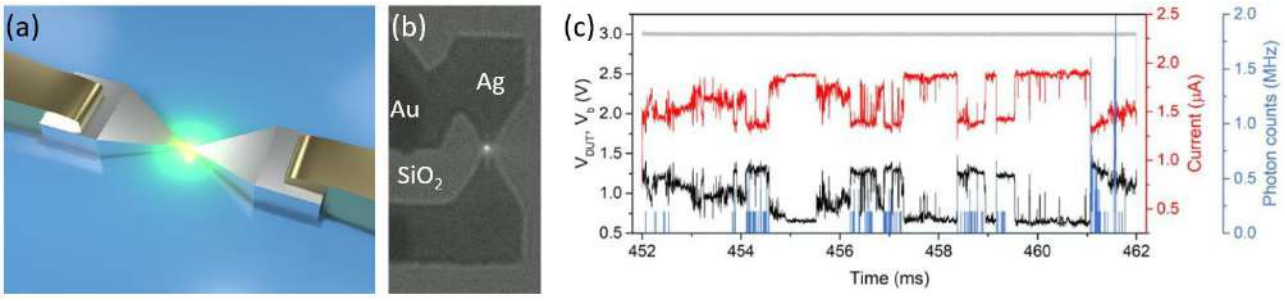

Figure 1. (a) Visualization of memristor light emission. (b) Bright-field image of memristive nanogap during light emission. (c) Time traces of the current flowing through the artificial memristive neuron (red trace), the actual voltage dropped at the memristor (black trace), and the photon emission (blue trace) during a single 10 ms voltage pulse of 3V (grey trace).

Several mechanisms leading to light emission in metal-insulator-metal memristors have been identified, including electron trap luminescence[3], inelastic tunneling[4], and overbias emission[4]. Depending on the voltage stimulation history of the memristive junction, the same device can exhibit emission resulting from one or a combination of the aforementioned mechanisms. Many luminescent point defects spanning a wide energy window can be present in the switching matrix even before the stimulating voltage is applied[5]. In addition, electroluminescence defects can also be self-generated during the switching process due to the formation and aggregation of oxygen vacancies, which provide a strong source for the memristors' photon emission. We also observe electromagnetic radiation with photon energies exceeding the kinetic energy of electrons given by the stimulating voltage when the memristor undergoes volatile switching. This emission is described by a thermal radiation model, where hot carriers radiatively decay to optical modes with an effective temperature surpassing 2000 K.

Our findings expand the capabilities of memristors to include not only their electrical but also optical properties. This is the first step towards developing more complex memristive devices that could operate with electrons and photons simultaneously. Exploring this kind of dual functionality enables new approaches for on-chip light generation, high-speed optical communication, and nanoscale optoelectronic integration, expanding the role of memristors in neuromorphic computing and advanced nanophotonic applications.

Electrically driven functional plasmonic nanocavities

Pan Wang

State Key Laboratory of Extreme Photonics and Instrumentation, College of Optical Science and Engineering, Zhejiang University, Hangzhou 310027, China
*corresponding author: nanopan@zju.edu.cn

Abstract: In this work, based on single-crystal metallic building blocks, we demonstrate electrically driven functional plasmonic nanocavities with multifunctionality.

Enhancement and active control of light-matter interactions at the atomic scale is important for developing next-generation nanophotonic and quantum optical devices. However, it is challenging to realize with conventional dielectric photonic nanostructure. In this work, based on single-crystal metallic building blocks, we demonstrate electrically driven functional plasmonic nanocavities with multifunctionality. First, we will introduce the fabrication of ultrasmooth single-crystal gold flakes with tunable thickness down to 1 nm and an atomic level prevision [1]. Then, we introduce the realization of low-loss plasmonic nanocaivites by depositing single-crystal gold nanocubes on an ultra-smooth, single-crystal gold flake, which are separated by a nanometer-thick alumina as the dielectric layer. Benefitting from the single-crystal structure of the used building blocks, as-fabricated plasmonic nanocavities have a low loss which approaches the theoretical optical quality limit [2,3]. Finally, we demonstrated electrical integration of plasmonic nanocavities, by applying a low bias across the nanometer-thick gap of the nanocavites, active modulation of strong coupling and electroluminescence were realized [4].

Electrically driven functional plasmonic nanocavities provide a versatile platform for strong enhancement and active control of atomic-scale light-matter interactions and open opportunities for developing next-generation optoelectronic and quantum optical devices that can seamlessly interface electronics and photonics at the nanoscale.

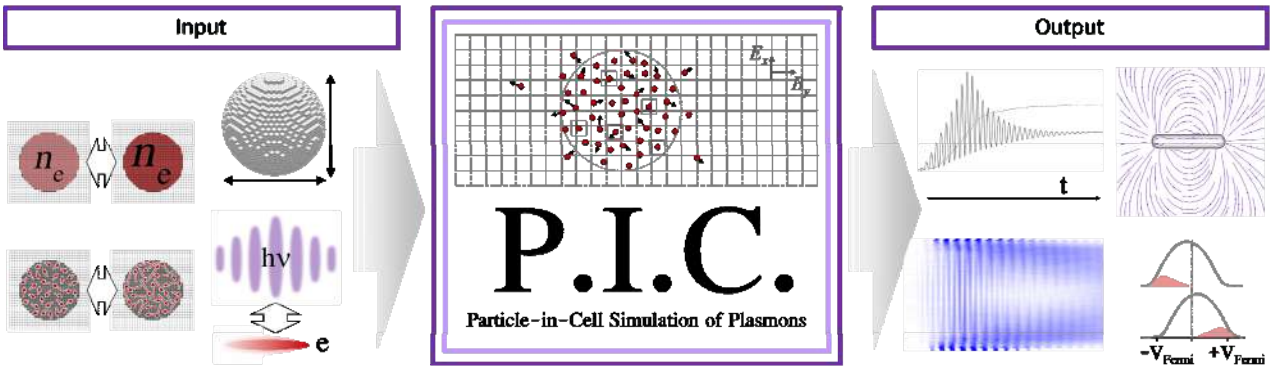
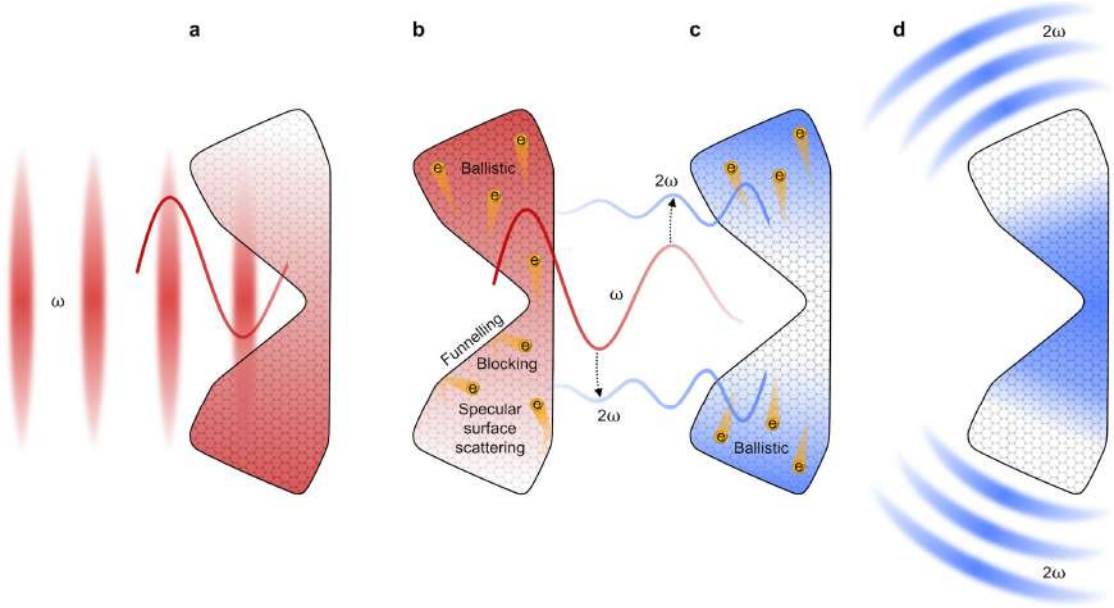
Particle-in-Cell (PIC) Simulations for Next-Gen Nanoscopic Photonics and Plasmonics

Lin Wu*



Singapore University of Technology and Design (SUTD), 8 Somapah Road, Singapore 487372
*Corresponding author: lin_wu@sutd.edu.sg

Abstract: Room-temperature metals and semi-metals, acting as cold quantum plasmas, enable Particle-in-Cell (PIC) simulations for next-gen nanoscopic studies in photonics and plasmonics. Our recent work examines graphene antennas and nonlinear electron transport in graphene plasmon resonators, revealing novel even-order nonlinearities for frequency-tunable infrared upconversion.



Since the 1940s, computational simulations have revolutionized physics, particularly in electromagnetism, where the interaction of charged particles governs many phenomena. Plasmas, often linked to extreme environments, can also be found in solid materials like metals and semi-metals, where quasi-free electrons behave as quantum plasmas. Traditional methods like Finite-Difference Time-Domain (FDTD) and Finite Element Method (FEM) effectively model static dielectric functions but struggle with dynamic materials, especially in quantum plasmas where electron dynamics significantly impact behavior. The Particle-in-Cell (PIC) method, traditionally used for plasmas, models both the electromagnetic field and charged particle motion self-consistently, making it ideal for simulating quantum plasmas in time-dependent scenarios[1-4].

In PIC simulations, resonator geometry, excitation source, electron density, and initial energy distribution are defined. Maxwell's equations and Vlasov's equations of motion are solved iteratively to update the electromagnetic field and particle dynamics. The particle velocity is deposited as current density for Maxwell's solver, and the particle pusher interpolates the field at each particle's position. This approach directly calculates the electric field, particle position, and momentum, allowing the derivation of parameters like plasmon amplitude, decay times, and particle distributions.

We recently proposed a new mechanism for second-harmonic generation via geometrically rectifying, or funnelling, ballistic electrons in THz optical resonators[4]. Our PIC simulations show that femtosecond electron-surface scattering is crucial in this process. We distinguish electron funnelling from nonlocal plasmonic drag and bulk Dirac anharmonicity, demonstrating that funnelling can reduce the required field intensity for second-harmonic generation by 3-4 orders of magnitude. We provide design guidelines for funnelling-induced second-harmonic generation, including resonance mode matching and material selection. This approach enables low-field, geometrically tunable THz upconversion and rectification, effective from sub-10 THz to tens of THz in graphene.

Hyperbolic photonic topological insulators and quantum sources

Lu He, and Xiangdong Zhang*

Key Laboratory of advanced optoelectronic quantum architecture and measurements of Ministry of Education, Beijing Key Laboratory of Nanophotonics & Ultrafine Optoelectronic Systems, School of Physics, Beijing Institute of Technology, 100081 Beijing, China.

*zhangxd@bit.edu.cn

In this talk, we will introduce hyperbolic photonic topological insulators and their application. We experimentally realize hyperbolic photonic topological insulators on silicon chips using coupled ring resonators and hyperbolic topological quantum sources. They show the higher utilization efficiency of resonators, showing great potential for integrated quantum chips.

Chiral plasmonic nanoparticle-molecule hybrids for circularly polarized OLEDs

Lei Shao[1*]

[1]State Key Laboratory of Optoelectronic Materials and Technologies, Guangdong Province Key Laboratory of Display Materials and Technologies, School of Electronics and Information Technology, Sun Yat-sen University, Guangzhou 510275, China

[*]corresponding author: shaolei5@mail.sysu.edu.cn

Abstract: We demonstrate circularly polarized organic light-emitting diodes with an emission dissymmetry factor of 0.31 based on the assembly of chiral plasmonic nanoparticles and supramolecular aggregates. The chiral nanoparticles serve as the chiral scaffold and chiral optical nanoantenna to modulate the circularly polarized absorption and emission of the supramolecular chromophores.

Organic light-emitting diodes (OLEDs) supporting the direct emission of circularly polarized (CP) light are essential for numerous technologies. It is challenging to achieve CP-OLEDs with large dissymmetry (g_{EL}) factors and high external quantum efficiencies (EQEs). In this work, we have developed CP-OLEDs exhibiting extraordinary circularly polarized electroluminescence (CPEL) asymmetry (emission dissymmetry factor $g_{EL} \approx 0.31$) and luminous efficiency (EQE $\approx$ 2.5%) based on (chiral plasmonic nanoparticle)–(molecule aggregate) hybrids. The chiral nanoparticles (NPs) serve as scaffolds directing the chiral stacking of molecule aggregates to generate chiral excitons or plasmonic nanoantennas polarizing emitted photons. The proposed method only involves the design of the emissive layer and does not require any specialized changes on the OLED device architecture or molecular modification on the chromophore. Our strategy is therefore compatible with the current manufacturing technology of OLEDs and can also be applied to devices with different structures. We believe designing (chiral NP)–(molecule aggregate) hybrids with both strong chiral excitonic and plasmonic properties will bring further improvement of the circular polarization asymmetry in the EL emissions. In addition, the capability of chiral plasmonic NPs in controlling the chiroptical properties of supramolecular chromophores enables rich chiral plasmon–exciton interactions at the single-nanostructure level, making chiral plasmonic NPs promising candidates for constructing other chiral photoelectric devices, such as non-reciprocal nanoscale light sources and deterministic spin–photon interfaces for quantum networks, without the need for precision design and complex manufacturing.

Strong coupling with excitons and one-dimensional photonic crystal modulated plasmonic nanocavities

Xiulai Xu *

School of Physics, Peking University, China
*corresponding author: xlxu@pku.edu.cn

Abstract: Strong light-matter interaction with plasmonic nanocavities with challenges like Ohmic losses, low quality factor and precise emitter positioning, makes it difficult for real applications. Here, we demonstrate room-temperature strong coupling by integrating plasmonic nanostructures with 2D materials, photonic crystals, and quantum dots, resulting in reduced exciton numbers and improved stability.

Plasmonic nanocavities can achieve strong light-matter interactions by confining electromagnetic fields below the diffraction limit. However, challenges such as Ohmic losses, low quality factor, and sensitivity to emitter positioning have hindered deterministic coupling at the single-quantum level. We systematically addressed these limitations through innovative cavity designs, integrating plasmonic nanostructures with photonic crystals, ultimately enabling room-temperature strong coupling with lowest exciton numbers using two-dimensional (2D) materials.

Firstly, we demonstrated robust plasmon-exciton coupling using gold bowtie nanocavities and mechanically exfoliated MoS_2 layers. By utilizing gold-assisted exfoliation and wet transfer techniques, large-area MoS_2 flakes were deterministically placed over bowtie arrays, achieving Rabi splitting of 80-110 meV. Due to the ultrasmall mode volume (~10^3 nm^3) and in-plane field localization, strong coupling at room temperature was desmonstrated with a reduced exciton number to N $\approx$ 40-48 (Figure 1a).

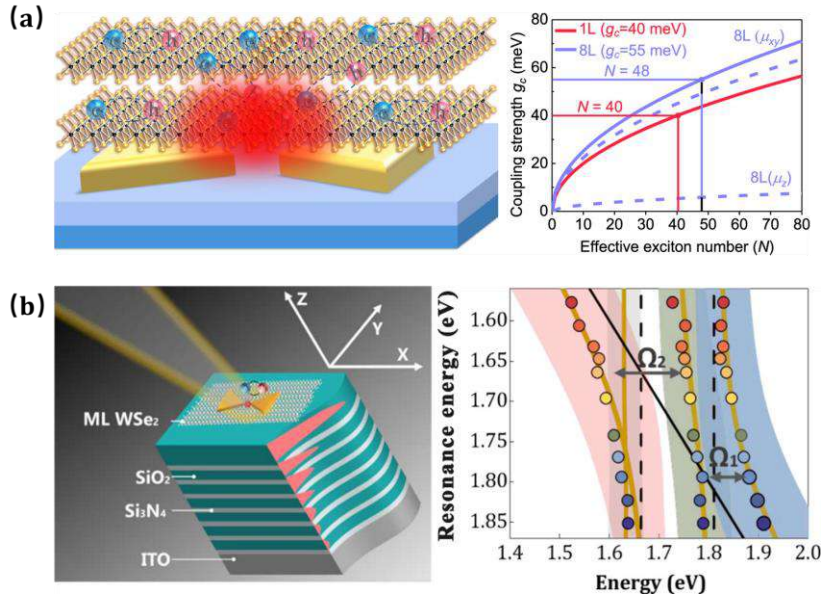

Figure 1 Strong coupling of 2D excitons with bowtie nanocavity at low exciton number. (a) Robust plasmon-exciton coupling with monolayer and few layer MoS_2. (b) Strong coupling using one-dimensional photonic crystal modulated bowtie with an exciton number less than 10.

Recently, we introduce a hybrid cavity nanostructure consist of bowtie nanocavity and one-dimensional photonic crystal (1DPC) to further compress mode volumes and tailor electric fields via Bloch surface waves (Figure 1b). The 1DPC composed of alternating Si_3N_4/SiO_2 layers strongly suppress the plasmon damping and enhanced in-plane field components, with a plasmonic mode volume down to 446 nm^3. Experimentally, we achieve a Rabi splitting of 186 meV with monolayer WSe_2, corresponding to an effective exciton number of about 8.

To extending this platform to strong coupling at the single quantum level, we embedded CdSe/ZnS quantum dots (QDs) in the hybrid cavity's nanogap. The uniform electric field distribution in nanogap indicates a robust coupling strength for the variations of QDs position. Dark-field scattering spectra show a stable Rabi splitting of approximately 170 meV for single QDs. The hybrid cavity's robustness against fabrication imperfections and quantum dot position marks a critical step toward scalable quantum photonic circuits.

[2] National Center for Nanoscience and Technology, China
[*]corresponding author: daiqing@sjtu.edu.cn

Abstract: Our research explores the manipulation of polaritons in low-dimensional nanomaterials for efficient on-chip optoelectronic interconnects. Key advances include enhanced excitation in van der Waals materials, precise transmission control in heterostructures, and graphene-plasmonic infrared sensing, providing novel solutions for nanoscale optical manipulation and advanced sensing applications.

Polaritons are well-established carriers of light, electrical signals, and even heat at the nanoscale. Achieving control over it is pivotal for the realization of nanoscale manipulation of light signals and even heat within on-chip devices. Our research focuses on efficient excitation, precise manipulation, and high-sensitivity detection of polaritons in one-dimensional to two-dimensional nanomaterials within complex dielectric environments and has achieved a series of original breakthroughs.

In terms of **excitation**, we have developed a new theoretical model for electronic excitation[1,2] and a novel excitation source based on synthetic waves of complex frequency[3,4]. These advancements have significantly enhanced the excitation efficiency of polaritons in van der Waals materials, providing new insights into the design of on-chip light sources.

For **manipulation**, through employing techniques such as suspension[1,5], heterostructures[6], chemical doping[5,6], and electrical modulation[7], we have achieved precise control over the transmission modes, propagation distance, and directions of polaritons, enabling phenomena such as negative refraction[7] and in-plane cloaking[8].

Regarding **detection**, we have developed an infrared sensing chip enhanced by graphene plasmons, enabling high-sensitivity infrared spectroscopy at the nanoscale[9-11]. This technology has been applied in biological sample analysis and catalysis research, demonstrating its potential for advanced sensing applications.

Our research presents innovative solutions for nanoscale optical manipulation and advanced sensing applications, paving the way for the development of highly integrated optoelectronic interconnect chips.

Thermal Emission Control and Applications of Metasurfaces

Xiaohe Shang[1], Ye Zhang[1], Fan Zhong[2], Shining Zhu[1] and Hui Liu[1*]

[1] Collaborative Innovation Center of Advanced Microstructures, National Laboratory of Solid State Microstructures, School of Physics Nanjing University Nanjing, China;

[*]corresponding author: liuhui@nju.edu.cn

Abstract: We propose an integrated metasurface-based thermal emission chip with multi-degree-of-freedom control (wavelength, polarization, direction) and advanced detection. These innovations enable precise infrared emission and detection for industrial inspection, medical diagnosis, and environmental monitoring by leveraging bound states in the continuum, micro-area thermal imaging, and AI-assisted signal analysis.

In recent years, thermal emission has attracted considerable research interest due to its significant potential in applications such as radiative cooling, near-field heat transfer, and thermophotovoltaics. Current efforts in thermal emission control and detection typically rely on micro-nano structures like multilayer films and photonic crystals, with relatively little attention given to the role of metasurfaces in thermal emission. This gap in research limits the precise control of thermal emission across multiple degrees of freedom, including wavelength, polarization, and direction, restricting further advancements in infrared light sources and detection technologies.

To address this challenge, our research group has proposed a metasurface-based thermal emission chip design to enable precise multi-degree-of-freedom control and detection of thermal emission[1]. Our work in thermal emission control has achieved significant milestones, including directional control of thermal emission[2,3], the application of topological and non-Hermitian systems in thermal emission[4,5], and the development of metasurface chips for wavelength, polarization, and spatial multiplexing, along with their application in indirect spectral detection[6,7].

Building on these achievements, we have proposed the development of a multifunctional, integrated metasurface-based thermal emission chip and a corresponding detection system. This includes (1) a polarization vortex thermal emission chip designed using bound states in the continuous(BICs); (2) polarization angle-resolved thermal emission measurement and micro-area thermal imaging characterization techniques; and (3) an artificial intelligence-assisted system for the efficient detection of complex spectral mixtures. These innovations provide new approaches to achieving precise multi-degree-of-freedom control of thermal emission and demonstrate the feasibility of translating thermal emission chips from theoretical design to practical applications. Furthermore, we have outlined an integrated technological path for their use in infrared detection. Moving forward, we will continue to explore the mechanisms for multi-degree-of-freedom control in thermal emission chips, providing both fundamental innovation and practical engineering solutions for applications in industrial inspection, medical diagnosis, and environmental monitoring.

Plasmon-Modified Light Emission from Monolayer Semiconductors

Hong Wei*

Institute of Physics, Chinese Academy of Sciences, Beijing 100190, China
*corresponding author: weihong@iphy.ac.cn

Abstract: The extraordinary properties of surface plasmons in metal nanostructures make it possible to enhance and manipulate light-matter interaction at the nanoscale. In this talk, I will present our work on the interaction between plasmonic nanostructures and monolayer transition metal dichalcogenides, with the focus on the light emission properties.

Metal nanostructures supporting surface plasmons can concentrate light into nanoscale volumes, enabling the manipulation of light beyond the diffraction limit. Two-dimensional semiconductor materials such as transition metal dichalcogenides possess unique optical properties, showing large application potentials. The combination of plasmonic nanostructures and two-dimensional semiconductor materials provides a versatile platform for investigating light-matter interaction at the nanoscale.

In this presentation, I will introduce our research on the coupling systems of plasmonic nanostructures and monolayer transition metal dichalcogenides. The interaction between them can not only lead to the plasmon-exciton strong coupling shown by the spectral splitting in the scattering or transmission spectra, but also modify the photoluminescence and Raman scattering properties of the monolayer semiconductors.

High-Contrast Ratio Optical Switching in multilayer Fabry-Perot Cavities with Phase Change Materials

Ruhao Pan[1*], Bo Wang[1], Zhiyang Tang[1], and Junjie Li.[1]

[1] Beijing National Laboratory for Condensed Matter physics, Institute of Physics, Chinese Academy of Sciences, Beijing 100190, China.

[*]corresponding author: panruhao@iphy.ac.cn

Abstract: This work proposed a multilayer Fabry-Perot (FP) cavity to achieve optical switches with high contrast ratio by introducing the $Ge_2Sb_2Se_4Te$ (GSST) as phase change material. Due to the distinctive FP resonances for the amorphous and crystalline GSST, a high contrast ratio of 2410/735 can be obtained by simulation/experiment.

Optical switches are widely utilized in the fields of optical communicating, computing, and data storage, and thus attracted tremendous attention of researchers[1, 2]. However, it is still a challenge to achieve high contrast ratio switches simultaneously with the advantages of compact size, low fabrication cost, and easy integration. Here, we design a multilayer FP cavity by introducing the GSST for its low intrinsic loss, high optical contrast, and non-volatile property[3] as shown in **Fig. 1**. The index changes of the GSST during the phase-change process contribute to the change of FP resonance, resulting in the reflectance with distinctive level for the amorphous and crystalline states, which resulting in an optical switching capacity at the communication band. The operating wavelength can be continuous tuned from 1460 nm to 1630 nm by modulating the thickness of the GSST and the dielectric layers in the cavity, meaning that our switches cover the “S”, “C”, and “L” band. The highest contrast ratio of 2410/735 can be obtained by simulation/experiment for the optimized thickness of the phase-change material (PCM). Interestingly, the contrast ratio of the switches can be tuned in the range of 570-730 by the GSST with different crystallization ratios for which can be continuously regulated by the annealing temperature. The demonstration of optical switches with GSST showing great advantages of small footprint, high contrast ratio, and low fabrication cost, providing a new strategy for the design of optical communication systems and data storage devices.

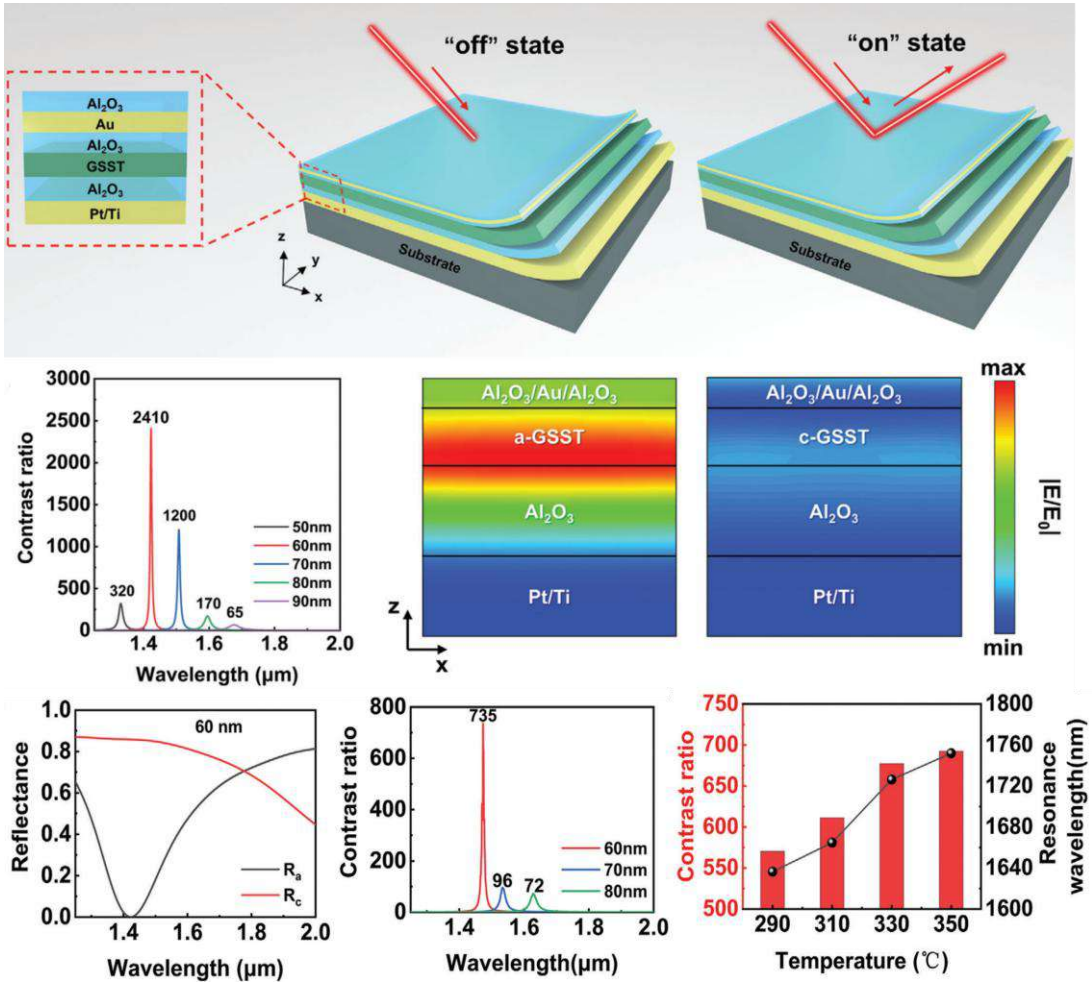

Fig. 1: The design of the GSST-based multilayer optical switches with its optical properties.

Monte Carlo Simulation for Dense Nanoparticle Dispersion with Rigorous Treatment of Particle Types and Distributions

Changgyun Noh[1], Seokhwan Min[1], and Jonghwa Shin[1*]

[1]Korea Advanced Institute of Science and Technology, 291 Daehak-ro, Yuseong-gu, Daejeon, Republic of Korea
[*]corresponding author: qubit@kaist.ac.kr

Abstract: We develop Monte Carlo-based optical simulation for nanoparticle dispersion with high accuracy and versatility. Our approach incorporates dependent scattering with structure factor and rigorously accounts for particle types and distributions. It is applicable to various structures, including multimodal probability density functions, multi-shell configurations, and multi-composition structures, enabling comprehensive optical analysis.

Nanoparticle dispersion is used to tailor a structure's optical properties by exploiting the scattering effects of the nanoparticles. Therefore, it is widely used in applications such as optical diffusers, antireflective coatings, displays, and radiative cooling due to its ease of processing and scalability. Accordingly, extensive research is underway to predict accurately the optical performance of this structure. For instance, methods that solve Maxwell's equations, such as the Finite-Difference Time-Domain (FDTD), Finite Volume (FV), and Finite Element Method (FEM)—are employed to predict the behavior of electromagnetic waves. However, these approaches are computationally expensive and time-consuming.

Consequently, a simulation tool that combines Monte Carlo methods with Mie theory is proposed to more efficiently predict the optical characteristics of this structure. However, previous studies either neglected inter-particle correlations or assumed that uniform size and type of nanoparticles are dispersed in the medium. Consequently, when the particle volume fraction is high or the probability density function is multimodal, the simulation results deviate from the experimental results. Therefore, we calculate the scattering cross section and phase function for overall particles in the dispersion based on Mie theory, ensuring accurate computations even for nanoparticle dispersions with bimodal or random distributions. In addition, we calculate the structure factor to account for the interaction between particles. These corrections are applied to the scattering cross section and phase function, as shown in Eqs. (1) and (2), and employed in the Monte Carlo simulation. In the equations, ζ is the near-field factor for accuracy, and $S(\theta)$ is the structure factor.

$$C_{sca,corr} = |\zeta|^2 \int_{\phi=0}^{2\pi} \int_{\theta=0}^{\pi} \frac{dC_{sca}}{d\Omega} S(\theta) \sin\theta \, d\theta d\phi \tag{1}$$

$$\Phi_{\mathrm{corr}}(\theta) = S(\theta)\Phi(\theta) \tag{2}$$

Unlike previous studies that calculated effectively, our approach computes the scattering properties of all particles within the structure. As a result, the simulation can be applied not only to structures containing solid spherical particles but also to those including various types of particles, such as multi-shell particles, and able to deal with dispersions with nanoparticles of varying sizes. This is illustrated in Fig. 1 below.

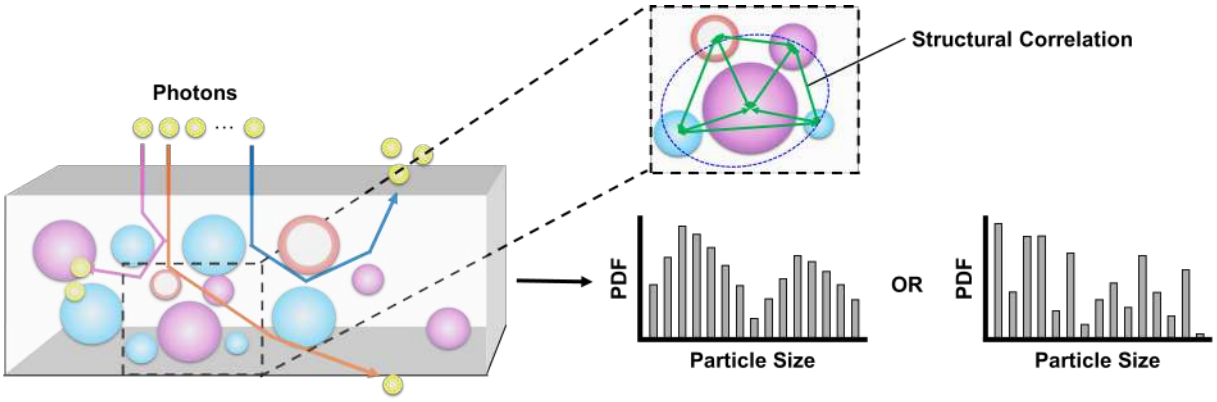

Figure 1. Schematic figure of simulation

This simulation can be utilized to accurately design nanoparticle dispersions composed of multiple particles and multi-layered structures. Therefore, we design the color paints with multilayer nanoparticle dispersions. The bottom layer contains TiO_2 nanoparticles for high reflection, while the layers above consist of Ag/SiO_2 core-shell nanoparticles. By controlling the SiO_2 core size, Ag shell thickness, the volume fraction of the nanoparticles, and the thickness of the layer, we can tune the reflection spectrum to achieve the desired paint color. As a result, by dispersing Ag/SiO_2 nanoparticles, we design paint with absorption peaks, thereby achieving a wide range of colors. Figure 2 illustrates one of the designed structures, along with their corresponding spectra and color under D65 illumination.

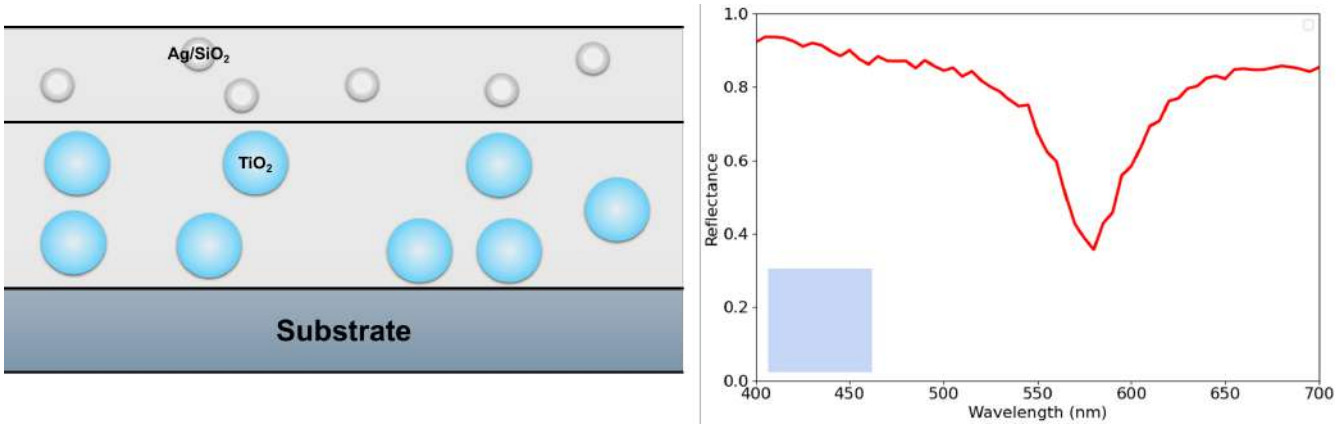

Figure 2. Multilayer nanoparticle color paint and its spectra and color

Strong near-field enhancement through SPhP and LSP coupling on CdO gratings

P. Ibañez-Romero[1], M. Villanueva Blanco[1], E. Martinez Castellano[1], J. Yeste[2], F. Gonzalez-Posada[3], T. Taliercio[3], V. Muñoz-Sanjosé[2] , M. Montes Bajo[1], and A. Hierro[1]

[3] Univ. Montpellier, IES. UMR 5214, F-34000, Montpellier, France

The coupling between plasmonic modes and phonons enables new approaches for tailoring optical properties and controlling light at the nanometer scale. Here, we demonstrate the dramatic amplification of the near-field driven by the coupling of sapphire's localized surface phonon polaritons and localized surface plasmons in CdO gratings.

CdO stands out as the best semiconductor for plasmonic applications in the mid-IR [1] thanks to its high plasma frequency and low losses. When nanostructured, it can host localized surface plasmons (LSP) whose resonant frequency can be tuned via nanostructure geometry. On the other hand, polar dielectrics, like sapphire, have drawn increasing attention in the last years due to their ability to host localized surface phonon polaritons (LSPhP) [2]. These modes allow sub-diffraction confinement in the mid-IR and very sharp resonances paired with extremely low losses [3]. We demonstrate the progressive coupling between CdO LSP and the LSPhP held by the sapphire-air interface by adequate design of CdO nanostripes. Experimental spectra obtained through Fourier Transformed Infrared Spectroscopy are backed by a Finite Element Methods model showing outstanding near field enhancement at the coupling frequency.

A set of samples was designed and fabricated using a novel protocol developed in-house. The process is illustrated in Figure 1a. It begins with the MOCVD deposition of CdO films on top of a r-plane sapphire wafer. Then, standard e-beam lithography followed by ICP etching is used to define periodic nanostripes (Figure 1b), with a period d=2 μm and an opening (w) from 1 μm to 200 nm. From now onwards we will use the fill factor (w/d) to refer to the geometry of the samples, ranging from 0.9 to 0.5.

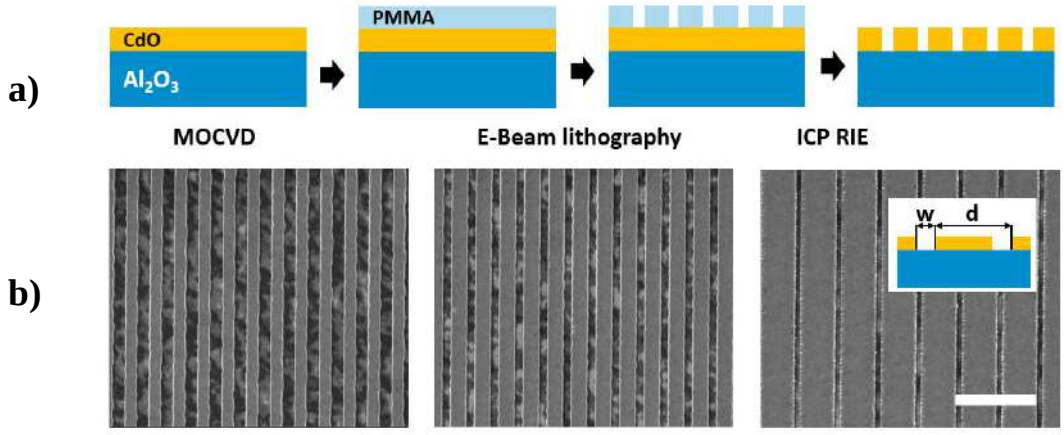

Figure 1. a) Processing scheme of the CdO nanostripes. b) SEM images of nanostripes with fill factors ranging from 0.5 (leftmost) to 0.9 (rightmost). The white bar measures 4 μm. The inset shows the design parameters.

The plasmonic response of the samples shown above is displayed in Figure 2a, where the black line corresponds to reflectivity measurements and the blue and red line are extracted from a FEM model, yielding a very high agreement. Starting with the sample with 0.5 fill factor, the response is characterized by a broadband LSP centered at 1400 cm^{-1} and a LSPhP located in sapphire's Reststrahlen band. As the fill factor increases (i.e the separation between stripes decreases and the stripe width increases), the LSP shifts towards lower energies effectively coupling with the LSPhP and thus increasing the overall absorption (red line) of the system at the latter's resonant frequency. Finally, when the distance between the stripes is small (fill factor 0.9) the LSP and the LSPhP become resonant, and the latter is shifted to slightly higher energies. At such frequency, the interaction in the near field is outstanding. The intensity of the electric field at the LSPhP frequency is plotted for the three samples in Figure 2b. When the LSP and the LSPhP are fully coupled, the intensity enhancement is around 1200, proving to be an outstanding platform for the observation of rare optical effects and its application in sensing systems and IR sources.

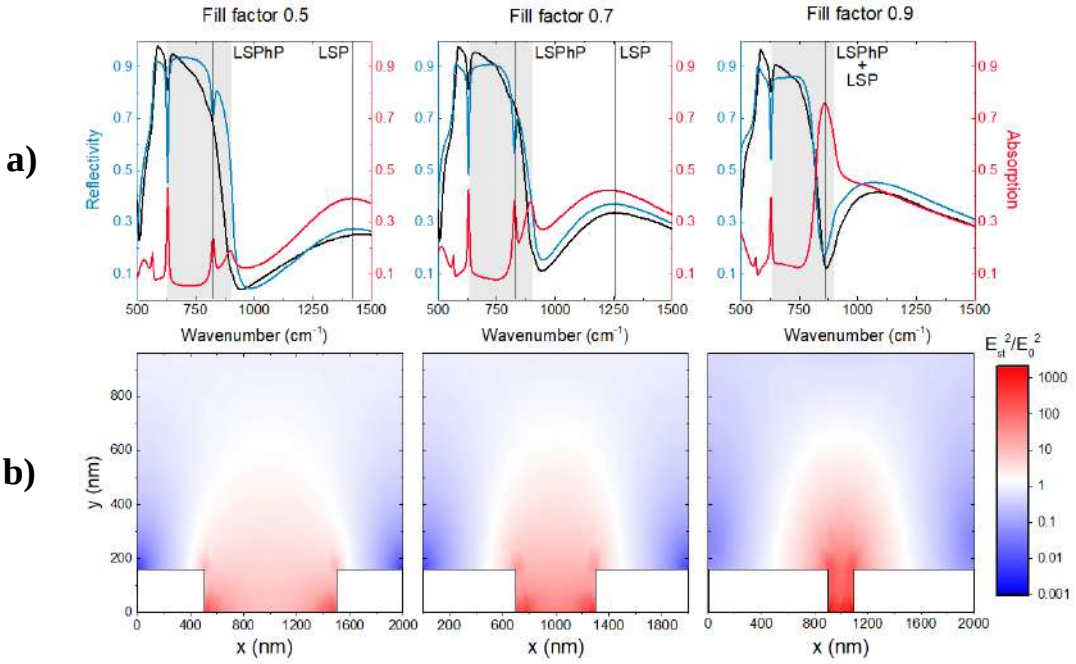

Figure 2. a) Measured (black) and modeled (blue) reflectance spectra for different fill factor nanostripes along with the modeled absorption (red). The shaded area corresponds to sapphire's Restsrahlen band. b) Near field simulations for different fill factors. The enhancement is obtained by comparing the electric field distribution with and without the stripes.

Abstract: Spectroscopic differences between photoexcited and surface plasmon polariton-induced hot electrons reveal distinct energy and momentum distributions. Time-resolved photoemission electron spectroscopy captures their dynamics in real- and momentum-space, enabling a clear separation of both carrier types. These results provide new insights into plasmonic energy conversion and hot electron generation.

Are the spectroscopic properties of plasmon- and photon-induced carriers fundamentally different? This question is crucial for the advancement of plasmonic energy conversion. Electrons excited at bulk plasmon resonance show a distinct distribution in energy and momentum space [1], while the electron distribution of surface plasmon-induced carriers is still under debate [2]. To address this issue for surface plasmons, we aim to separate the energy and momentum distributions of surface plasmon polariton-induced hot electrons from those of photoexcited ones. Exciting a circular ring-slit geometry with radially and azimuthally polarised light, we can clearly separate the plasmon and photon-induced hot carriers in space and time with two measurements. Our time-resolved photoemission electron microscope is then able to capture their signatures in real time. In this contribution, we show that there are spectroscopic differences between photoemitted electrons and those generated by plasmoemission in the centre of the structure.

Abstract: We study how molecular chirality influences electromagnetically induced transparency and lasing without inversion, revealing key chiroptical effects and quantum coherence phenomena. These insights are essential for advancing spectroscopic techniques, improving the detection and characterization of chiral molecules, and enhancing applications in quantum optics and molecular spectroscopy.

Chiral sensing plays a key role in the pharmaceutics because the specific enantiomeric form of drugs affects their functionality and toxicity [1], and thus nanophotonic-based platforms [2] are promising for nanomedicine. Here we focus on the behavior of a single chiral molecule in vacuum, Fluorooxirane, as a model system for exploring quantum coherence phenomena. Fluorooxirane, chosen for its rigid chiral scaffold despite its instability, was subjected to both a strong pump field and a signal field without any temporal delay. The interaction revealed interesting results, sparking hypotheses about the observation of Electromagnetically Induced Transparency (EIT) or Lasing Without Inversion (LWI) under these conditions.

We developed an analytical model using the N-level approximation, which was then reduced to a two-level system. The density matrix equation was solved perturbatively to derive analytical expressions for the coherences of both the pump and signal fields:

$$\begin{aligned}\dot{\rho}_{1,i} &= \left[i\left(\omega_i - \omega_1\right) - \frac{\gamma_i}{2} \right] \rho_{1,i} + \frac{1}{i\hbar} \rho_{1,i} \left(\overline{d_{i,i}} - \overline{d_{1,1}} \right) \cdot \left[\overline{E_P}(t) + \overline{E_S}(t) \right] \\ &+ \frac{1}{i\hbar} \left\{ \overline{d_{1,i}} \cdot \left[\overline{E_P}(t) + \overline{E_S}(t) \right] + \overline{m_{1,i}} \cdot \left[\overline{B_P}(t) + \overline{B_S}(t) \right] \right\}\end{aligned} \tag{1}$$

From above equation (1) The interaction between coherences is mediated by the interaction Hamiltonian, involving three dipole moments: the static electric dipole moment, the electric transition dipole moment, and the magnetic transition dipole moment arising from molecular chirality, resulting in transparency and amplification effects. We further employ the Chiral Optical Theorem to calculate the rate of absorption of energy, starting from its classical counterpart by evaluating the current density and molecular absorption:.

$$\sigma_{\text{abs}} = -\frac{1}{I_0}\frac{dU}{dt} = -\frac{\omega}{\varepsilon_0 c} \operatorname{Im} \left\{ \begin{aligned} &\overline{\hat{n}_E} \cdot \left[\hat{\alpha}_{dE}{}^{*} : \overline{\hat{n}_E}^{*} \right] + \frac{1}{c^2} \left(\overline{\hat{k}} \times \overline{\hat{n}_E} \right) \cdot \left[\hat{\alpha}_{mB}{}^{*} : \left(\overline{\hat{k}} \times \overline{\hat{n}_E}^{*} \right) \right] \\ &+ \frac{1}{c} \overline{\hat{n}_E} \cdot \left[\hat{\alpha}_{dB}{}^{*} : \left(\overline{\hat{k}} \times \overline{\hat{n}_E}^{*} \right) \right] + \frac{1}{c} \left(\overline{\hat{k}} \times \overline{\hat{n}_E} \right) \cdot \left[\hat{\alpha}_{mE}{}^{*} : \overline{\hat{n}_E}^{*} \right] \end{aligned} \right\} \tag{2}$$

From equation (2) we determine the absorption cross section which depends over the orientation of the molecule and polarization of light. By analyzing the linear response, nonlinear response and the molecular orientation of the molecule we observed Electromagnetically Induced Transparency (EIT) at very low intensity 100 MW/ cm^2.

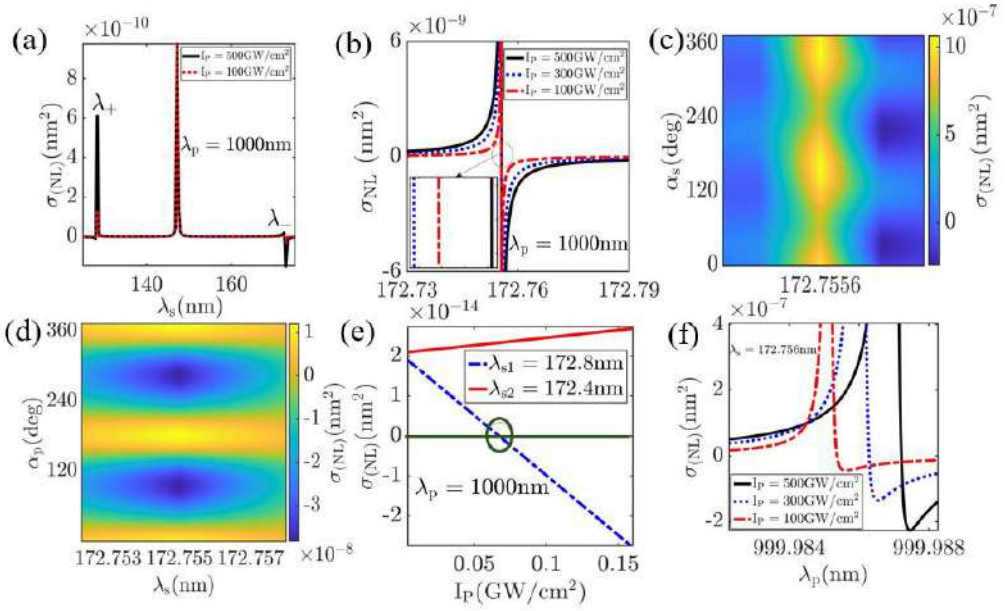

Fig. 1 (a–f) Dependence of the nonlinear absorption cross-section on various parameters for Fluorooxirane in vacuum.**(a, b, f)** Variation of the nonlinear absorption cross-section as a function of the signal wavelength, considering a fixed pump wavelength λ_P =1000nm ,while increasing the pump intensity I_P =100,300,500 GW/cm^2 .**(c, d)** Influence of the angle of linear polarization of the signal field and pump field on the nonlinear absorption cross-section, with the pump intensity fixed at I_P = 500 GW/cm^2.**(e)** Dependence of the nonlinear absorption cross-section on the pump intensity, with a fixed pump wavelength λ_P =1000nm for two distinct signal wavelengths λ_S =172.8nm,172.4nm. The marked line in this plot highlights the emergence of Electromagnetically Induced Transparency (EIT) as a function of increasing intensity.**(f)** Dependence of the nonlinear absorption cross-section on the pump wavelength, while progressively increasing the pump intensity I_P =100,300,500 GW/cm^2.All plots are obtained with fixed damping rate **(a-f)** Υ=1.15*10^{7}s^{-1} for Fluro oxirane in vacuum. We observe, additional peaks appear on top of the primary absorption peak, indicating frequency mixing between the pump and signal fields. The nonlinear response dependence on pump intensity reveals that the absorption cross-section of the molecule can either increase or decrease depending on the signal field wavelength, eventually reaching zero, as observed in Figure **(e)**. This phenomenon, known as Electromagnetically Induced Transparency (EIT), occurs when the molecule effectively ceases to absorb light. In this regime, the population remains unchanged since the pump field is not resonant with the molecular transition. Instead of promoting electrons from the lower to the upper level, the pump field induces coherence at the signal frequency due to the molecule's static electric dipole moment. This coherence modulates the absorption through interference, potentially leading to gain. This mechanism, referred to as Lasing Without Inversion (LWI), enables signal amplification without requiring population inversion.

Influence of the plasmonic lattice Kerker effect on second-harmonic generation

S. Boroviks[1*], B. S. Garcia[1], and O. J. F. Martin[1]

Abstract: We study the Kerker effect associated with the excitation of multipolar surface lattice resonances and its influence on nonlinear optical response. Observing that the appearance of the Kerker effect is associated the strong absorption, we show that it diminishes second-harmonic generation despite strong near-field enhancement.

A surface lattice resonance (SLR) is a Fano-type resonance that occurs in two-dimensional arrays of plasmonic nanoparticles [1]. Emerging from the diffractive coupling of localized surface plasmon resonances, the SLR features a sharper linewidth (i.e. higher quality factor). Typically, the dipolar response is considered in the limit of small particles; however larger nanoparticles arranged in arrays with subwavelength periodicity (referred to as metasurfaces) support higher order multipolar modes [2]. This allows to achieve more intricate behavior, such as unidirectional scattering, known as lattice Kerker effect (KE) [3].

An example of such a structure and its optical response (reflection spectrogram) is shown in Fig. 1. We perform numerical simulations (Fig. 1 a, b) and experimental validations (Fig. 1 c, d), which agree fairly well. Intriguingly, we observe that the KE is accompanied by the appearance of a bound state in the continuum (BIC) mode that is not excitable at normal incidence. However, it manifests in the reflection spectrogram as a quasi-BIC mode, which becomes observable at off-normal incidence.

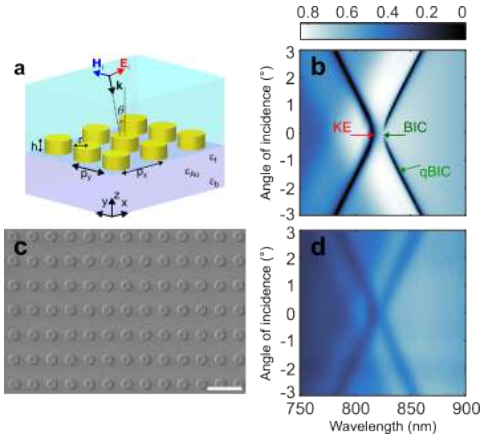

Figure 1

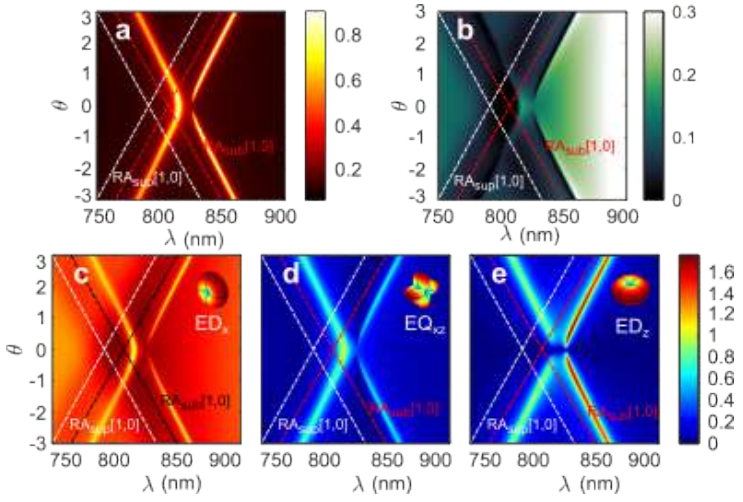

Figure 2

To gain further insights into the physical mechanisms behind the KE, we study the absorption (Fig. 2a) and transmission (Fig. 2b) of the system, and we perform multipole decompositions (Fig. 2c-e). As can be seen, the KE occurs in the vicinity of Rayleigh anomaly (RA) and is associated with very strong absorption induced by excitation of electric dipole along *x*-axis direction (ED_x) and electric quadrupole in *xz*-plane (EQ_{xz}). In turn, the quasi-BIC mode is associated with the dipole oriented along the *z*-axis.

Further, we experimentally study the nonlinear optical response of the system, in particular second-harmonic generation (SHG). Although several works [4-6] suggest that excitation of the SLR in a plasmonic metasurfaces enhances the nonlinear optical response, our findings indicate that it is not always the case. As shown in Fig. 3, the linear reflection minima associated with the KE correspond to the SHG minima, whereas maximum is achieved at the linear reflection maximum, which is associated with the dipolar resonance. We attribute the observed behavior to the competition between the absorption and the near-field enhancement. Although, in the limit of small particles, some degree of absorption is beneficial for SHG [7], in the case of the SLR-mediated KE, the absorption overtakes the benefits of the strong electric field at the surface of the nanoparticles and diminishes the SHG.

Abstract: We investigate the chiroptical response of plasmonic nanostructures based on Aluminum-doped zinc oxide (AZO) and a layer of pharmaceutical chiral drug solutions. We systematically study the localized surface plasmon resonances (LSPRs) to enhance the vibrational circular dichroism (VCD) of the chiral drug solution to develop innovative chiroptical sensing techniques.

Chiral sensing plays a crucial role in numerous scientific disciplines, particularly in pharmaceutical industries, biotechnology, and pharmacology, where detection of specific enantiomers of a chiral molecule is important for toxicity [1] and functionality assessment. Despite the capabilities of advanced chiral sensing techniques to precisely detect enantiomeric imbalances, compatibility with real-time analysis and wider nanomedicine applications is still in high demand. Here, we investigate plasmon-enhanced VCD facilitated by the LSPRs in AZO-based plasmonic nanostructures embedding realistic chiral drug solutions, specifically an isotropic assembly of Ladarixin (adopted to treat diabetes patients because of its ability to serve as a dual allosteric inhibitor of CXCR1, CXCR2, and CXCL8 (IL-8) receptors) dissolved in water. Employing a robust computational approach [2], we calculate the bi-anisotropic optical parameters of the chiral sample considering a dilute molecular number density $n_{mol} = 10^{-2}$ nm^{-3}. We model the LSPRs of the considered nanostructures, see Fig. 1, within the electrostatic limit through an analytical approach leading to the calculation of their absorption cross-sections. In turn, we obtain the VCD differential absorption cross-section (VCDDA) $\Delta\sigma = \sigma_R - \sigma_L$, where σ_R and σ_L represent the respective absorption cross-section upon excitation by right and left circular polarization radiation. By measuring such VCDDA, it is possible to retrieve the enantiomeric imbalance $\Delta n_{mol} = n^{(S)}_{mol} - n^{(R)}_{mol}$ as $\Delta\sigma$ is proportional to Δn_{mol}. Thanks to intense near-field confinement generated by the LSPRs, we attain a plasmon-induced VCDDA enhancement factor ranging from $\simeq 3$ to $\simeq 20$. Our findings have the potential to design promising chiroptical sensing platforms capable of investigating the chirality of molecular systems at the nanoscale level.

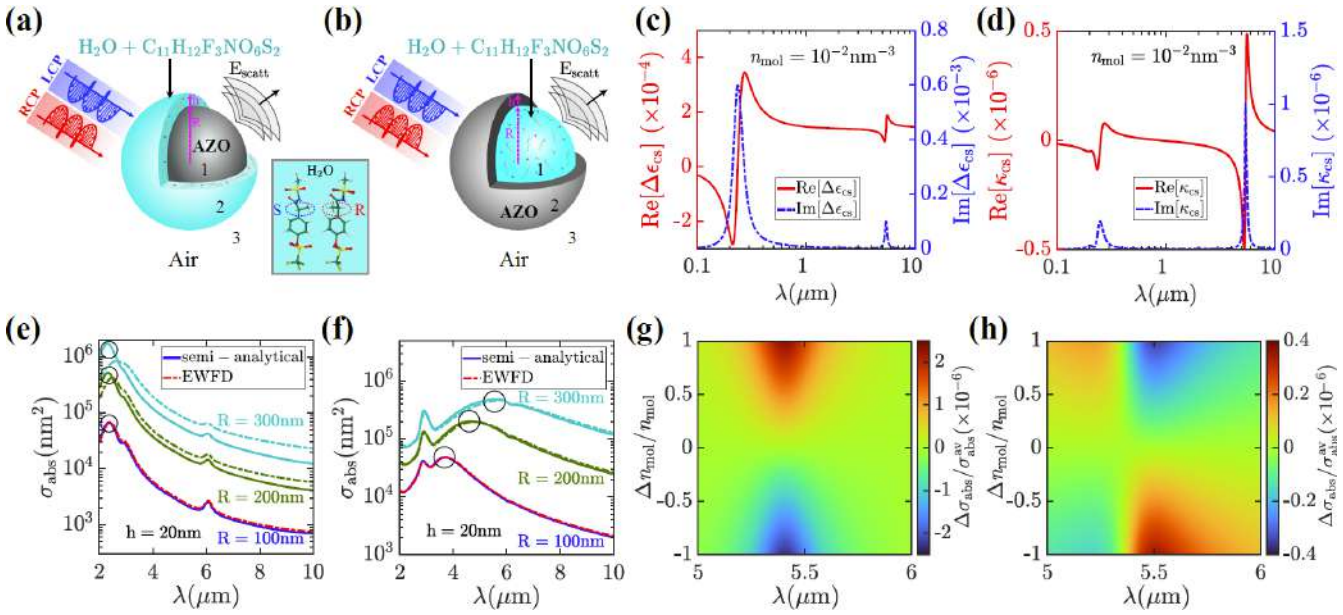

Fig. 1: Schematic of (a) Type-1 plasmonic nanostructure consisting of Al-doped ZnO (AZO) nanosphere of radius R surrounded by an aqueous Ladarixin layer with thickness h, immersed in air, (b) Type-2 plasmonic nanostructure which contains AZO-based nanoshell with inner/outer radii R/R+h, embedding aqueous Ladarixin at its core and immersed in air. Dependence of (c) relative dielectric permittivity $\epsilon_r(\lambda)$ and (d) chiral parameter $\kappa(\lambda)$ over vacuum wavelength λ, evaluated at a fixed molecular density n_{mol} of R and S-Ladarixin dissolved in water. Dependence of the absorption cross-section $\sigma_{abs}(\lambda)$ of (e) Type-1 and (f) Type-2 nanostructures over λ upon excitation by right circular polarization for several R and fixed h = 20 nm. Dependence of the relative vibrational circular dichroism differential absorption over λ and enantiomeric imbalance evaluated for (g) Type-1 and (h) Type-2 nanostructures with R = 100 nm and h = 20 nm.

Possibility of the zinc oxide refractive index changing to explanation the shift of the of the ZnO/Ag nanocomposites related LSPR peak due to magnetic field pre-treatment

S. M. Redko[1*], G. V. Milenin[1], V. V. Shvalagin[2], O. A. Kapush[1], A. V. Fedorenko[1], R. A. Redko[1]

Abstract: The modeling of the absorbance of ZnO/Ag nanocomposites with MiePlot 4.16 Software were carried out to obtain information about principal possibility of LSPR peak position changing due to changing of ZnO nanoparticles refractive index due to magnetization in external magnetic field. Obtained results are in good agreement with experiment.

The blue shift of LSPR peak from 450 to 410 nm due to magnetic field (60 mT) pre-treatment of the ethanol solution of ZnO nanoparticles has been detected [1]. It was quite unexpected because undoped ZnO, actually, is paramagnetic material and any action of external magnetic field should not lead to any changing in LSPR peak position of ZnO/Ag nanocomposites, which were prepared after magnetic field action doe to photocatalytic reduction of silver. However, observed feature may take place when the magnetization of ZnO nanoparticles is occurred in external magnetic field [2]. This is relatively a new phenomenon, when nanostructures of inorganic materials exhibit ferromagnetic-like properties [3]. This is mainly due to the presence of defects – vacancies and interstitial atoms. Thus, observe in [1] shift can take place due to some changes in ZnO nanoparticles, as carrier of ferromagnetic properties. Naturally that magnetization of these nanoparticles may take place. And due to this magnetization the changing of refractive index could occurs. The last thing could result to LSPR peak shift as well as it was observed in [4].

To confirm this assumption the modeling with MiePlot 4.16 Software was carried out. For refractive index of silver (shell) Palik database was used. Core/shell radii of ZnO/Ag structure for modelling were assumed to be 2.5/6.0 nm. Fig. 1 (*a-f*) demonstrates shift of LSPR peak position due to changing of refractive index of zinc oxide core. As can be seem from this figure, principal possibility of proposed assumption was confirmed. However, for complete agreement with experimental results further investigations are required. According to [2, 3] the surface of ZnO nanoparticles has ferromagnetic-like properties while the core remains paramagnetic ones. So, three layers model (paramagnetic core/ferromagnetic surface/silver shell) is required to more accuracy modeling.

This work was supported by the IEEE program "Magnetism for Ukraine".

Quantum Quasinormal Mode Theory for Dissipative Nano-Optics and Magnetodielectric Cavity Quantum Electrodynamics

Abstract: The rapid evolution of nanoscale architectures for cavity quantum electrodynamics has posed crucial challenges for the theory of non-hermitian systems. We introduce a formalism for the quantization of quasinormal modes in the presence of magnetodielectric media, enabling a unified and rigorous approach for simulating photonic, plasmonic and magnonic cavities.

Introduction: Quantum nanophotonics has recently forged a rich nexus of nanotechnology with photonic quantum information processing, offering remarkable prospects for driving quantum technologies down to nanoscale spatial and ultrafast temporal regimes, whilst simultaneously elevating their functionality towards ambient temperatures [1]. In particular, nanoscale architectures for cavity quantum electrodynamics (cQED) are poised to play an instrumental role in next-generation quantum technologies, whereby the confined photonic, plasmonic or magnonic modes of a resonator can become inextricably intertwined with the excitonic, phononic or spin-related excitations of matter, giving rise to a panorama of polaritons and facilitating such quintessential functionalities as single-qubit coherent control, single-photon non-linearities and quantum sensing. The unprecedented pace of experimental progress in this field has placed evermore ambitious demands on the power and predictive scope of theoretical methodologies, where the development of fully quantum dynamic approaches that capture polaritonic effects in three-dimensional (3D), dispersive and non-hermitian, magnetodielectric cQED systems has become imperative.

To this end, we propose a quantum quasinormal mode (QNM) formalism for addressing problems in dissipative nano-optics and magnetodielectric cQED. Our approach offers a unified and rigorous, yet practical simulation methodology for photonic, plasmonic and magnonic cavities interacting with quantum emitters and spin qubits, paving the way towards a fully quantum-mechanical description of such phenomena as quantum nanoplasmonic coherent perfect absorption, lasing in $\mathcal{PT}$-symmetric photonic systems, magnonic strong coupling and cavity-mediated spin-photon interfaces at the nanoscale.

Quantum QNM theory: Our theory is formulated within the framework of macroscopic QED, which describes the quantized electromagnetic field in the presence of arbitrary, 3D, dispersive and lossy, linear media characterized by permittivity $\varepsilon(\mathbf{r},\omega)$ and permeability $\mu(\mathbf{r},\omega)$ distributions. The electric field operator satisfies the equation

$$\nabla\times\mu^{-1}(\mathbf{r},\omega)\nabla\times\hat{\mathbf{E}}(\mathbf{r},\omega)-\frac{\omega^2}{c^2}\hat{\mathbf{E}}(\mathbf{r},\omega)=\mathrm{i}\mu_0\omega\mathbf{j}_{\mathrm{N}}(\mathbf{r},\omega)\ ,\ \hat{\mathbf{E}}(\mathbf{r})=\int_0^\infty \mathrm{d}\omega\,\hat{\mathbf{E}}(\mathbf{r},\omega)\ , \tag{1}$$

with the noise current density

$$\hat{\mathbf{j}}_{\mathrm{N}}(\mathbf{r},\omega)=\omega\sqrt{\frac{\hbar\varepsilon_0}{\pi}}\sqrt{\Im(\varepsilon(\mathbf{r},\omega))}\hat{\mathbf{f}}_{\mathrm{e}}(\mathbf{r},\omega)+\sqrt{\frac{\hbar}{\mu_0\pi}}\nabla\times\left(\sqrt{-\Im(\mu^{-1}(\mathbf{r},\omega))}\hat{\mathbf{f}}_{\mathrm{m}}(\mathbf{r},\omega)\right)\ , \tag{2}$$

which stands in accordance with the fluctuation-dissipation theorem and ensures the preservation of the fundamental commutation relations. The bosonic operators $\hat{\mathbf{f}}_{\mathrm{e}}(\mathbf{r},\omega)$, $\hat{\mathbf{f}}_{\mathrm{m}}(\mathbf{r},\omega)$ correspond to the joint excitations of the electromagnetic-field-dressed media (polaritons) and diagonalize the Hamiltonian of the system. Note that this formula can also be generalized for materials that exhibit amplification in certain domains, in which the creation and annihilation operators switch roles [2]. By utilizing the classical dyadic Green's function $G(\mathbf{r},\mathbf{r},\omega)$, the electric field operator can be formally expressed as

$$\hat{\mathbf{E}}(\mathbf{r}) = \mathrm{i}\mu_0 \int_0^\infty \mathrm{d}\omega\, \omega \int \mathrm{d}^3 r\, G(\mathbf{r},\mathbf{r}',\omega)\hat{\mathbf{j}}_{\mathrm{N}}(\mathbf{r},\omega)\ . \tag{3}$$

To circumvent the large and practically cumbersome continuum of modes, we employ a discrete QNM expansion of the Green's function, ascertained via an auxiliary field eigenvalue technique with a complex coordinate transformation, tantamount to perfectly matched layers (PMLs) [3]. In the classical theory, a complete set of QNM/PML modes $\tilde{\mathbf{E}}_\mu(\mathbf{r})$ is obtained that can be orthogonalized and normalized, and which are capable of reconstructing the Green's function and scattered fields in a compact domain containing the resonator. Inspired by this idea, we can also use effective PML media within the quantum theory, which are themselves magnetodielectric materials with gain components in the 3D case. In this way, radiation losses are converted into material losses within the PMLs, and the regularization of the QNM fields renders feasible their quantization. Although the PMLs are treated like real materials in this approach, which exhibit fluctuations according to Eq. (2), it can be shown that in the unmapped region, all the N-point correlation functions of the electric and magnetic fields are unaltered by the presence of the PMLs and thus the correct quantum dynamics are reproduced. If we use these QNM/PML modes to expand the electric field operator, an effective Hamiltonian for the system can be derived that involves off-diagonal mode coupling terms $\hbar\tilde{\omega}_{\mu\nu}\hat{a}_\mu^\dagger\hat{a}_\nu$ and the usual coupling of the modes to a continuum of bath modes, where all the coupling coefficients can be calculated directly from the electromagnetic properties of the system. From that point, standard methods and approximations for treating dissipative cQED systems, like the derivation of Langevin and master equations in the presence of few-level emitters and spin qubits, can be used to establish a fully time-dependent quantum treatment.

Conclusions: Commencing from macroscopic QED, we have introduced a formalism for the quantization of QNMs in the presence of dissipative magnetodielectric media, enabling a unified and rigorous approach for simulating photonic, plasmonic and magnonic cQED phenomena.

Large Purcell Enhancement with High-Quality Factor in Dielectric Nanoantenna-Microtoroid Structure

Zihan Mo[1], Yali Jia[1*], Xinchen Zhang[1], Yu Tian[1], and Ying Gu[1,2*]

Abstract: By combining the advantages of the high-quality factor of microtoroids and the ultra-small mode volume of a nanoantenna, we theoretically achieve large Purcell enhancement with narrow linewidth in dielectric nanoantenna-microtoroid structure.

1. Introduction

Single-photon sources with high emission rates are crucial components of rapidly developing on-chip quantum devices. Enhancing the Purcell effect at the single quantum level contributes to improving the performance of single-photon sources. Meanwhile, the high-quality characteristic of spontaneous emission spectrum facilitates the realization of single-photon emission. However, it is difficult to meet the above two requirements at the same time. Dielectric structures with high refractive index and low loss have been developed through the theory of Mie resonance, which confines the electric or magnetic field inside and around the nanostructure. Although dielectric nanostructures own a small mode volume, the great scattering losses limit their applications. The high-Q whispering gallery microcavities (WGMs) ultra-localize the cavity's electric field, resulting in an extremely narrow spontaneous emission spectrum. Unfortunately, the Purcell factors of WGMs based on dielectric materials are only tens to hundreds due to the large mode volume. In order to achieve Purcell enhancement with high-quality factor, the idea of designing hybrid micro-nano structures has been considered. The dielectric nanoantenna has a small mode volume and no absorption loss, but the photons are scattered around and difficult to collect. The WGMs localizing the electric field excellently are expected to build a natural photon collection channel for nanoantenna to guide the scattered photons into the WGMs. Thus, it is possible to achieve high-Q Purcell enhancement in low-loss dielectric hybrid structures.

2. Model & Results

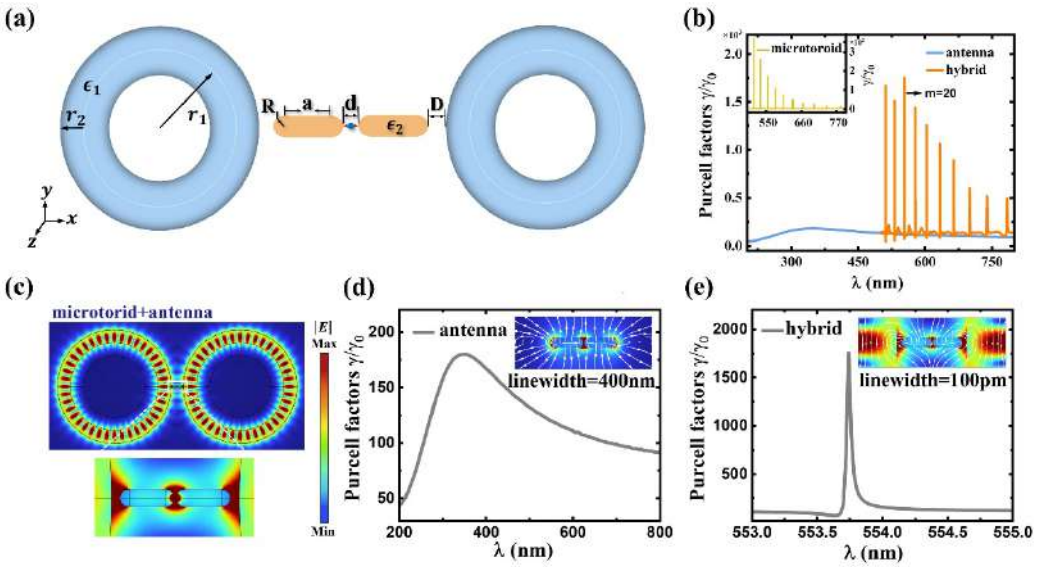

Fig. 1. (a) The schematic of the dielectric nanoantenna-microtoroid structure. The x-polarized quantum emitter is located at the center of the nanoantenna. (b) The Purcell factor of single dielectric nanoantenna and hybrid structure. Inset: the Purcell factor of single microtoroid. (c) The electric field of the xy plane (wavelength at 553.74 nm) in the hybrid structure when the azimuthal mode number m = 20. (d) The linewidth of the spontaneous emission spectrum for the single dielectric nanoantenna. Inset is the electric field and energy flow diagram of the nanoantenna. (e) The linewidth of the spontaneous emission spectrum for the hybrid structure at azimuthal mode number m=20. Inset is the partial electric field and energy flow diagram of the hybrid structure.

The schematic diagram of the proposed system is shown in Fig. 1(a), where the dielectric nanoantenna is coupled to the microtoroids through a nanoscale gap $D = 20nm$. Two WGMs are both microtoroids of $r_1 = 1000nm$ and $r_2 = 300nm$. The dielectric constant of the microtoroids is $\varepsilon_1 = 3.13$, which can be made by Al_2O_3 material. A dielectric nanoantenna with radius $R = 20nm$, length $a = 80nm$, gap $d = 5nm$, and dielectric constant $\varepsilon_2 = 12$ is inserted between two microtoroids, and its material can be considered as GaP. Then, an x-polarized quantum emitter is placed into the gap of the nanoantenna. The local field at ends of the nanoantenna is coupled with the evanescent field of microtoroids, so that the photons originally scattered are bound in the microtoroids [Fig. 1(c)]. It can be seen from the electric field diagram of Fig. 1(c) that the whispering gallery mode in the hybrid structure is still well maintained.

As shown in Fig. 1(b), the large Purcell enhancement has been achieved in dielectric nanoantenna-microtoroid structure. The maximum Purcell factor γ/γ_0 can reach 1752 at the azimuthal mode number of microtoroids m=20. Compared to the Purcell factors of 155 for single GaAs microdisk, 580 for microtoroid, and 47 for silicon nanoantenna arrays, we demonstrate a significant enhancement in the spontaneous emission rate. For the azimuthal mode number m ranging from 15 to 22, the Purcell factors of the hybrid structure are all greater than 500. A single dielectric nanoantenna achieves a maximum Purcell factor of only 180 when the emitter is located in the gap. For the bare whispering gallery mode at wavelength 500-800 nm [inset in Fig. 1(b)], when the emitter is placed close to the outer surface, the maximum Purcell factor reaches 372. Therefore, we can achieve stronger emission enhancement in the hybrid structure than individual dielectric nanoantenna or dielectric microtoroids.

For high-performance single-photon sources, the spontaneous emission spectrum also exhibits high-Q characteristic to facilitate practical applications. In our mechanism, the linewidth of the nanoantenna is reduced from hundreds of nanometers to the order of hundreds of picometers in the hybrid structure [Fig. 1(d), Fig. 1(e)]. The photons are difficult to collect and utilize in a single nanoantenna [inset in Fig. 1(d)], which leads to the broadening of the spontaneous emission spectrum. In the hybrid structure, the microtoroid alters the electromagnetic environment around the nanoantenna, which creates a natural photon collection channel for the scattered photons from the nanoantenna. As shown in the energy flow line of the inset in Fig. 1(e), the scattered photons can be guided into the microtoroids. The narrowed linewidth of the spontaneous emission spectrum is conducive to the realization of single photon emission.

3. Conclusion

In this work, we theoretically demonstrate large Purcell enhancement with high-quality factor in dielectric nanoantenna-microtoroid structure.

Abstract: We present electrooptical characterization results for Ge photodetectors with TiN nanohole arrays as miniaturized sensors for the detection of refractive index changes. Fabrication was carried out in cost-effective CMOS compatible 200 mm wafer Si technology.

Integrated biosensors have potential applications ranging from agriculture to personalized medical diagnostics. Commercial plasmonic biosensing predominantly relies on external instruments, such as microscopes or spectrometers, which limits miniaturization. This challenge can be addressed with on-chip refractive index (RI) sensors that employ plasmonic nanostructures for compact sensing approaches. Specifically, the integration of plasmonic nanohole arrays (NHAs) with Ge photodetectors constitutes a promising device concept [1], which can potentially be realized on the cost-effective silicon platform. In these devices, changes in the RI of a medium adjacent to the NHAs are directly converted to electrical signals, i.e. photocurrent variations. Compared to the realization of a proof-of-concept device [1], transitioning the device concept to large-scale production necessitates modifications for compatibility with CMOS manufacturing processes, introducing additional constraints in fabrication and design [2, 3].

Here, we present results of the electrooptical characterization of on-chip refractive index sensors for the detection of RI changes. Fabrication was carried out in CMOS compatible 200 mm wafer Si technology. In our devices, plasmonic NHAs made from sputtered TiN are combined with Ge photodetectors for an operating wavelength range between 1200 and 1550 nm. We present optical characterization results for the plasmonic NHAs alone as well as responsivity spectra of the on-chip RI sensors, with devices submerged in different liquids for the detection of changes in bulk RI (Fig. 1). In our devices, plasmonic resonances induced in the TiN NHA lead to dips and peaks in the responsivities of the Ge photodetectors. A change in refractive index of the liquid above the nanohole array can be seen to induce peak shifts as a result of changes in the optical properties of the NHA. In simulation, the transmission through the TiN NHA is calculated using the commercial FDTD simulation software Ansys Lumerical and the sensor responsivity is then obtained by multiplying the result with responsivity spectra obtained from a reference device without the NHAs [1]. While there are qualitative differences between simulation and experimental results, the sensitivity is well reproduced by simulation results and exceeds 900 nm/RIU. Large damping in TiN leads to broadening of resonances, we present strategies to modify the NHAs in order to improve sensing performance together with first experimental results.

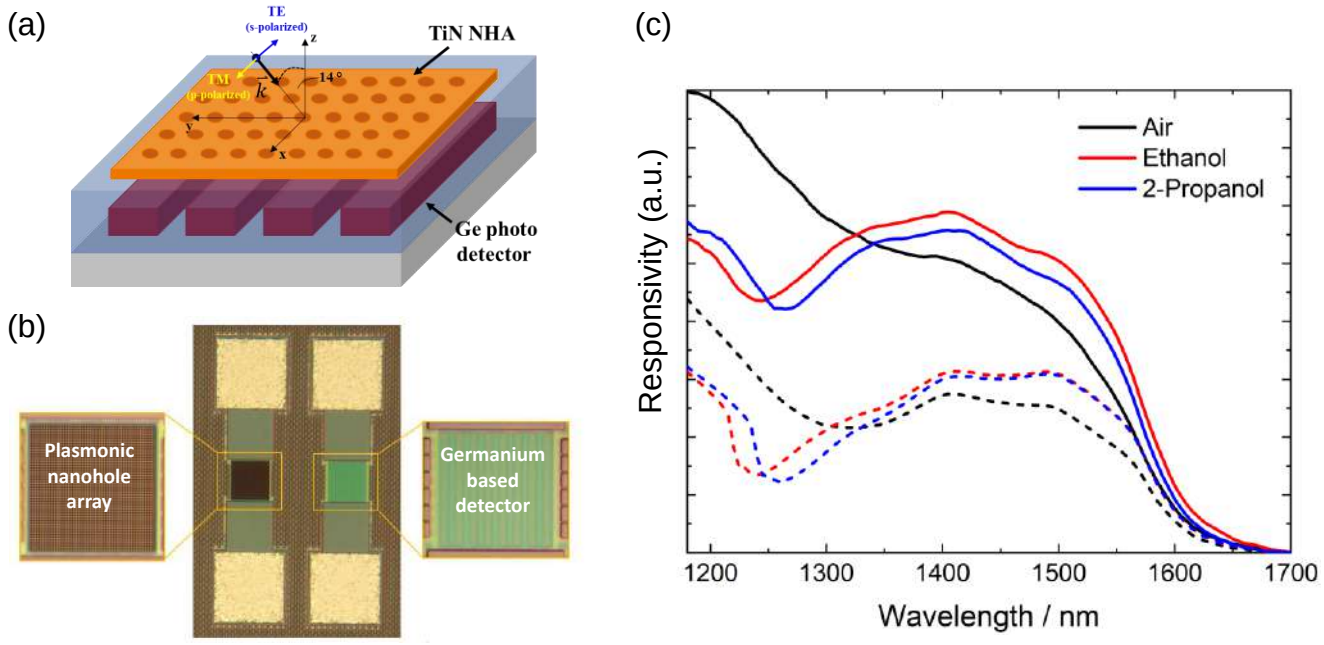

Fig. 1 (a) Schematic view of the device concept [3] (b) Microscope images of the devices with and without TiN nanohole arrays (c) device responsivities in air and submerged in liquids with different refractive indices ($n_{Ethanol}$ = 1.353 and $n_{2\text{-}Propanol}$ = 1.369) obtained from simulation (dashed lines) and experiment (solid lines).

Our results indicate that integrating NHAs with Ge photodetectors is an interesting approach for on-chip RI sensing, achievable with standard industrial manufacturing techniques, and we report performance metrics such as sensor resolution. Our work can be a starting point for the development of cost-efficient on-chip RI sensors on the silicon platform.

Tunable impedance matching layer based on piezoelectric materials with external circuits

Han Jia[1*], and Yuzhen Yang[1]

[1] Institute of Acoustics, Chinese Academy of Sciences, Beijing 100190, People's Republic of China
[*]corresponding author: hjia@mail.ioa.ac.cn

Abstract: A tunable impedance matching layer is designed and fabricated. It is composed of periodical piezoelectric disks with shunting capacitors. An external digital control system is introduced to adjust the effective acoustic impedance of the PZT disks through digital potentiometers and microprogrammed control unit, enabling digital manipulation of wave transmission.

In this work, a digital metalayer is designed to control the elastic wave transmission. The schematic diagram of the proposed digital metalayer is illustrated in Fig. 1. The digital metalayer consists of eight PZT disks, and each disk is connected to a corresponding external electric impedance Z. The metalayer as a tunable medium is inserted between two rods to form a digital wave transmission control system.

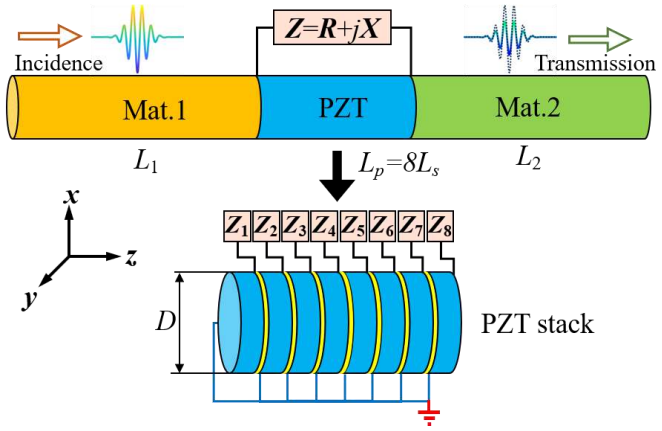

Fig. 1 The schematic diagram of the transmission energy control by the interlayer PZT stack with PSCs.

The amplitude modulation of the transmitted waves versus C_e (external electric impedance) around 30kHz and 60kHz are measured and shown in Figs. 2(a) and 2(b), respectively. Here, the incident signals are Gaussian pulses with a narrow bandwidth of 2kHz. It can be seen that the amplitudes are obviously affected by C_e for both measurements. In order to exhibit clearly the effect of the external capacitance C_e on the wave energy transmission, the curves of transmitted amplitude versus frequency with different values of C_e are shown in Figs. 2(c) and 2(d). The value of C_e is adjusted from -8.5nF to 7.35nF. The 'Wo' represents the case that SS and PMMA rods are bonded directly without the digital metalayer, while the 'Op' represents the case that the PZT disks are in the open-circuit state. It can be observed that the max values of the 'Op' curves are over three times than those of the 'Wo' curves at 30kHz and 60kHz. Since the initial acoustic impedance of the PZT disk is between SS and PMMA, the wave transmission energy increases when the PZT disks are inserted. When the SCCs connect with the PZT disks, the transmitted amplitudes can be further adjusted by the digital wave transmission control system. Compared with 'Op' curves at 30kHz and 60kHz, the max values of transmitted amplitudes increase about 35% when $C_e = -0.86\text{nF}$. The transmitted amplitudes can also be turned down by the same system. The min values

of transmitted amplitudes are almost 45% of the 'Op' curves when $C_e = -1.0\text{nF}$. The digital metalayer has an excellent adjustment capacity in wave energy transmission at both 30kHz and 60kHz.

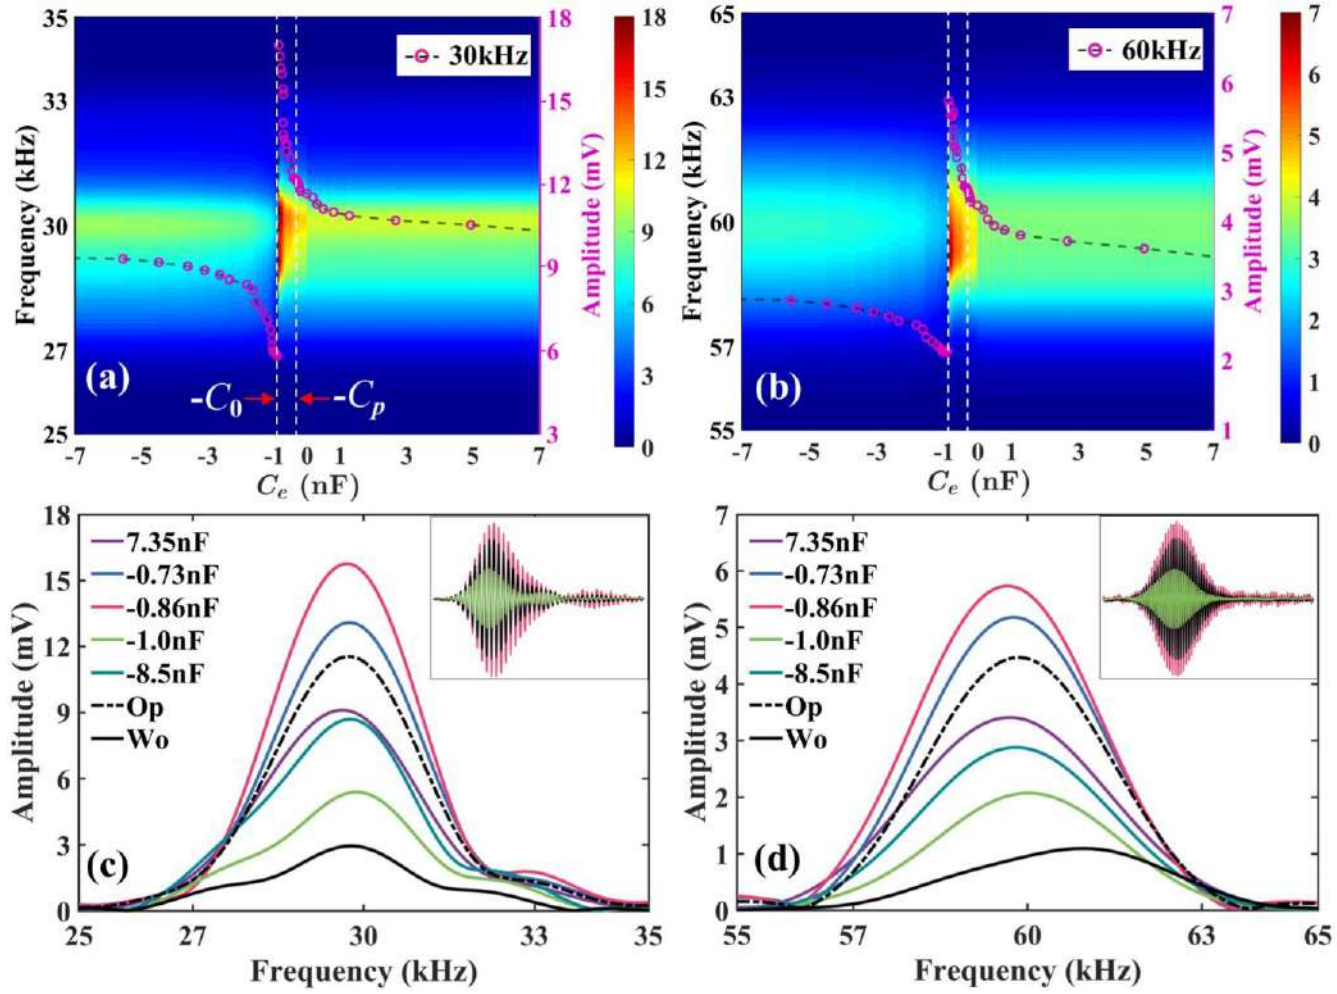

Fig. 2 Transmission spectra and curves of 30kHz and 60kHz with the external capacitance C_e.

Abstract: We present a highly sensitive side-coupled Fabry-Perot (FP) photonic sensor with multi-slot subwavelength grating (SWG) metamaterials, which enhances light-matter interaction through strong optical confinement in slot regions. The sensor, fabricated on a silicon-on-insulator (SOI) platform, exhibited a measured sensitivity of 520 nm/RIU when tested with NaCl solutions of varying concentrations. The SWG-based mirrors feature a broadband photonic bandgap, enhancing the sensor's versatility and making it a promising platform for biochemical sensing, environmental monitoring, and chemical analysis.

1. Introduction

Silicon photonic sensors on SOI platforms provide compact, cost-effective, and high-performance solutions for sensing. Their CMOS compatibility enables full integration, supporting portable lab-on-a-chip systems for point-of-care and home healthcare. Incorporating subwavelength grating (SWG) metamaterials into photonic sensors significantly enhances sensitivity by increasing optical field overlap with the analyte, making SWG-based sensors highly promising [1, 2].

This work focuses on an FP-based photonic sensor employing a multi-slot SWG structure, where strong optical field confinement in slot regions boosts light-matter interaction and enhances sensing performance. Additionally, the SWG-based mirrors exhibit a broadband photonic bandgap, improving sensor robustness and allows for the detection of various analytes, making the design adaptable for different sensing applications.

2. Device Design and Working Principle

The sensor structure, depicted in Fig. 1, consists of a side-coupled FP cavity with a multi-slot SWG metamaterial configuration. SWGs are created by periodically interleaving the silicon core with low-index materials. When the period ($P_{SWG,x}$) is much smaller than the operating wavelength, the structure

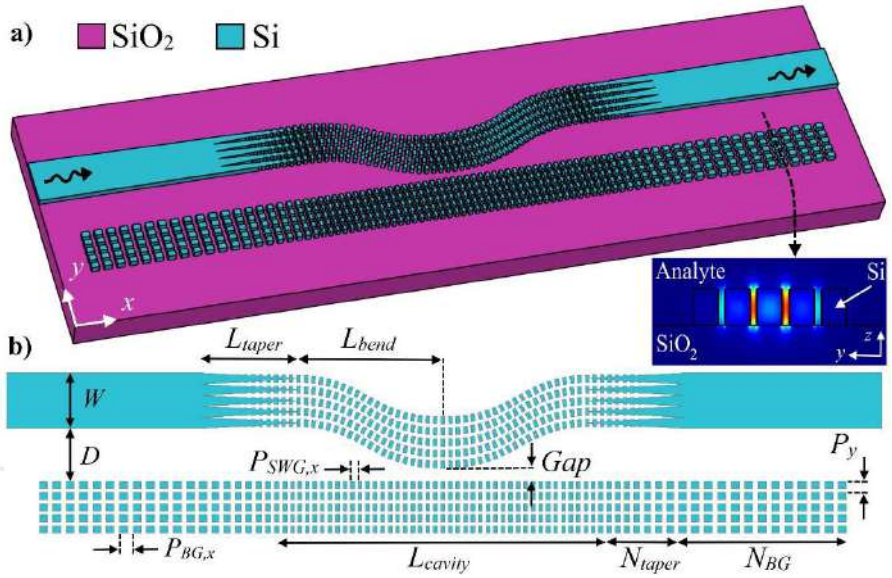

Fig. 1 a) 3D schematic and b) top-view of the sensor. Electric field distribution illustrates strong mode confinement in slots.

behaves as a lossless homogeneous medium, as diffraction and reflection effects are negligible. However, for larger periodicities ($P_{BG,x}$), the structure enters the Bragg reflection regime, creating mirrors in the FP cavity [3]. The designed SWG mirrors possess a broadband photonic bandgap, which enhances reflection across a wide range of wavelengths. This broader spectral coverage increases sensor flexibility, allowing it to function effectively across different operating wavelengths and detect a variety of analytes with improved stability. The optical mode distribution shows strong confinement in the slots, enhancing light-matter interaction and sensor sensitivity. To optimize mode matching and reduce insertion loss, tapers were employed. The geometrical parameters of the fabricated device are P_y=450 nm, $P_{BG,x}$=490 nm, $P_{SWG,x}$=250 nm, N_{BG}=500, N_{taper}= 100, L_{taper}=21 µm, L_{bend}= 110 µm, L_{cavity}= 62.5 µm, *Gap*= 400 nm, W=2.25 µm, and D= 13.8 µm. The gap between the slots in the y-axis is fixed to 100 nm.

3. Experimental Results

The photonic structure was fabricated on a 220 nm-thick silicon layer atop an 8 µm-thick SiO_2 insulator. Patterning was performed using electron beam lithography, followed by inductively coupled plasma etching. The sensor was tested by placing a drop of deionized (DI) water on its surface. The corresponding transmission spectrum, illustrating the sensor's broadband response, is shown in Fig. 2(a). Subsequently, NaCl solutions with concentrations of 5, 10, and 20 mg/mL were applied, and the transmission spectra were recorded, as shown in Fig. 2(b). The key performance metrics of a refractive index sensor include sensitivity (S) and limit of detection (LOD). Our sensor achieved a sensitivity of $S=\Delta\lambda/\Delta n$=520 nm/RIU, determined by the ratio of the resonance wavelength shift ($\Delta\lambda$) to the corresponding refractive index change (Δn). The quality factor, defined as $Q=\lambda_{res}/FWHM$, where $FWHM$ is the full-width at half maximum, was measured to be Q=4200. The smallest detectable refractive index change is calculated as $LOD=FWHM/S$ and was found to be $LOD=7.1\times10^{-4}$ RIU.

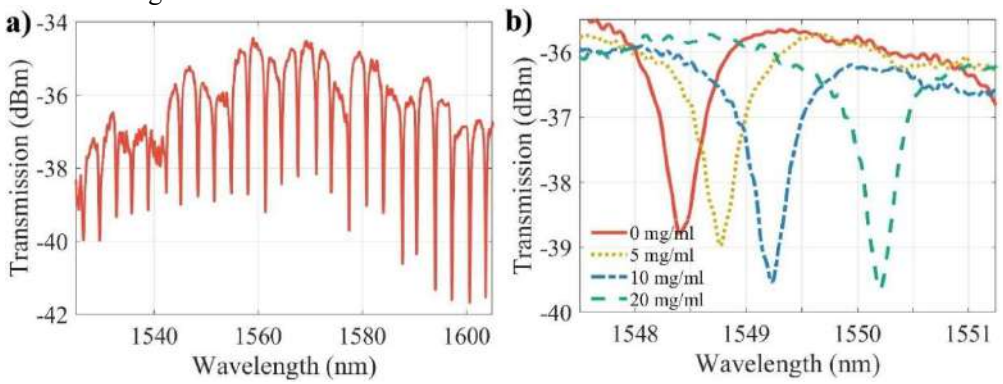

Fig. 2. Transmission spectrum for a) DI water and b) varying NaCl concentrations.

4. Conclusion

This work demonstrates a highly sensitive photonic sensor based on a side-coupled FP cavity with multi-slot SWG metamaterials. The strong field confinement in the slot regions enhances light-matter interaction, leading to an experimental sensitivity of 520 nm/RIU. This result highlights the potential of the proposed sensor for applications in biochemical sensing, environmental monitoring, and lab-on-chip systems.

Abstract: Scattering-based microscopy with an evanescent field enhances signal-to-noise by suppressing background. Waveguides generate evanescent waves, but edge-coupling of light is difficult to use. Bonding a VCSEL to a waveguide platform enables an easy coupling via a grating coupler. Integrating a metasurface into the VCSEL tilts emission, improving waveguide excitation.

Scattering-based microscopy offers an alternative to conventional fluorescence microscopy [1] with certain configurations achieving super-resolution through techniques like structured illumination [2] or coherent light [3]. Compared to fluorescence, scattering microscopy has several advantages: 1) it is *label-free*, there is need for fluorescent tags; 2) it allows unlimited experiments, as it does not suffer from photobleaching; and; 3) it avoids saturation effects that limit fluorophore-based detection rates [4].

To suppress the background and only collect the scattered light, darkfield imaging (DF) and total internal reflection (TIR) are frequently used. In TIR, an *evanescent field* is generated which induces scattering from the object. Another way to achieve evanescent fields is to couple the excitation light to a waveguide. Multiple configurations have been realized using materials such as silicon dioxide and a polymer [5], microscope slides [6], or silicon nitride [7]. However, existing platforms rely on external lasers for end-coupling into the waveguide, making them complex to operate and more susceptible to external disturbances.

Integrating a laser directly onto a waveguide enables the fabrication of a fully on-chip illumination source. This approach eliminates the need for additional equipment and creates a scattering-based TIR illumination platform compatible with standard microscopes.

Vertical cavity surface emitting lasers (VCSELs) are well-suited for integrated photonics due to their high conversion efficiency and the ability for wafer-scale testing. However, perfectly vertical illumination from a VCSELs onto a grating coupler compromises efficiency [8]. To improve this, the light needs to strike the grating coupler at an angle. Tilting the VCSEL package can create this angle, but it comes at the cost of flatness and wafer scalability [9].

A promising solution to achieve the desired coupling angle is to directly inscribe a metasurface onto the VCSEL's substrate. This configuration maintains high coupling efficiency without sacrificing scalability or flatness. A concept image can be viewed in Figure 1.

VCSELs have also recently been used in label-free imaging in both darkfield and TIR modalities, where a monolithically integrated metasurface deflects the beam at a high angle, enabling the application [10]. Building on this, we are now expanding the concept by coupling VCSEL light into a silicon nitride waveguide, providing more uniform illumination with ultralow background noise and a wider field of view.

This work was funded by the Knut and Alice Wallenberg Foundation and performed in part at Myfab Chalmers.

Excitation of multiple Fano resonances through broadband oblique-wire-bundle metamaterial absorbers and targeted molecules

Kai-Lin Hsiao[1] and Tsung-Yu Huang[1,*]
[1]Department of Materials Engineering, Ming Chi University of Technology, New Taipei, Taiwan
[*]corresponding author: huang.tsungyu@mail.mcut.edu.tw

Abstract: To improve the absorption sensitivity of sensors, we have studied the absorption interaction with multiple functional groups in the sample through oblique wire bundle (OWB) metamaterial absorber with molecular functional groups' absorption. We developed four Fano resonances with three PMMA functional groups and one carbon functional group for better sensitivity.
Keyword: oblique-wire-bundle (OWB), metamaterial absorber, Fano resonance.

1. Introduction

To detect ingredients from an unknown sample with higher sensitivity and specificity is crucial especially regarding food safety and chemical detection. To achieve such a goal, a detection method without labelling procedure should be developed. There appeared many different techniques for detection of chemical structures such as mass spectroscopy, nuclear magnetic resonance spectroscopy, infrared spectroscopy, Raman spectroscopy, etc., and infrared absorption and Raman scattering provide footprints of compositions of a sample and are both applied in so many different fields such as bio-, chemical- and gas-sensors. Besides, signals from both the two methods could be further enhanced through surface modification, also known as surface enhanced infrared absorption (SEIRA)[1–3]and surface enhanced Raman scattering (SERS)[4–6]. Among these different methods, one promising kind of SEIRA is to couple a narrow absorption band from molecules' vibration modes to a broadband absorption often introduced by a metamaterial for excitation of Fano resonance that revealed high quality resonance, extended interaction time due to slow group velocity and spectrum reversal for a better signal to noise ratio.

In this work, we designed an oblique wire bundle (OWB) metamaterial absorber on substrate. There is a 150-nanometer-thick layer of aluminum and an MgF_2 seed layer. Through advanced electron beam lithography technology and electron gun evaporator, in the experiment, MgF_2 presents a shape of a rectangular frustum due to the undercutting of the resist during the lithography process. The sample was then placed on the platform of an electron gun evaporator with a tilt angle of 86 degrees to ensure a coverage length of 1430 nm, ensuring that the metal nanowires only grew on top of the seed layer during deposition. Since the OWB metamaterial absorber has a broadband absorption spectrum, we expect that the OWB metamaterial absorber can exhibit a strong Fano resonance, and for comparison, **Figure 1** depicts the scheme and the absorbance spectra of the OWB and planar metamaterial absorbers at x- and y-polarized incidence. The OWB metamaterial absorber has a bandwidth of up to 111 THz (69 to 180 THz) in the x-polarization range of 100 to 180 THz, and a wider bandwidth in the y-polarization range. In contrast, the planar metamaterial has an absorption peak of 0.6 with a bandwidth of 15.65 THz under x-polarization. It is worth pointing out that the small peak/valley metamaterial absorber at 70.5 THz frequency in the OWB and planar spectra can be attributed to the stretching vibration mode of C=O in CO_2. Here, there is an absorption peak in the spectrum of an OWB metamaterial absorber, but there is an absorption dip in the spectrum of a planar absorber, which may originate from the background and the changes in the CO_2 concentration measured by the device. Nevertheless, due to the larger hot spot area and stronger field enhancement, the OWB metamaterial absorber enhances the modes vibrating from CO_2, resulting in stronger absorption compared to the planar metamaterial absorber.

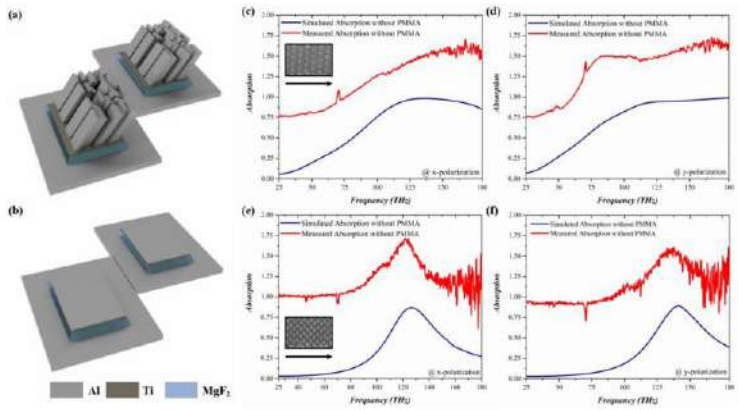

Figure 1. Schemes of (a) an oblique wire bundle (OWB) and (b) planar metamaterial absorbers. Measured and simulated absorption spectra of (c, d) oblique wire bundle (OWB) and (e, f) planar metamaterial absorbers.

From the blue curve in **Figure 2**, it can be seen that the OWB metamaterial absorber favors the Fano resonance of all four vibration modes, and the line shapes are clearly asymmetric, which indicates the Fano resonance; in addition, the signal is stronger at y-polarization incidence, at 88.5 and 90 THz compared with that at x-polarization incidence, which is evidence of the better enhancement of the y-polarization. On the other hand, the planar metamaterial absorber exhibits Fano resonance only for the strongest vibrational mode with the least damping, i.e., the O = C = O stretching mode of CO_2, and only a superposition of absorption for the other three modes. Nevertheless, planar metamaterial absorbers can improve the absorption compared to PMMA absorbers.

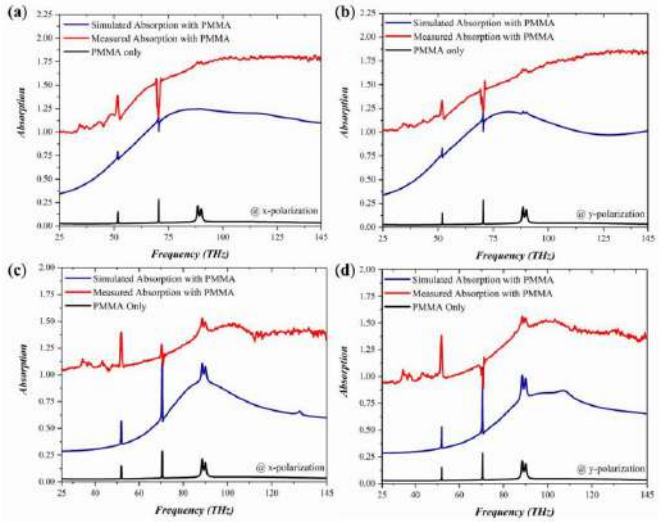

Figure 2. Measured and simulated absorption spectra of the (a, b) OWB and (c, d) planar metamaterial absorbers under the x- and y-polarizations with PMMA. The OWB metamaterial absorber could couple to all the four molecular vibration modes and developed Fano resonance while the planar metamaterial absorber could only couple to the vibrational mode of CO_2 with a superposition behaviour for all the other three modes from PMMA.

Slanted Anisotropic Metasurfaces for Enhanced Reflectance Minimization in CMOS Image Sensors

M. Cho[1], and J. Shin[1*]

[1]Department of Materials Science and Engineering, KAIST, Daejeon 34141, Republic of Korea.
[*]corresponding author: qubit@kaist.ac.kr

Abstract: We propose a slanted anisotropic metasurface (SAMS) to minimize reflectance in silicon photodetectors by adapting to incidence angle and polarization variations. Using slanted TiO_2 elliptical nanodisks, our SAMS achieves broadband antireflection in the visible spectrum over ±40° angles through enhanced impedance matching, promising improved optical performance.

Silicon photodetectors in CMOS image sensors suffer from significant reflection losses, reducing light absorption and overall efficiency. To mitigate this, antireflective coatings (ARC) are commonly applied. However, conventional single-layer ARCs (1-ARC) rely solely on film thickness as the primary structural parameter, limiting their broadband antireflection capabilities across varying incidence angles and polarization states. The fundamental limitations of 1-ARC arise from several factors: (1) The refractive index (n, k) values of conventional ARC materials remain relatively constant, making it difficult to maintain impedance matching across the entire visible spectrum. As a result, a design optimized for a single wavelength becomes ineffective at shorter and longer wavelengths, leading to residual reflectance at the spectral edges. (2) The angle of incidence varies significantly depending on the position of the silicon photodetector (Si PD) within the CMOS sensor array. While different ARC thicknesses could provide better antireflection for specific angles, fabricating spatially varying film thicknesses across the sensor is impractical. (3) Traditional ARC materials lack anisotropic optical properties, and even if anisotropic materials are used, 1-ARC designs cannot align the optical axis according to the spatial distribution of the Si photodetector surface. These limitations result in persistent impedance mismatch across broader angular ranges and polarization conditions, particularly at oblique incidence. In addition to 1-ARC, various anti-reflection techniques like multilayer coatings, nanoparticles, surface texturing, and metasurfaces [1-3] have been explored, mainly for uniform incident angles in solar panels. However, CMOS image sensors face varying angles and polarization across the silicon photodetector, making broadband reflectance reduction still an unresolved challenge.

To overcome these challenges, we propose a slanted anisotropic metasurface (SAMS) that dynamically adapts to the spatially varying incidence conditions in CMOS image sensors. As shown in Figure 1(a), the SAMS consists of slanted TiO_2 elliptical nanodisks arranged in a triangular lattice on a crystalline Si substrate. The structural parameters were optimized using a particle swarm optimization (PSO) algorithm to minimize reflectance for specific incidence angles and polarization states.

Objective function F, is defined as

$$F = \frac{\sum_{400}^{700} R_{p-pol} + \sum_{400}^{700} R_{s-pol}}{Total\ points} \quad (1)$$

In Equation (1), $R_{\text{p-pol}}$ and $R_{\text{s-pol}}$ represent the reflectance for p-polarized and s-polarized light, respectively, calculated over the visible wavelength range from 400 nm to 700 nm. The total points corresponds to the wavelength intervals used within this range. By optimizing slanted design, we can introduce artificial dispersion and give controlled anisotropy, enabling enhanced impedance matching across a wide range of incidence angles and polarization conditions. To illustrate the performance of the SAMS, we present reflectance results for normal incidence (θ=0°) and oblique incidence (θ=30°) as representative cases. Figures 1(b) and (c) compare the reflectance spectra of the SAMS and a conventional 1-ARC under these conditions. At normal incidence, Figure 1(b) shows that the SAMS achieves near-zero reflectance across the visible spectrum, significantly outperforming the 1-ARC. For oblique incidence, Figure 1(c) demonstrates that the SAMS maintains low reflectance for both s- and p-polarized light, whereas the 1-ARC still exhibits relatively higher reflectance due to impedance mismatch.

By leveraging its slanted nanostructures, the SAMS provides broadband antireflection in the visible spectrum for incidence angles up to ±40°, offering a scalable and robust solution for next-generation CMOS image sensors. With its superior optical performance compared to traditional ARC approaches, the SAMS enables improved light collection efficiency, making it highly suitable for high-performance imaging applications (Detailed research findings will be presented in the conference poster session).

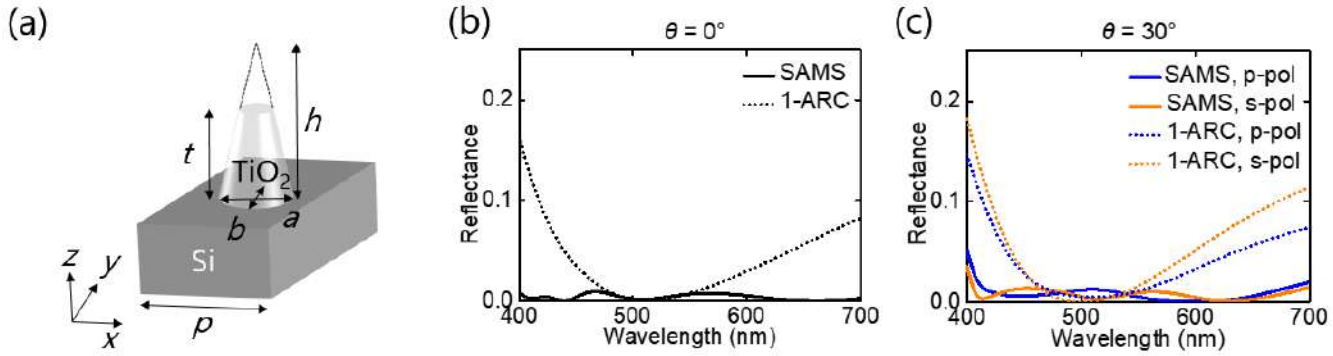

Figure 1. Reflectance spectra of the SAMS and 1-ARC, optimized at specific incidence angles with an azimuthal angle of φ=0°. Abstract

The temperature sensitivity of a metamaterial that operates as a passive sensing device in the millimeter-wave regime is analyzed. Broad-side coupled split-ring resonators are manufactured on two glass substrates, with a dielectric spacer between them. The sensor effect is the tuning of the resonance frequency due to a temperature-dependent change in the permittivity of the dielectric spacer. The experiment shows a sensitivity of $(10.5 \pm 1.0)\,\mathrm{MHz/°C}$.

1 Introduction

Millimeter-wave metamaterials have gained importance in different applications because of their applicability as wireless sensors. For temperature sensing this can be beneficial given the constraints in temperature range and mechanical setup [1]. Different designs have been proposed depending on the target temperature range, for example [2] showed a metamaterial design with double split-ring resonators filled with sea water and a temperature range of 10°C to 30°C. Kairm et. al [3] used a closed ring resonator design to propose a sensor system for 450°C to 800°C. Temperature sensors based on mm-wave metamaterials can be implemented with a separate read-out element and allows to sense the temperature locally. The approach in this work with metamaterials is the additional feature of sensing temperature at the same location without interfering with wiring and electronics.

2 Metamaterial design

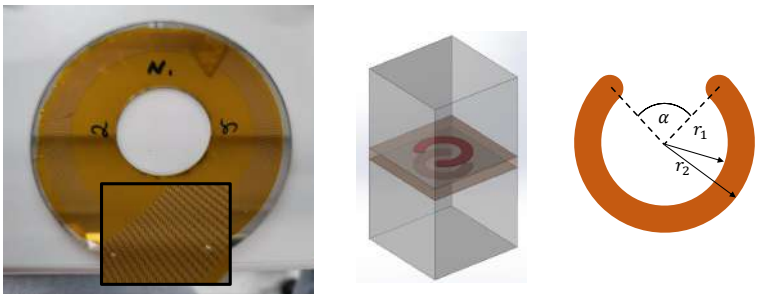

Figure 1: Metamaterial design under test, $r_1 = 140\,\mu\mathrm{m}$, $r_2 = 230\,\mu\mathrm{m}$, $\alpha = 90°$.

For the metamaterial design we chose broadside-coupled split ring resonators (BCSRR) which are processed on two separate glass disks. The glass disks are 700 µm thick and are glued together (polysiloxane) with a separation film (Kapton) holding a layer of glue on both sides. The nominal thickness of the film with the glue is 140 µm. A simulation was done to estimate

the size of the rings based on the permittivity of the used materials. The target resonance frequency of the metamaterial was designed to be in the range of 60 GHz to 70 GHz. In this range commercial mm-wave chips are available for read-out. The size parameters for the split rings are shown in fig. 1. The backside of one of the disks is coated with a thin layer of titanium to reflect the incoming waves and measure the reflection spectrum of the metamaterial.

3 Measurement results

The reflection spectra of the metamaterial were recorded using a Vector Network Analyzer (VNA). The horn antenna was placed directly above the metamaterial at a distance of 15 mm.

For the temperature measurement we used the ambient room temperature of a temperature stabilized laboratory as this has a sinusoidal variation from 21° to 23°. A Pt100 temperature sensor as reference was mounted on the metamaterial and for every 30 s a reflection spectrum (S11) and a temperature value was recorded. From the measurement data the resonance minimum was calculated and plotted as a time series with the temperature data. (see fig. 2). From the data we calculated the Pearson correlation coefficient to estimate the correlation of the temperature T to $f_{\min}$ and the temperature inertia of the system. We assumed a linear relation as the temperature difference is only $\Delta T \approx 2°$. The data gives Person coefficient of 0.919 with a time shift of 4 minutes coming from the temperature inertia of the setup. The linear fit for the temperature and the resonance frequency yields to a sensitivity of (10.5 ± 1.0) MHz/°C.

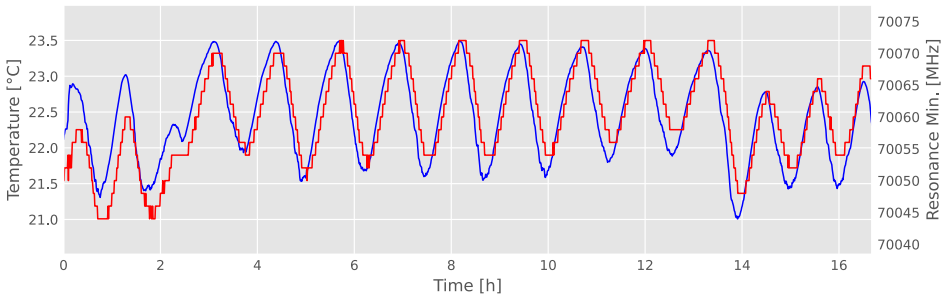

Figure 2: Time series of temperature and resonance minimum for the metamaterial.

Abstract: 6G technologies will require fast and efficient mm-wave beam steering, yet methods to achieve this are still evolving. Here, we experimentally demonstrate a novel mm-wave spatial light modulator based on an optically controlled metasurface. Our system is capable of arbitrary beam shaping – including multicasting and orbital angular mode generation.

With the rapidly increasing demand for high-speed communication systems, high efficiency reconfigurable beam-steering technologies are essential to support high-frequency operations beyond the GHz and into the THz regime [1]. Here, we present the design and implementation of a novel reconfigurable mm-wave metasurface, capable of arbitrary spatially-varying phase modulation of reflected beams. This control is achieved all-optically, by photo-activating local areas of the surface to dynamically encode target phase holograms. We demonstrate high-precision beam focusing, steering, orbital angular momentum mode generation and beam splitting (multicasting) at 50 GHz. Our approach enables dynamic control reflected beam direction and shape, while substantially reducing the hardware complexity in comparison with conventional phased arrays. Furthermore, numerical simulations and experimental results demonstrate significant improvements in beamforming efficiency, steering accuracy, and focusing power at 50 GHz, compared to standard amplitude-only modulation [2,3]. Our concept is scalable to THz frequencies, holding promise for next-generation 6G networks and applications in low-latency communication and high-speed data transfer networks.

Abstract: We present an optimized bilayer meta-substrate for hyper-sensitive strain sensing, achieving a near-ideal Poisson's ratio of -1. By tuning the geometrical factors of auxetic structures, we maximize gauge factor performance beyond conventional designs. Experimental validation confirms enhanced sensitivity, demonstrating the potential for precision biomechanical monitoring and next-generation flexible sensors.

Real-time detection of ultra-small deformations in complex structures is crucial for advanced biomechanical engineering. While flexible strain sensors offer adaptability to various shapes, their sensitivity remains inferior to spectroscopic imaging techniques. Crack-based strain sensors utilizing Meta-Cracks exhibit significantly high strain resolution of 10^{-5} scale, capable of detecting infinitesimal strain through a novel crack-opening mechanism.[1] These sensors achieve exceptional GFs exceeding 1000 at strains as low as 10^{-4} when integrated with substrates exhibiting a Poisson's ratio of -0.9.[1] The hypersensitivity is attributed to a crack-opening behavior that remains independent of orientation, as verified through simplified models and finite element analysis.[1]

Building upon the previous study on strain sensors utilizing Meta-Cracks[1], we investigate the role of meta-substrate design in optimizing sensor sensitivity. While prior work employed reference auxetic structures without systematic characterization of Poisson's ratio effects, our study strategically tailors the mechanical properties of bilayer meta-substrates to enhance strain sensitivity. By precisely engineering the geometry of the meta-material layer, we achieve a Poisson's ratio close to -1, which maximizes crack opening efficiency and strain-induced resistance changes. This approach integrates theoretical modeling, finite element simulations, and experimental validation to establish an optimized design paradigm for meta-substrates in strain sensing applications.

We successfully fabricated and tested a meta-substrate-integrated strain sensor with a near-optimal Poisson's ratio (-1). Figure 1 shows the normalized crack gap distance (D/D_0) presenting continuously increasing states in all orientations under −0.9 Poisson's ratio, and getting saturated to the same crack opening rate, while presenting the crack narrowing behavior in specific orientations under 0.3 Poisson's ratio. Experimental results of Meta-Crack sensor with a Poisson's ratio of near -1 confirmed a substantial increase in sensitivity, surpassing prior auxetic designs. This advancement opens new avenues for hyper-sensitive, conformal, and biocompatible

strain sensors applicable to biomedical monitoring, soft robotics, and precision mechanical diagnostics. Moreover, this research contributes to the fundamental understanding of meta-material mechanics in functional sensor applications and provides a scalable design methodology for next-generation flexible electronic devices.

A Broadband Artificial Magnetic Conductor Utilising Magnetodielectric Substrate and Multilayered Metasurface

C. P. Gallagher[1], S. J. Berry[2], C. R. Lawrence[2], and A. P. Hibbins[1]
[1]The University of Exeter, United Kingdom

c.gallagher2@exeter.ac.uk (corresponding author)

Abstract

We present an artificial magnetic conductor comprising a multilayered metasurface and a magnetodielectric composite. The metasurface confines the electric field, prioritizing the bandwidth enhancement of the relative permeability over the reduction from the relative permittivity. This design achieves a 110% bandwidth (300-1100 MHz) with a significantly sub-wavelength height <15 mm.

1 Introduction

Microwave metasurfaces are technology enablers that present the unprecedented ability to control the interaction between matter and electromagnetic waves. Applications such as electromagnetic filtering [1], broadband absorption [2], beamforming [3] and antenna miniaturisation [4] have all seen enhancements in recent years owing to the development of microwave metasurfaces. However, there are still limitations on the bandwidth that can be achieved with microwave metasurfaces when using standard dielectric substrates. Broadband technologies can be developed using magnetodielectric composites to enhance the bandwidth, but these rely heavily on developing composites that have significantly higher relative permeability than relative permittivity. This is no simple task for microwave applications, as the permeability is considerably lower than at, for example, 10s of MHz. Here we present a multilayered metasurface that, on resonance, confines the electric field outside the magnetodielectric composite. This confinement of the electric field means the bandwidth enhancing effects of the relative permeability in the composite takes precedence over the diminishing effects arising from the relative permittivity. Using this design, an artificial magnetic conductor is presented for operation over the frequency range 300 – 1100 MHz, boasting a bandwidth in excess of 110%. The total height of the artificial magnetic conductor is 15 mm, corresponding to a size less than $\frac{\lambda}{28}$ for the central operating frequency (700 MHz). We present simulation results for the operation of an equiangular spiral antenna when using this AMC as the groundplane for the antenna, and compare these results for simulations of the performance of the same antenna in freespace. The AMC groundplane allows design and fabrication of conformal antennas for communications that will have a minimal footprint in terms of depth. These AMC groundplanes are hence important for the development of communications antennas in, for example, the aerospace industry where antennas would ideally conform to the shape of the aircraft fuselage, and require as little internal space as possible.

Abstract: We propose a 3D spherical reciprocal invisibility cloak using shell-based dielectric metamaterials, minimizing scattering and ensuring effective concealment. The cloak operates from 2.8 to 4.33 GHz with 1.63 GHz bandwidth, offering simpler design, broader bandwidth, and improved fabrication feasibility for transformation optics applications.

Traditional invisibility cloaks based on transformation optics (TO) and scattering cancellation face challenges such as customization requirements, bandwidth limitations, and fabrication complexity. To address these issues, we propose a 3D spherical reciprocal invisibility cloak, composed of shell-based dielectric metamaterials, which can be fabricated using advanced ceramic manufacturing techniques.

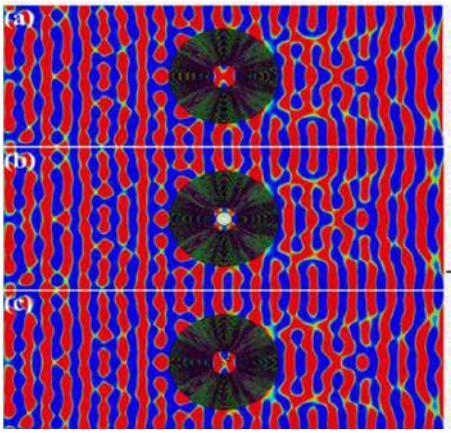

Figure 1 presents the structural parameters and simulated electric field distribution of the 24-layered reciprocal cloak. The cloak is designed with anisotropic material properties, where odd layers correspond to TE modes and even layers to TM modes. The simulation results confirm that the cloak effectively minimizes scattering and maintains smooth wavefronts, ensuring the concealment of hidden objects. The scattering cross-section analysis indicates variations of 8.44% and 1.11% along the θ and ϕ directions, with an average field deviation of 7.2%, verifying its excellent cloaking performance. To further evaluate the cloak's efficiency, Figure 2 presents the simplified design parameters and corresponding electric field distribution. Figure 2 demonstrates the simplified cloak's material parameters and field distribution. Here, c (mm) represents the shell thickness, while ε and μ values correspond to the anisotropic material properties of different layers. Through optimized design, the number of metamaterial layers is reduced, significantly improving computational efficiency. Additionally, the simulation results show that the cloak operates within the frequency range of 2.8 GHz to 4.33 GHz, with an average relative deviation below 7%, ensuring effective concealment of hidden objects. The cloak achieves a total bandwidth of 1.63 GHz, exhibiting excellent frequency response performance. Compared with existing designs, our cloak features a simpler structure, broader bandwidth, and improved fabrication feasibility. Moreover, we provide the anisotropic material properties of the shell-based dielectric metamaterials, including permittivity (ε) and permeability (μ), applicable to both TE and TM modes, ensuring the cloak's performance and manufacturability. The study confirms that the proposed spherical reciprocal invisibility cloak effectively conceals both metallic and dielectric objects, making it suitable for optical camouflage, radar stealth, and electromagnetic wave control. This approach provides a scalable solution for next-generation transformation optics applications.

Abstract: In this paper, we study how a cylindrical shell made from a radially anisotropic material can modify the electric field inside an isotropic core, either by enhancing or suppressing it. We present a water-air metamaterial that enhances electric fields by 10 dB across a broad frequency range.

We consider a radially anisotropic cylinder with a diagonal permittivity tensor in cylindrical coordinates, with components in the radial, azimuthal and axial directions [1]. An electric field which is polarized in the polar plane is influenced by the radial component ε_r and the azimuthal component ε_θ. In the scope of the quasi-static approximation, such cylinders can be constructed by a metamaterial of wedges or of shells, as shown in Figure 1b and described in reference 2. The anisotropy ratio defined by $v^2 = \varepsilon_\theta / \varepsilon_r$ is less than or greater than 1, respectively. The electric field inside a radially anisotropic cylinder is proportional to r^{v-1}, where r is the radial coordinate. This implies that in the case of a wedge metamaterial, the electric fields theoretically increase to infinity as they approach the cylindrical axis, while in the case of a multi-shell metamaterial, the electric fields are suppressed.

For practical reasons, we consider core-shell cylinders with an empty core of finite size in which the electric fields are enhanced or suppressed. These have an isotropic core of radius a, surrounded by a shell of a radially anisotropic material, forming a cylinder of radius b (Figure 1a). Although the electric field in the shell (whether isotropic or anisotropic) is not uniform, the electric field in the isotropic core material remains constant. We can define an enhancement factor A for the electric field in the core, which is: $E_{core} = A\, E_0$, where E_0 is the incident electric field. This factor has already been derived in previous work [3,4]. As the anisotropy ratio v approaches zero, A approaches b/a. If v instead goes to infinity, A tends to zero.

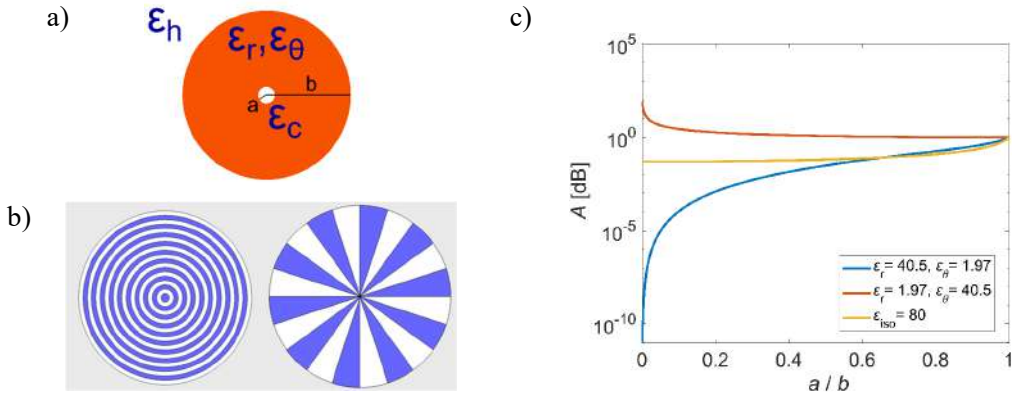

Figure 1. a) Schematic of a radially anisotropic core-shell cylinder. b) Schematic of the shell and wedge metamaterial realization. c) Enhancement factor for water-air metamaterials in the effective medium approximation as a function of the core-to-cylinder radius ratio for a water content of 50%.

To achieve a significant permittivity contrast, we chose to study water-air metamaterials in the microwave frequency range. At a frequency of 1 GHz, water has a permittivity of 80 and is nearly lossless. Figure 1c shows the enhancement factors of such cylinders as a function of the core-to-cylinder ratio. These theoretical considerations are valid in the quasi-static regime. In our experiments the enhancement is also affected by Mie resonances with the structure. Employing radially anisotropic structures with an optimized water content of 20%, we can smooth out these resonances and achieve a broadband enhancement of an incident electric field by 10 dB (Figure 2a).

We fabricated the wedge structure by 3D printing a polymer scaffold with an outer diameter of 6 cm and an empty core of 6 mm. Water was then filled into the designated areas (blue for visualization purposes). A horn antenna is used to direct an electromagnetic field onto the structure, while the power is measured in the air-filled core. The experimental setup is shown in Figure 2b. In Figure 2a, we plot the calculated intensity enhancement in dB scale of the printed structure alongside that of the pure metamaterial. The differences in these results are due to the effect of the polymer scaffold.

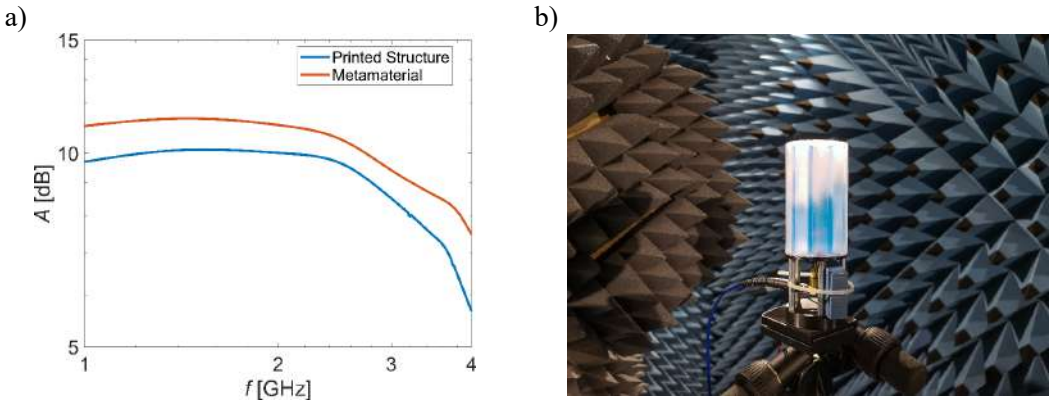

Figure 2. a) Calculated enhancement factor as a function of frequency for the water-air metamaterial and the printed structure. B) 3D printed structure in the measurement chamber with water in the wedge areas

In summary, we have developed a metamaterial-based, non-resonant and omnidirectional antenna which relies solely on water and air. The electric field enhancement is achieved through an effectively radially anisotropic shell. Similar to the wedge metamaterial, we aim to fabricate a water-based multi-shell cylinder designed to cloak its core material.

JB, ME and AP thank Dassault Systèmes for providing their simulation software “CST Studio Suite”.

Abstract: Here, we propose a miniaturized imaging system based on integrating scattered light spatial frequencies under angled illumination. We employ spatially arranged vertical-cavity surface-emitting lasers to configure the azimuthal beam rotation. This, integrated with silicon and gallium arsenide metasurfaces, facilitates fast biological specimens imaging beyond the classical diffraction limit.

Fluorescence microscopy offers a way to achieve sub-wavelength resolution in cell images; however, photobleaching and motion blur hinder its effectiveness. Consequently, there is a need to develop rapid marker-free imaging systems. In an optical system, the highest resolvable spatial frequencies of the image are constrained by the numerical aperture of the objective lens. Angled illumination is recognised as an effective method for capturing higher spatial frequencies, thus improving image contrast and resolution. The 2π azimuthal rotation of the angled illumination has been utilised as a strategy to construct a synthetic aperture that maximises the collected spatial frequencies [1, 2]. While this method produces images with higher resolution and contrast, in practice, the image acquisition speed of the system is limited to 100 Hz due to the use of scanning mirrors [3]. An elegant solution for miniaturizing optical systems is found in the combination of vertical-cavity surface-emitting lasers (VCSEL) with metasurfaces [4, 5]. Metasurfaces consist of a collection of sub-wavelength-sized structures and can replicate and combine the functions of traditional bulk optical elements as well as surpass their capabilities by manipulating the phase of the incident field with sub-wavelength resolution. The application of VCSELs as the light source for metasurfaces ranges from biosensing [5, 6] to the generation of holographic images [7].

Here, we suggest a novel approach for performing fast 2π rotational angled microscopy and enhancing its image acquisition rate. We leverage VCSEL-based meta-optical systems to miniaturize conventional 2π rotational angled microscopes (Fig. 1b). The meta-device is constructed from VCSELs with a working wavelength of 980 nm arranged in a circular pattern to facilitate rotational illumination (Fig. 1c). Each of the VCSELs can be electrically switched at speeds of tens of gigabits per second. We design a Pancharatnam–Berry metasurface to function as a half-wave plate, rotating the output VCSEL polarization to the required state (Fig. 1d). The inherent divergence of a VCSEL is exploited for spatial broadening of the beam as it propagates through a glass spacer, thus achieving the beam diameter required for illumination. A polarization-independent metalens is engineered to collimate the beam (Fig. 1e). A phase-gradient metasurface (Fig. 1f) deflects light to the imaging spot at an angle of 70 degrees. It is worth noting that, due to the very large incident angles, aside from the light portion that decouples through scattering, the input beam undergoes total internal reflection (TIR) and

will not be captured by the imaging system. This implies that the metasurface/VCSEL-based 2π-rotating microscope can be operated in TIR mode.

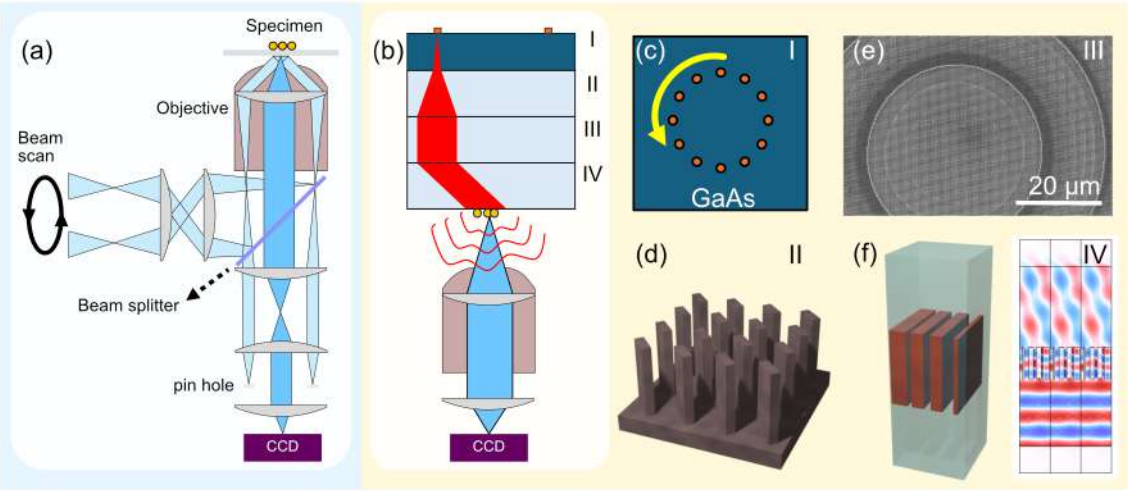

Figure 1: *On-chip* 2π*-rotating coherent microscopy.* (a) Schematics of a conventional rotational microscopy setup, adapted from [1]. (b) Conceptual schematics of a surface-emitting laser-based on-chip device with integrated all-dielectric metasurfaces for 2π-rotating microscopy. (c) Top view of the device with individually addressable vertical-cavity surface-emitting lasers (VCSEL). (d) Design of a GaAs metasurface acting as a phase-retarding plate. (e) Scanning electron micrograph of a silicon metalens for laser beam collimation. (f) Design of a silicon metagrating and electromagnetic simulation results for high-angle beam deflection.

Our research findings may facilitate the commercialization of on-chip microscopes if combined with flat imaging optics and detectors, decreasing their image acquisition time and making them more affordable and widely accessible. Moreover, the substantial enhancement in acquisition speed provided by this approach will reduce motion blur due to Brownian particle diffusion, resulting in sharper images.

This work was funded by the Knut and Alice Wallenberg Foundation and performed in part at Myfab Chalmers.

Abstract: A parity-time symmetric optical waveguide enabling unidirectional propagation of light is proposed. Its numerical investigation via the finite-difference time-domain method and experimental realization by means of femtosecond direct laser writing is presented. A possible application of such a device is foreseen in optical neural networks.

Due to the associated higher speed and lower power consumption, optical neural networks (ONNs) have recently emerged as a promising computing modality. Consequently, a growing research effort is invested in the development of novel hardware architectures that implement the artificial neural networks (ANNs) by means of different optical devices [1].

Here, as our first step in this direction, we aim to achieve unidirectional propagation of light. To this end, we propose a specially designed optical waveguide that respects the parity-time (PT) symmetry of non-Hermitian photonics [2]. Such a structure exhibits different reflectivities depending on the propagation direction of light, and could, therefore, serve in controlling the propagation of light. To fulfill this requirement, both the real and imaginary parts of the structure's effective refractive index must be periodically modulated and phase-shifted with respect to each other. A conceptual design of such a waveguide is shown in Figure 1(a). In this work, we focus on the design and fabrication of the proposed PT-symmetric structure.

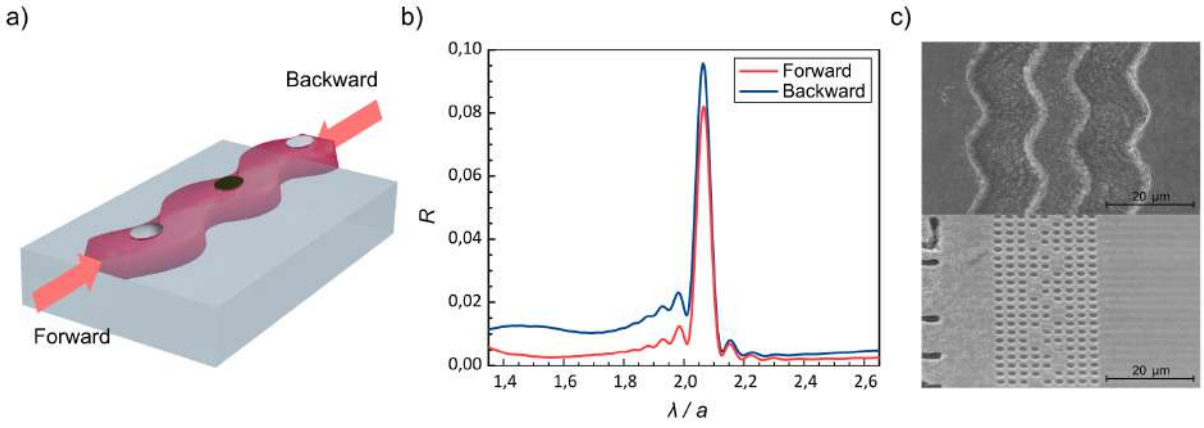

Figure 1: PT-symmetric structure for unidirectional propagation of light. (a) Conceptual design of a periodically modulated dielectric waveguide with metallic islands deposited on top. (b) Simulated forward and backward reflectivities of the device as a function of wavelength λ normalized to the modulation period a. (c) SEM images of fsDLW ridge and PhC waveguides.

We study the propagation of light through the device under investigation using the finite-difference time-domain (FDTD) method. The initial numerical investigation of a non-optimized PT-symmetric waveguide structure (see Figure 1(b)) already indicates a difference in the reflectivity R for light incident in the forward and backward directions. With a careful further optimization of the design, as well as an appropriate choice of the constituting materials, the reflection from one side could be significantly suppressed and increased – from the other, therefore, maximizing the contrast ratio between the two.

Finally, to realize the proposed PT-symmetric structure experimentally, we employ femtosecond direct laser writing (fsDLW). Several different approaches to waveguide fabrication are tested, including laser-ablated ridge and photonic crystal (PhC) waveguides. Scanning electron microscope (SEM) images of the latter implementations are presented in Figure 1(c).

Towards an Inverse-Designed Low-Cost Waveguide Absorber

Christoph Schmidt[1*], Alexander Schossmann[1,2], and Alexander Bergmann[1,2]
[1]Graz University of Technology, Inffeldgasse 33/I, 8010 Graz, Austria
[2]Christian Doppler Laboratory for Structured Matter Based Sensing, 8010 Graz, Austria

Abstract: The paper introduces an inverse-designed waveguide absorber optimized for minimum reflections within the frequency range of 60 GHz to 90 GHz, with a structure that is manufacturable with cost-efficient 3D SLA printing. Validation of simulations indicates similar or even better performance than traditional absorbers, exhibiting an improved Voltage Standing Wave Ratio of 1.03.

1 Introduction

Waveguide absorbers with high return loss are crucial in microwave engineering, especially for terminating ports with impedance-matched loads. This is done by using special material (e.g., graphite or ferrite), removing impedance discontinuities, and ensuring a complete energy transfer into the absorber. Conventional absorbers, however, are constructed from specialized materials and require precise machining, leading to high costs. [1] Conversely, a 3D-printed methodology has demonstrated promising outcomes as a low-cost alternative. However, it depends on the empirical shape and material selection [2]. This work presents a novel methodology for a inverse-designed waveguide absorber, optimized to minimize reflections within the frequency range of 60 GHz to 90 GHz. Utilizing Inverse Design (ID), we propose a compact and cost-effective absorber that can be manufactured by consumer-grade 3D Stereolithography (SLA) printing techniques.

2 Inverse Design Formulation

Using ID, one may identify counterintuitive structures by Topology Optimization (TopOpt). The given problem is based on Maxwell's wave equation (Eq. 2) aiming to minimize the reflection coefficient S_{11} at the waveguide termination. The S_{11} parameter is used to determine the power dissipation. The gradient-based MMA solver is used for optimization. The optimization problem is formulated as a set of $N = \texttt{len}(\texttt{range}(60, 0.5, 90)\text{GHz}) = 61$ discrete sub-problems.

$$\max_{\varepsilon_r} \frac{1}{N} \sum_{N} \left(1 - |S_{11}|^2\right) \quad \text{with} \quad S_{11} = \frac{\int_{\partial\Omega} (\boldsymbol{E} - \boldsymbol{E}_1) \cdot \boldsymbol{E}^*}{\int_{\partial\Omega} (\boldsymbol{E} - \boldsymbol{E}_1) \cdot \boldsymbol{E}} \tag{1}$$

$$\text{s. t.:} \quad \nabla \times \left[\boldsymbol{\mu}_r^{-1} (\nabla \times \boldsymbol{E})\right] - \left(\omega^2 \mu_0 \boldsymbol{\varepsilon} - \mathrm{i}\omega\sigma\right) \boldsymbol{E} = \boldsymbol{0} \tag{2}$$

To guarantee a manufacturable design, the Solid Isotropic Material with Penalization (SIMP) method employing a Filter- and Threshold approach (Eq. 3) and a continuation scheme is utilized [3, 4]. We employ the continuous optimization variable $\theta_c \in [0, 1]$, which is subjected to filtering to remove small features ($\theta_c \to \theta_f$) and is then thresholded to enforce a near binary (black and white) designs ($\theta_f \to \theta$). The variable θ is then mapped linearly (Eq. 4) to the relative permittivity ε_r and the loss tangent $\tan\delta$.

$$0 \leq \theta_c \leq 1, \quad \theta_f = \theta_c + r_f^2 \nabla^2 \theta_f, \quad \theta = \frac{\tanh(\beta \cdot \eta) + \tanh(\beta(\theta_f - \eta))}{\tanh(\beta \cdot \eta) + \tanh(\beta(1 - \eta))} \tag{3}$$

$$\varepsilon_r = \varepsilon_{r,\text{Opt}} + \theta(\varepsilon_{r,\text{Air}} - \varepsilon_{r,\text{Opt}}), \quad \tan\delta = \tan\delta_{Opt} + \theta(\tan\delta_{Air} - \tan\delta_{Opt}) \tag{4}$$

3 Simulation and Verification

The 2D design is based on a *WR12* waveguide geometry, ensuring compatibility with standard components. The optimization domain measures 10 mm × 30 mm and is enclosed within a metal cavity. For the simulation's material parameters, standard 3D SLA printing resin properties ($\varepsilon_r = 2.76$; $\tan\delta = 0.025$) [5] have been taken.

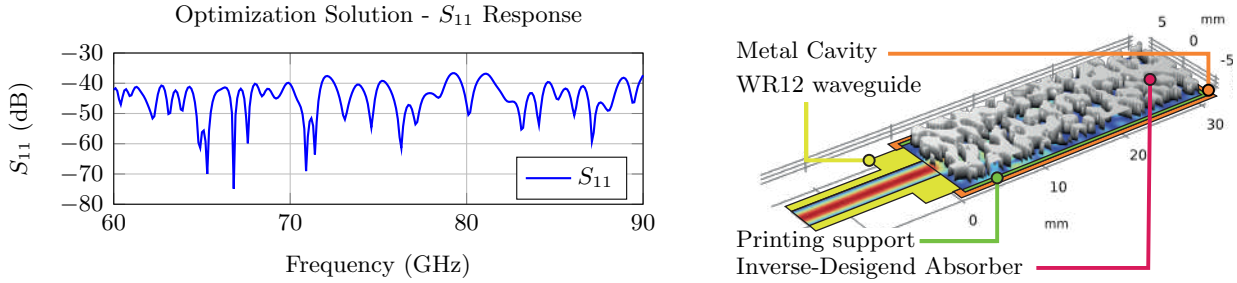

Figure 1: S_{11} spectra of the simulation and the corresponding optimized design.

A summary of the performance comparison regarding return loss and VSWR (Voltage Standing Wave Ratio) between the inverse-designed absorber and a commercially available WR-12 waveguide load is presented in Table 1.

Table 1: Comparison of WR-12 Waveguide Loads

	Frequency (GHz)	**Return Loss (dB)**	**VSWR** (Maximum)
Our Design	60–90	−36 to −75	1.03 : 1
Pasternack PE-W12TR1001	60–90	> −20	1.2 : 1
Flann 26040 Terminations	60.5–92	> −35	1.035 : 1

4 Conclusion and Outlook

This work introduces an inverse-designed waveguide absorber as a cost-effective alternative to traditional calibration loads. A compact and efficient design is achieved, demonstrating comparable or better performance in simulations across the 60 GHz–90 GHz range. The results indicate that good performance is achievable within a small area of 30 mm × 10 mm. The structure is designed for fabrication using commercially available 3D SLA printing, ensuring easy manufacturability. Future work will focus on fabricating the inverse-designed absorber and experimentally validating its performance regarding simulated results, including the return loss and overall absorption efficiency in a controlled measurement setup.

Abstract: Liquid crystal (LC) metasurfaces exhibit excellent tunability in multidimensional control of terahertz waves. We design a programmable metasurface with in-plane switching to enhance the response speed of LC. The simulated spectral response agrees well with the experimental results, manifesting its applications in the fields of computational imaging and dynamic holography.

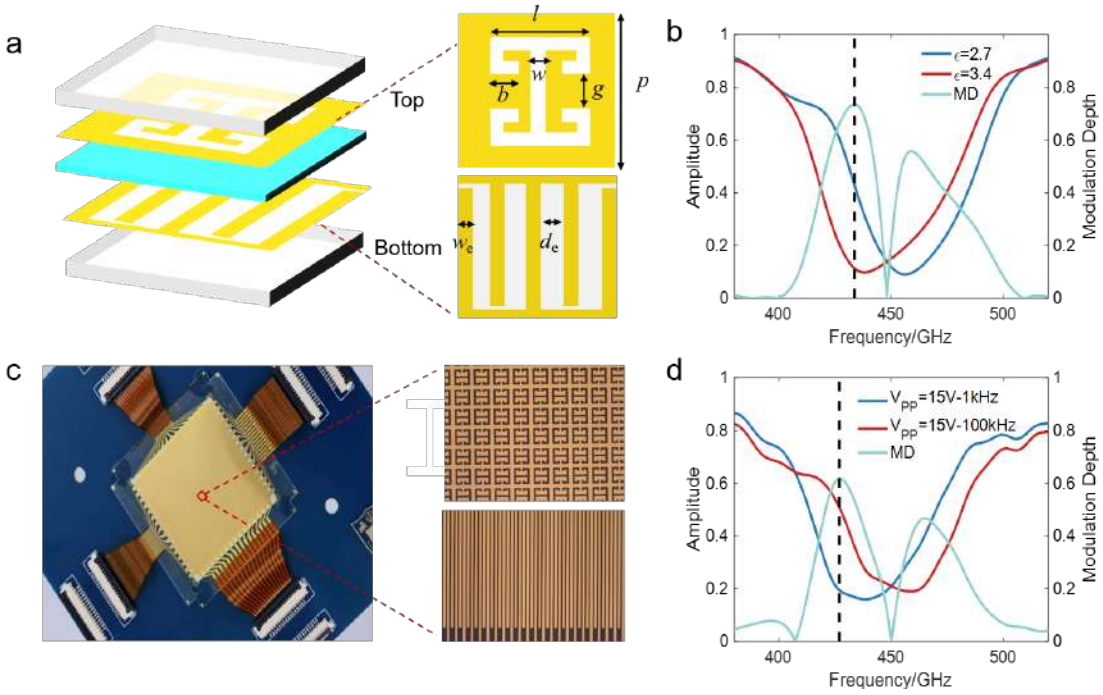

Figure 1 Device structure and spectral response of LC programmable metasurface. (a) Schematic of the unit cell structure and the diagram of metal layers. (b) Simulated THz transmission spectra using dual-frequency LC. (c) Optical image and microscopic image of fabricated devices. (d) Measured THz transmission spectra using dual-frequency LC.

We propose an LC-based programmable transmissive metasurface[1] with a fast response time. Figure 1a illustrates the structure of a unit cell and the diagram of the top and bottom metallic layers. From top to bottom, the unit cell consists of quartz substrate, gold layer, LC, gold layer, and quartz substrate. The thickness of both top and bottom quartz substrates is 500 μm, while that of the gold layer is 300 nm. The geometrical parameters

of the metal layers are defined as follows: p = 300 μm, b = 50 μm, l = 240 μm, g = 30 μm, w = 30 μm, w_e = 30 μm and d_e = 8 μm. A 10-μm-thick dual-frequency LC (Jiangsu Hecheng Display Technology, DP002-016) was selected as the spacer, as it exhibits a large birefringence at 0.2–1.1 THz and does not need an alignment layer to define the orientation of LC molecules. The loss tangent of the LC is set to 0.058.

The unit cell is numerically modeled and the simulated spectral response of the metasurface is presented in Fig. 1b. The results reveal a substantial switching contrast around 438 GHz, where the normalized transmission amplitude varies from 0.5 to 0.16. The modulation depth (*MD*) is defined as $MD = \frac{T_{off} - T_{on}}{T_{off}}$, where T denotes the signal amplitude and the calculated *MD* reaches up to 68%.

The optical image of the fabricated metasurface and its microscopic image are shown in Fig. 1c. Figure 1d illustrates the measured transmission amplitude response under biased voltage with different frequencies. The peak-to-peak voltage is set to 15 V. The dual-frequency LC is controlled by saturation voltages at 1 kHz and 100 kHz for the "on" and "off" states, respectively. The fabricated device achieves a maximum *MD* of 62.5% at 428 GHz, with the normalized transmission amplitude varying from 0.48 to 0.18. The experimental results show good agreement with the simulations, with slight frequency deviation primarily attributed to fabrication tolerances.

Table 1 Comparison of the dual-frequency LC response time under vertical field switching(VFS) and in-plane switching (IPS)

	Normal Switching	IPS
τ_{on}	7.8 ms	38.8 ms
τ_{off}	502.4 ms	48.4 ms
τ_{all}	510.2 ms	87.2 ms

Subsequently, the response time of the device was measured under both VFS and IPS conditions, with the results summarized in Table 1.

In conclusion, we demonstrate that the combination of IPS and dual-frequency LC effectively enhances the response speed of the programmable metasurface[2][3]. The design shows great potential for applications in computational imaging and dynamic holography.

Abstract: An electromagnetic (EM) wave-based method of computing approximate analogue solutions to the Helmholtz equation is presented. This is done by exploiting a grid-like network of metatronic circuits at microwave frequencies. The behavior of the network is analogous to a numerical finite difference grid.

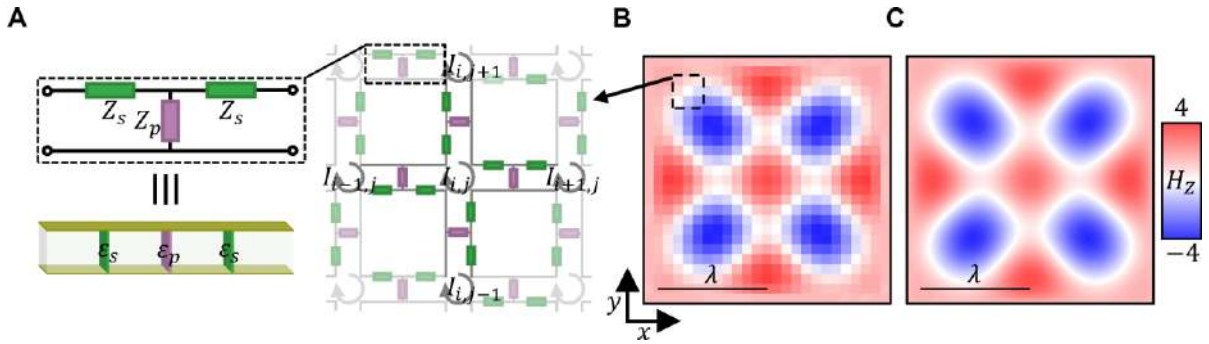

Figure 1. A. (Right) Circuit representation of a PDE solving network designed to solve the Helmholtz equation. The unit cell consists of a junction having four T-circuits (top-left) connected in series. (Bottom-left) Waveguide based-metatronic circuit implementation of a T-circuit. **B.** Numerical simulation for a $\mathbf{25 \times 25}$ network of waveguide based metatronic T-circuits solving a $\boldsymbol{g|_{\partial\Omega} = 1}$, $\boldsymbol{h = 0.2}$, $\boldsymbol{k = 3}$ boundary value problem **C**. Analytical solution.

In recent years, the advantages of electromagnetic (EM) waves, such as an inherent capability for parallel operations, have been exploited to enable high-speed computing operations[1]. EM wave-based processors have been demonstrated performing digital (or quasi-digital)[2] and analogue[1] operations, including elementary switching[3–8], differentiation[9–11], integration[12,13] and convolution[13,14]. Additionally, computationally intensive tasks, such as integral[15,16] or partial differential equation[17–19] (PDE) solving has also been reported. As it is known, analogue PDE solvers can be implemented using circuits[20]. The behavior of such networks is analogous to numerical finite difference grids, with the junctions between circuit elements acting as grid points. Similar approaches have been utilized to solve the Poisson equation $[\nabla^2 g(x,y) = 0]$ at higher frequencies[17,18].

Motivated by the potential applications of metatronic circuits for analogue computing, in this work we present a method of solving PDEs in the form of the Helmholtz equation $[\nabla^2 g(x,y) + k^2 g(x,y) = 0]$ by exploiting a network of waveguide-based metatronic T-circuits at microwave frequencies. A schematic representation of this network is presented in Fig. 1A. Like the previously discussed methods, the network emulates an area of finite difference simulation space with the PDE parameters (grid separation h and wavenumber k) determined by the emulated impedances of the metatronic circuit elements (Z_s and Z_p). Numerical simulation results obtained using CST Studio Suite®, for a 25×25 network solving a $g|_{\partial\Omega} = 1$, $h = 0.2$, $k = 3$ Dirichlet boundary value problem are presented in Fig. 1B. Analytical results for the same scenario are depicted in Fig. 1C As it can be seen, there is a clear agreement between the results indicating the PDE solving network is producing an accurate solution.

A Metamaterial Coherent Detector for mmWave Operation

N. Rozman[1], O. Khatib[2], and W. J. Padilla[2,*]

[1]Leidos Inc., USA
[2]Duke University, USA
[*]corresponding author: willie.padilla@duke.edu

Abstract: A coherent detector, that is both sensitive to phase and amplitude, has yet to be established at high frequencies. To address this gap, we experimentally demonstrate a frequency, phase, and power-sensitive metamaterial coherent detector (MCD) for operation at millimeter (mmW) wavelengths.

Metamaterials have become a promising choice for developing high-frequency components because they can be tailored to cover a wide range of the electromagnetic spectrum through geometric tuning. Metamaterial detectors can leverage engineered absorption in order to measure electromagnetic signals. Metamaterial absorbers have been experimentally demonstrated for a wide variety of applications, including hyperspectral imaging [1], refractive index sensing, and IR detection [2]. Electromagnetic metamaterial absorbers may be fashioned from metal-based metamaterials, [3] or from all dielectric structures, [4] both of which achieve near-unity absorption A at a desired frequency, $f0$. [5]

Our approach leverages two port excitation from opposite sides of the absorber, which can be modeled by temporal coupled mode theory (TCMT), that provides is a general framework useful for describing idealized resonant systems with an added weak disturbance. [6] In this case, the metamaterial is strongly absorbing when radiation of equal power is incident from both sides and is in-phase (symmetric absorber) or out-of-phase (anti-symmetric absorber). In electromagnetic wave absorbers, the perturbation represents a weak coupling of the resonant systems together, and the method is analogous to time-dependent perturbation theory. [7]

In this work, we experimentally demonstrate a metamaterial coherent detector (MCD) whose response is dependent on both the amplitude and phase of an incident electromagnetic wave. The coherent detector uses a metal-based anti-symmetric metamaterial absorber with an integrated pyroelectric material (Fig. 1a). The metasurface was designed to detect incident mmWave radiation at $f_0 = 91.5$ GHz when two out of phase counter-propagating beams are applied to both sides of the detector (Fig. 1c and 1e).

To demonstrate the coherent nature of the detector, the back reflecting mirror was moved

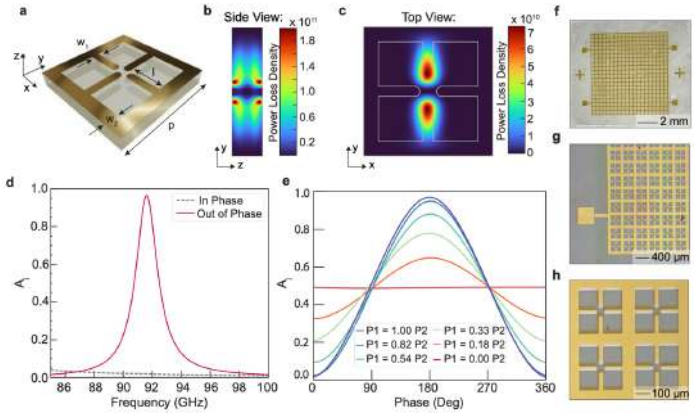

Figure 1 - Frequency, phase, and power-sensitive metamaterial coherent detector. (a) Rendered schematic of the unit cell geometry comprised of two identical patterned metamaterial layers on both sides of a pyroelectric thin film. (b,c) Simulation of the power loss density for out-of-phase excitation at the resonance frequency. (d) Frequency-dependent absorption is shown for out-of-phase (red, solid) and in-phase (gray, dashed) radiation. (e) Normalized phase-sensitive absorption for varying, uneven port power excitation. (f) Image of the coherent detector and. (g,h) optical microscopy images of the metamaterial pattern.

along the optical axis (z-axis of Fig. 2) in a direction away from the device, effectively modifying the phase difference $\Delta\phi$ of radiation incident on the metasurface. Experimental measurements of the detected metamaterial pyroelectric current (Imm) as a function of mirror distance are plotted in Fig. 2b-d for three different operating frequencies. The dependence of the detected metamaterial pyroelectric current as a function of mirror position, or $\Delta\phi$, is plotted as the blue curve for 80 GHz (Fig. 3b), red curve for 91.5 GHz (Fig. 2c), and green curve for 100 GHz (Fig. 2d). The detected signal oscillates as a function of mirror position, or $\Delta\phi$, demonstrating phase-dependent absorptance. As expected, the amplitude of the detected pyroelectric current is relatively small at frequencies of 80 and 100 GHz, with peak values of approximately I_{mm} = 40 pA and Imm = 35 pA, respectively, which is attributed to the lower absorptance values realized by the metasurface.

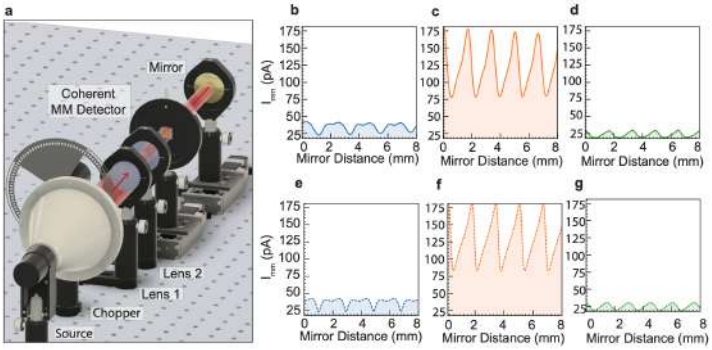

Figure 2 - (a) A schematic depicting the optical configuration used to experimentally test the metamaterial coherent detector. Experimental (b-d) and theoretical (e-g) pyroelectric current signal at frequencies of 80 GHz (b,e), 91.5 GHz (c,f), and 100 GHz (d,g) as a function of mirror distance.

In summary, our study has successfully conceptualized, simulated, and experimentally validated the first metamaterial coherent pyroelectric detector. Our design was specifically tailored for frequency-selective coherent detection of mmW radiation, but it can be scaled to operate at other electromagnetic bands. WOur study has successfully conceptualized, simulated, and experimentally validated the first metamaterial coherent pyroelectric detector. Our design was specifically tailored for frequency-selective coherent detection of mmW radiation, but it can be scaled to operate at other electromagnetic bands. Our investigation highlights the detector's sensitivity to frequency, phase, and power. This work marks a significant stride in coherent detection, opening avenues for advancements in high-frequency detectors. Our findings lay the groundwork for further exploration and development in this domain, promising potential innovations in the field of metamaterial-based detectors.

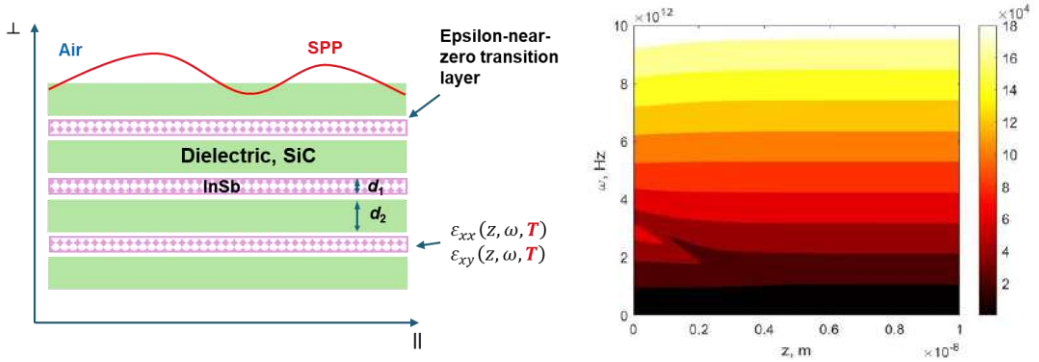
Tunable nanostructured metamaterial with epsilon-near-zero transition layer



T. Gric[1], E. Rafailov[2]

[1] Department of Electronic Systems, Vilnius Gediminas Technical University, Vilnius, Lithuania

Abstract: Propagation of surface plasmon polaritons at the boundary of semiconductor based nanostructured metamaterial with epsilon-near-zero transition layer is investigated. The dispersive properties are altered by a dielectric function being temperature dependent allowing for sensing applications.

The metamaterials offer much-needed atypical material features to help with the subwavelength concentration of electromagnetic fields, which is the focus of nanophotonics research [1]. By investigating propagation of surface plasmon polaritons (SPPs) at the boundary of semiconductor based nanostructured metamaterial with epsilon-near-zero transition layer, we demonstrate that the surface plasmon's dispersion along with the absorption is altered by a continuous dielectric function that is temperature dependent opening the wide avenues for sensing applications.

A continuous function $\varepsilon(z)$ of the normal to the interface coordinate z describes the properties of the nanostructured metamaterial structure due to the existence of the transition layer. It should be topologically equal to a kink, however the major results for the spectrum of SPP are not sensitive to the particular form of $\varepsilon(z)$ [2]. Here, we'll look at a semiconductor-based metamaterial heterostructure made up of stacked anisotropic semiconductor sheets separated by dielectric layers, as schematically shown in Figure 1.

(a) (b)

Fig. 1. Diagram showing the contact between air and an infinitely layered nanostructured metamaterial made of alternating dielectric and semiconductor layers (a). Real part of the propagation constant β (b). Herein, d_1=6 nm, d_2=10 nm, T=350K.

To describe the optical response of such a system, we employ the effective-medium technique [3], which is suitable when the wavelength of the light in question is substantially larger than the thickness of any layer. It is based on the average of the structure parameters. The effective homogeneous media for the semi-infinite periodic structure are thus still covered in this work.

By matching the tangential components of the electrical and magnetic fields, the dispersion relation for the

surface modes localized at the boundary separating an anisotropic media and dielectric is inferred at the interface. Because the relevant layers are represented by semiconductors, we assume that the permittivities $\varepsilon_{xx,xy}(\omega)$ are frequency dependent.

It should be mentioned that the frequency range of surface wave existence may be significantly controlled by adjusting the permittivities and thicknesses of the layers [4] utilized in the metamaterial. One must evaluate the tangential components of the electric and magnetic fields at the interface and generate a single surface mode with the propagation constant in order to determine the unique dispersion relation for the surface modes restricted at the interface between metamaterial and air [5].

$$\beta(z,\omega) = k\sqrt{\frac{\left(1-\varepsilon_{||}(z,\omega)\right)\varepsilon_{\perp}(z,\omega)}{1-\varepsilon_{\perp}(z,\omega)\varepsilon_{||}(z,\omega)}}, \tag{1}$$

where k is the wavevector's absolute value in vacuum and β is the wavevector component parallel to the interface.

Abstract: Barium titanate (BTO) displays diverse exotic characteristics, therefore, various studies on its engineering have been conducted. However, accurate optical constants of BTO have not been reported. Here, we firmly determined the complex refractive index of BTO from the visible to the mid-infrared range by using Mueller-matrix spectroscopic ellipsometry on BTO.

Barium titanate ($BaTiO_3$, BTO) is one of the earliest reported lead-free ferroelectric polydomain crystal materials, first documented in the 1940s [1]. Numerous studies on BTO have been conducted to analyze and engineer its exotic physical characteristics—including ferroelectricity, pyroelectricity, piezoelectricity, and biocompatibility—which primarily originate from differences in the bonding energy of ionic bonds (Ba^{+2}/TiO_3) and covalent bonds (Ti/O) [2]. Additionally, the high dielectric constant (ε_r > 2,000) of a-axis BTO facilitates various applications, such as multilayer ceramic capacitors, ferroelectric tunnel junctions, and positive temperature coefficient thermistors. BTO exhibits a tetragonal structure (symmetry group *P*4*mm*) at room temperature with anisotropy between the crystallographic c-axis and the other axes. From an optical perspective, BTO shows low optical losses from the near-ultraviolet to near-infrared range, along with transparency, and the Pockels effect, an ultrafast second-order linear electro-optic effect, enables the development of diverse optical components and nonlinear optical systems. In order to accurately characterize the Pockels tensor coefficients of BTO, its intrinsic complex refractive indices must be precisely determined to observe refractive index modulation under an applied electric field. However, the absence of accurate optical constants of anisotropic BTO along ordinary and extraordinary axes due to the ferroelectric multidomain makes it difficult to utilize BTO as an active matrix of nanophotonic devices.

Standard spectroscopic ellipsometry (SE) is a widely used, efficient, and non-destructive optical measurement technique for determining materials' optical thickness and refractive index. The measurement quantities are based on the complex ratio of *p*- to *s*-polarized Fresnel reflection coefficients, corresponding to the two on-diagonal elements of the 2 × 2 complex-valued Jones matrix. While SE effectively quantifies the amplitude and phase ratio of completely polarized light, it struggles to describe the non-ideal polarization states of light, which can frequently arise in anisotropic materials. To overcome these limitations, Mueller-matrix (MM) SE extends the analysis by employing 4 × 4 real-valued Mueller matrices and 4 × 1 Stokes vectors, offering a comprehensive representation of polarization effects, including depolarization and cross-polarization [3]. This capability enables precise optical characterization of complex optical systems and intricate materials.

In this work, we optically characterize the refractive indices, extinction coefficients, and birefringence of BTO across a broad spectral range, from the visible to the mid-infrared range, using transmission and reflection measurement modes. Due to the presence of multi-domains in a-axis BTO, where the c-axis lies in the sample

plane but lacks macroscopic long-range order, we introduce a smearing effect to the Euler angle associated with the optic axis in our ellipsometry model. This modeling approach allows us to extract a single set of ordinary and extraordinary refractive indices consistent for both a-axis and c-axis BTO samples. Furthermore, we utilize strong interference fringes observed in the ellipsometry data, caused by the differing phase velocities of the *p*- and *s*-polarized waves propagating through the sample. These fringes enhance sensitivity to birefringence in the transparent region. To further refine our measurements of the extremely low extinction coefficients (k) in regions where the sample remains partially transparent, we incorporate transmittance data from UV-Vis spectrometry and FTIR measurements. Finally, to validate our fitted data, we calculate rigorous coupled-wave analysis and finite element method simulations, the results of which closely align with the experimental data. We envision that our work will contribute to flourishing BTO-based nanophotonic devices such as photonics integrated circuits and active metasurfaces in various operating ranges, leveraging the physically fitted and practically verified optical characteristics of BTO.

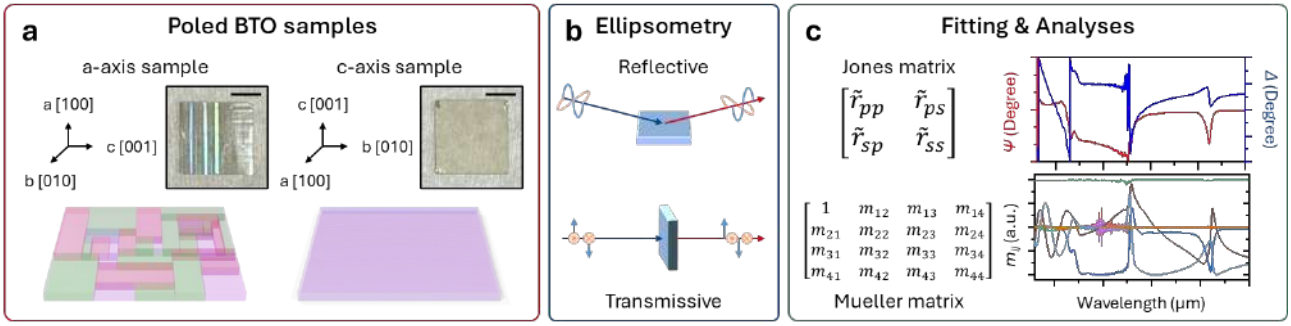

Figure. Schematic illustration of our workflow. (a) Poled BTO samples with a-axis and c-axis orientations. The a-axis BTO sample exhibits a ferroelectric multidomain structure. Scale bar: 2 mm. (b) Spectroscopic ellipsometry was performed for both reflective and transmissive measurements. (c) The acquired ellipsometry data were fitted and analyzed to extract physical optical constants using Jones matrices and Mueller matrices, respectively.

Abstract: Perylene crystals were irradiated by electron-beam to induce chemical reactions. Mass spectrum shows oligomerization of the molecules. Raman spectroscopic analysis of the product indicates that dimers are produced. Periodic subwavelength structure was fabricated on perylene crystals. Scattering spectrum of the structure shows a peak originated from the diffraction effect.

Polycyclic aromatic hydrocarbons (PAHs) consisted of several aromatic rings show broad absorption band and high luminescence quantum yields. For this reason, the PAHs are promising for organic optoelectrical devices.[1] PAHs can be oligomerized by the irradiation of high energy beams such as ultraviolet and electron beam (e-beam). By precisely controlling the e-beam irradiation, the oligomerization of the PAHs and the reaction area can be controlled. In this way, fabrication of periodic subwavelength structures with the oligomerized PAHs are feasible. In this study, we prepared the oligomer of perylene molecules by the e-beam irradiation and fabricated subwavelength periodic structures of the perylene oligomer using the space-selective reaction.

Powder of the perylene was heated to prepare the crystal on the sample substrate by the sublimation. Then, the crystal was placed in a low-vacuum scanning electron microscope and the e-beam was irradiated to the surface of the crystal. To fabricate the periodic structures, the sample substrate was raster-scanned by the closed loop piezo stage. The morphology of the sample was evaluated by an atomic force microscope (AFM). Mass of the reaction products was evaluated by the matrix assisted laser desorption/ionization mass spectrometry. Optical properties of the products were evaluated by extinction, Raman, and photoluminescence (PL) spectroscopy. Scattering and PL properties of the periodic structure were evaluated by dark-field (DF) and the confocal microscope, respectively.

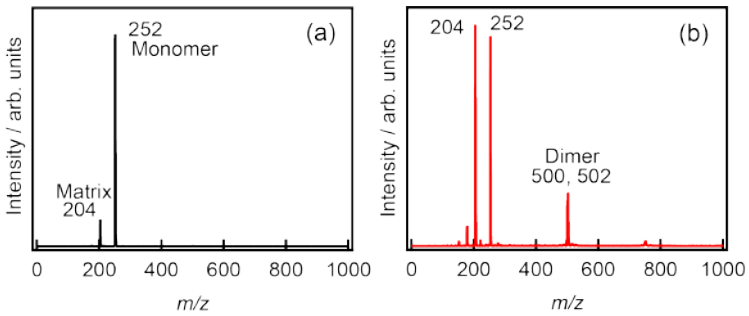

Figure 1. Mass spectra of the crystal (a) without and (b) with the e-beam irradiation.

Figure 1(a,b) shows the mass spectra taken on the crystal without and with the e-beam irradiation, respectively. In Fig. 1(a), the spectrum shows the ion peaks at m/z = 204 and 252, which are assignable to the matrix and the monomer, respectively. On the other hand, in Fig. 1(b), the spectrum shows the peaks at m/z = 500 and 502, in addition to m/z = 204 and 252. The peaks at m/z = 500 and 502 are assignable to the molecular species that the

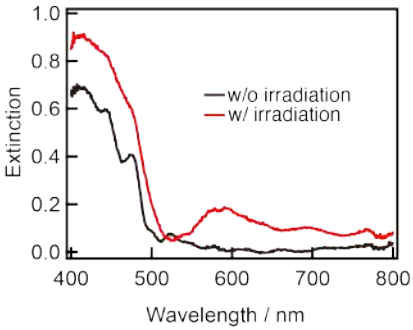

Figure 2. Extinction spectra of the crystal without (black) and with (red) the e-beam irradiation.

mass is 2 or 4 smaller than that of the perylene dimer. This result implies the formation of the one or two C-C bonds after releasing two or four H atoms.

Figure 2 shows the extinction spectra taken on the crystal without (black) and with (red) the e-beam irradiation. The irradiated crystal shows the increase of the absorption in the longer wavelength region compared to that of the neat crystal. This indicates that the formation of the perylene polymer with the extended π-conjugated molecular orbital. By using the Raman spectroscopy, the molecular structure was investigated and found that the perylene molecule was oligomerized to dimer with ribbon-like shape.

The periodic dotted pattern with a pitch of 600 nm was fabricated on the perylene crystal. Figure 3(a) shows the AFM image of the fabricated structure. The black area represents the surface of the crystal. We found from the figure that the irradiated area was protruded from the crystal surface. Figure 3(b) shows the line profile along the red line shown in Fig. 3(a). Height and width of the protrusion were determined to be ~50 nm and ~300 nm, respectively. This result indicates that the reaction area can be controlled with subwavelength scale.

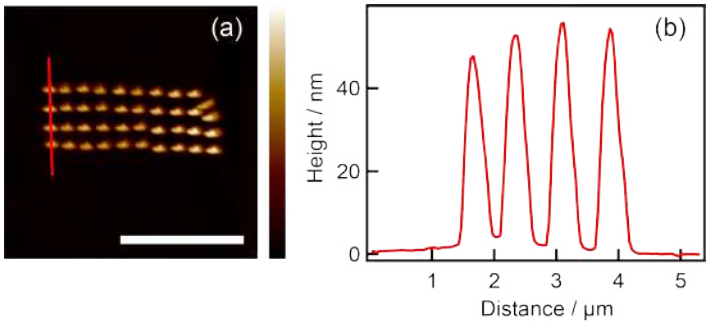

Figure 3. (a) AFM image of the dotted pattern on the perylene crystal. Scale bar: 5 μm. (b) Line profile along the red line shown in (a).

Figure 4(a,b) shows the DF scattering images of the structure in Fig. 3 taken at the wavelengths of 870 and 460 nm, respectively. In the figures, black square shows the fabricated area of the periodic structure, and the white dashed line shows the edge of the crystal. In Fig. 4(a), the edge of the crystal shows the strong scattering, and the dotted area show only minor signal. On the other hand, in Fig. 4(b), the dotted area shows the strong signal. Figure 4(c,d) shows the DF scattering spectra at the edge of the crystal and the periodic structure, respectively. In Fig. 4(c), the spectrum shows a broad scattering peak at ~690 nm. In contrast, in Fig. 4(d), the spectrum shows a sharp peak near 450 nm. The peak is only observable on the periodic structure area, and thus origin of the peak is attributed to the diffraction effect of the periodic structure.

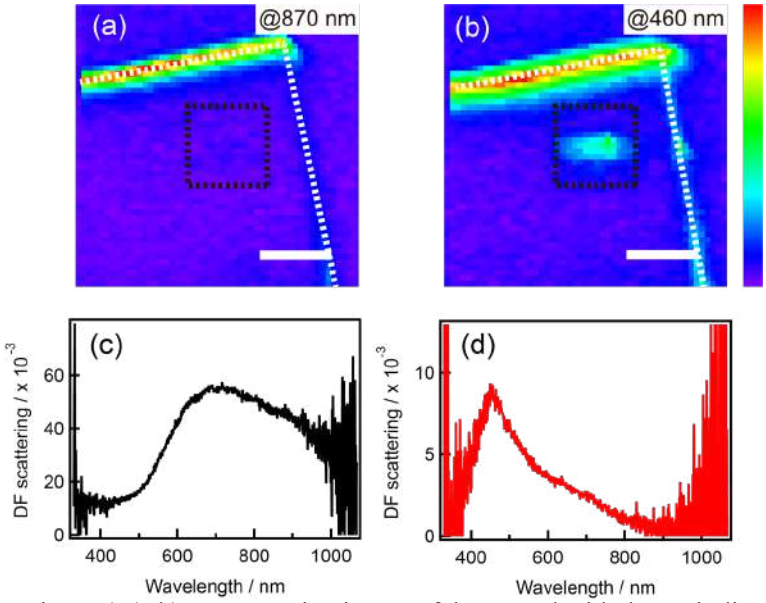

Figure 4. (a,b) DF scattering image of the crystal with the periodic structure shown in Fig. 3 taken at 870 and 460 nm, respectively. Scale bars: 5 μm. Black square shows the fabricated area of the periodic structure, and white dotted line shows the edge of the crystal. (c,d) DF scattering spectra taken at the edge of the crystal and the periodic structure, respectively.

Abstract: Transparent conducting oxides are highly-doped semiconductors exhibiting remarkable nonlinear optical properties in the near-infrared spectrum—a feature previously overlooked despite their long-standing application in photovoltaics and touchscreens. Here we report the spatio-spectral fission of an ultra-fast pulse trespassing a thin film of aluminium zinc oxide with a non-stationary refractive index.

Figure 1. – Spatio-spectral fission of an optical pulse trespassing a non-stationary ultra-thin layer. The scheme can also describe a fs-pulse going through an optically pumped subwavelength film of aluminium zinc oxide operating at the cross-over wavelength.

The theory of wave propagation in non-stationary media originated from the concept of time-varying permittivity [1]. Experimental demonstrations of the effects of time-varying media on light propagation first emerged in plasma physics under the name of photon acceleration. In these settings, significant effects can be observed when photons interact with a plasma undergoing an abrupt electron density transition [2], [3].

More generally, when a propagating wave encounters a sudden change in the environmental refractive index, it experiences a phenomenon known as time refraction [2], [3], [4], [5]. This effect is analogous to the behavior of a wave at a spatial material interface and results in a frequency shift of the photon, described by the equation $\omega_1 n_1 = \omega_2 n_2$, where ω_1 and ω_2 are the angular frequencies before and after the time boundary, and n_1 and n_2 are the refractive indices before and after the transition. In its differential form, $d\omega/\omega = dn/n$, this equation explicitly states that a large change in the refractive index over a very short time is required for a frequency conversion process to be experimentally measurable.

Due to this requirement, substantial experimental advancements in time-varying materials have been slow, despite their vast potential and intrinsic scientific interest. Typically, real-world temporal index changes are either extremely fast or large, but these two characteristics generally exclude each other [6]. Recently, transparent conducting oxides (TCOs) have proven of critical importance in overcoming this trade-off in the near-infrared region. These materials possess a bandwidth exceeding 260 nm [7], [8] and enable unity changes in the refractive index [8].

In this work, an ultra-thin time-varying layer is attained by optically pumping a sub-wavelength film of aluminum zinc oxide (AZO) operating in its near-zero-index (NZI) region. The optical excitation induces a steep

refractive index gradient, initially increasing and then decreasing, thereby exerting opposite effects on the front and back of a synchronized probe. Consequently, the transmitted pulse undergoes spatial splitting into two halves, each containing approximately half of the total spectral power (see Fig.1). These two "fission products" also exhibit strong spectral shifts that are opposite in sign for each half and centered around the NZI carrier wavelength. Our analytical model, adapted from the generalized spatio-temporal Snell's law for subwavelength time-varying layers, quantitatively accounts for all measurable macroscopic parameters, including spectral shifts, angular shifts, and energy redistribution. The spatio-spectral fission observed here represents one of the most extreme nonlinear optical phenomena occurring over deeply subwavelength propagation lengths. These findings open new possibilities for the temporal engineering of material optical properties while also providing insights into previously reported results that did not account for the spatial distribution of the propagating pulse.

Abstract: Next-generation communication technologies require miniaturization and more energy-efficient devices. Two-dimensional materials provide a promising platform for advancing atomic-scale applications. Here, we demonstrate control of circularly polarized photoluminescence in a WS_2 monolayer placed on thulium iron garnet substrate under linearly polarized excitation by switching the magnetization direction.

Information transfer between nanoscale devices is a major bottleneck in integrated circuits due to high energy consumption. This process is hindered by short spin relaxation lengths, requiring the conversion of spin information into charge currents, which increases power dissipation. Replacing electrons with photons as information carriers offers a promising solution to reduce energy consumption and enhance speed through optical interconnects.

Two-dimensional (2D) materials provide an ideal platform for achieving this goal. In the monolayer state, they exhibit new properties that differ from the bulk. Transition metal dichalcogenides (TMDs) are 2D semiconductors which show a direct bandgap in the monolayer limit. This, combined with the enhancement of Coulomb interactions in low-dimensional systems lead to the formation of tightly bound excitons. Furthermore, these materials present strong spin-orbit interaction and naturally break spatial inversion symmetry, resulting in optical selection rules for the K and K' valleys, where each valley couples with a different helicity of circularly polarized light. By combining TMDs with magnetic materials, it is possible to modify their band structure and induce new properties in the system. These characteristics make TMDs a promising platform for encoding magnetic information into light polarization.

However, due to the degeneracy of the K and K' valleys, efficiently generating circularly polarized light using linearly polarized excitation is unachievable. By Integrating TMDs with magnetic materials we can break the degeneracy allowing the selectively excitation of one of the valleys, resulting in the control of the light emission. Through proximity effect between 2D magnets and monolayer TMDs, an exchange field can emerge, inducing Zeeman splitting in the energy levels breaking the degeneracy of the two valleys. Additionally, spin-dependent charge transfer can offer a non-radiative decay channel which leads to preferentially light emission from a single valley. These phenomena have been demonstrated using 2D magnets such as CrI_3 and $CrBr_3$ [1,2,3]. However, the major drawbacks of these materials are their air instability and low Curie temperatures, significantly below room temperature, making experiments challenging and limiting their practical applications.

In this work [4], we use the magnetic proximity effect between Thulium Iron Garnet (TmIG) [5] and TMDs to generate circularly polarized photoluminescence after exciting with linearly polarized light (Figure 1). TmIG is a magnetic material that is air-stable, has a Curie temperature well above room temperature, and a switching field in the millitesla range making it ideal for applications. We show a degree of polarization of the emitted photoluminescence depends on the magnetization direction, establishing a link between the emitted light and the magnetization of TmIG.

We observe that changing the magnetization direction of TmIG results in a switch in the helicity of the circular polarization of the emitted light in a tungsten-based TMD (WS_2). Additionally, we detect a redshift in the excitonic peak associated with magnetization confirming the proximity interaction between the TMD and TmIG. This study opens the possibility of encoding magnetization information into light polarization offering a novel platform for

more energy-efficient optical interconnections in integrated circuits.

Abstract: A scanning tunneling microscope (STM) is used to tailor the excitonic properties of transition metal dichalcogenides (TMD). We demonstrated STM-induced generation of neutral and charged excitons in TMD monolayers and achieved full control of the TMD photoluminescence quantum yield at a submicrometer scale.

A scanning tunneling microscope (STM) is used to electrically activate the luminescence of two-dimensional (2D) materials within a nanoscale tunnel junction, in order to spatially resolve the variations of the excitation quantum efficiency on the nanometer scale. An optical microscope and spectrometer is used to spatially, angularly, and spectrally resolve the emitted light, in order to investigate the emission processes and identify the involved excitonic species. In this way, we demonstrate the STM-induced generation of neutral and charged excitons in monolayer transition metal dichalcogenides (TMD) [1,2]. Moreover, we introduce a new technique that makes it possible to monitor in real space the effects of locally injected charge carriers on the radiative quantum efficiency of TMDs, which was not possible using the techniques reported until now. In our technique, the wide-field laser-induced photoluminescence (PL) microscopy image of molybdenum diselenide ($MoSe_2$) monolayers is captured while charge carriers are injected into the monolayers via electron tunneling from (or to) the tip of an STM. As shown in Figure 1, we found that local electron injection into the $MoSe_2$ monolayer induces a long-range quenching of the PL intensity of the TMD. Conversely, we show that we can enhanced the PL response of the $MoSe_2$ monolayers by inverting the bias voltage polarity between the STM tip and the TMD.

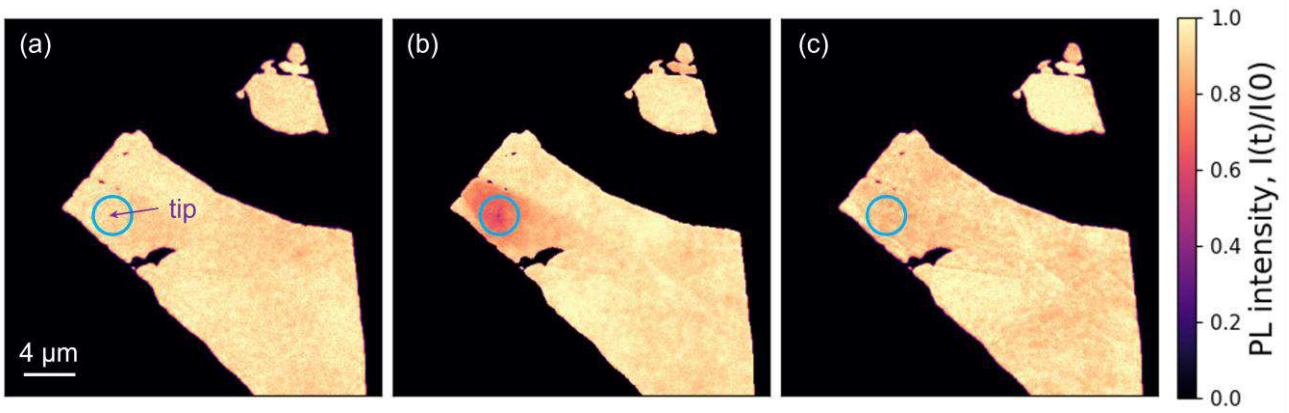

Figure 1: PL quantum yield of two $MoSe_2$ monolayers deposited onto an indium tin oxide (ITO) coated glass cover slip. The image (a) was taken before inducing a tunneling current through the sample. The image (b) was taken while inducing a tunneling current through the sample. The image (b) was taken while inducing a

tunneling current through and the image (c) was taken several seconds after cutting the tunneling current.

Our results show that the presence of the electrically biased STM tip and the tunneling current acts as a gate nanoelectrode, which locally modifies the charge carrier density and thus the luminescence properties of the TMD monolayer. In a series of experiments where we periodically varied the setpoint current or the potential applied to the junction, we show the role played by this effect in STML measurements, in particular the impact this effect has on the current-dependent linearity of the electroluminescence process. These results, presented here for the first time, shed new light on the mechanisms at the heart of STML in 2D semiconductors.

Abstract: Light-matter interactions in transition-metal dichalcogenides (TMDCs) for optoelectronic applications enable advanced nanophotonics functionalities. This work demonstrates photoluminescence enhancement in TMDCs monolayer on patterned SiO_2 and h-BN using an optical microcavity approach. The method enables efficient light confinement to optimize light-matter interactions in two-dimensional materials at room temperature.

1. Introduction

Atomically thin TMDCs with the chemical formula MX_2 (M = Mo, W and X = Se, S) exhibit unique optical properties and electronic structures for two-dimensional optoelectronic applications such as photodetectors, photovoltaics, and light emitters. TMDCs like WS_2, MoS_2, WSe_2, and $MoSe_2$ show an indirect-to-direct bandgap transition with large excitonic (i.e., coupled electron-hole pairs) binding energy ranging from 1.5 – 2 eV when thin down to a monolayer. Therefore, their photoluminescence (PL) quality is higher than that of their bulk counterparts. Consequently, excitons dominate the optical and electrical properties of these materials[1], [2], [3], [4]. Most 2D TMDCs show a direct bandgap with large excitonic binding energy in the visible wavelength range [5]. Tungsten disulfide (WS_2) monolayers show unique and promising properties compared to other TMDCs monolayers for optoelectronic applications. Notably, WS_2's high excitonic binding energy results in better light-matter interaction that enhances light absorption and emission [6]. WS_2 monolayers exhibit a higher photoluminescence quantum yield (QY) than MoS_2, making them more effective for light-emitting devices. Also, WS_2 direct bandgap (~2 eV) makes it better suited for visible light optoelectronic applications such as photodetectors and photovoltaics, unlike $MoSe_2$ and WSe_2 which have bandgaps in the near-infrared region. However, light-matter interaction with atomically thin materials such as TMDCs is generally weak [7]. In this presentation, we report on improving the light-matter interaction to enhance the PL properties of a TMDCs material, namely WS_2.

2. Fabrication

We prepared h-BN flakes by exfoliation and transfer from a bulk crystal to a Si/SiO_2 substrate. After that, we patterned the flakes to fabricate linear gratings using electron beam lithography (EBL) and reactive ion etching (RIE). Then we transferred exfoliated WS_2 monolayers on h-BN and SiO_2 gratings.

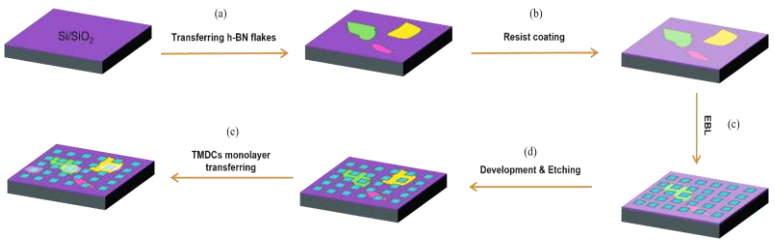

Figure 1. Nanofabrication process (patterning). (a) h-BN flakes transferring on the substrate (not-to-scale drawing), (b) CSAR coating, (c) patterning using EBL on top of the h-BN and SiO_2, (d) development and etching by RIE, (e) TMDCs monolayers transferring on h-BN and SiO_2 gratings after removing CSAR.

3. Results and Discussion

The results of the WS_2 treatment are shown in Figure 2. The PL enhancement was 2-fold for SiO_2 and more than 2-fold for h-BN grating based on PL peak area. This value can certainly be increased by optimization of fabrication parameters (e.g., pitch and groove size).

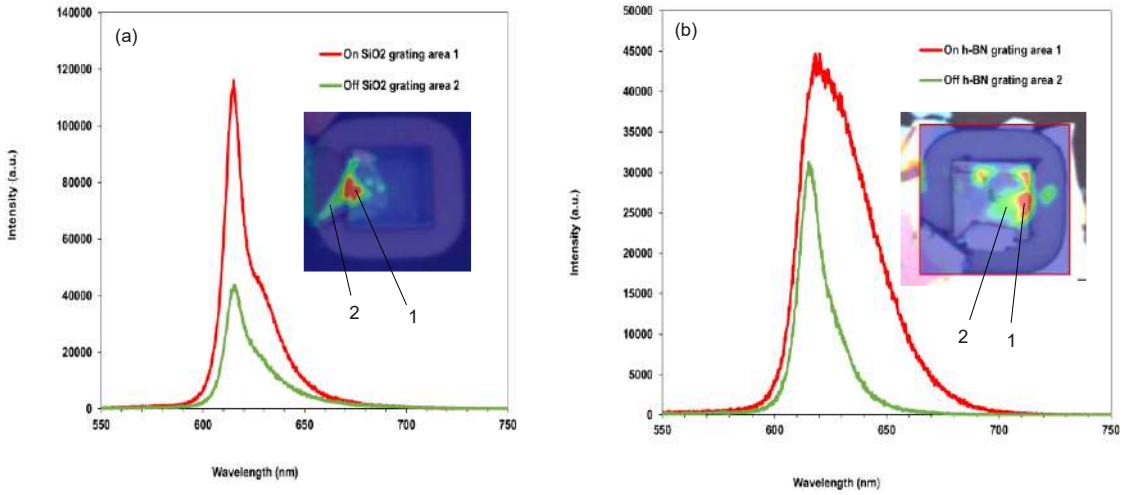

Figure 2. Enhancement of a WS_2 monolayer PL on SiO_2 and h-BN gratings: (a) PL spectra of the monolayer on and off the SiO_2 grating (the inset shows the PL map), (b) PL spectra of the monolayer on and off the h-BN grating (the inset shows the PL map).

4. Conclusion

We have proved that the proposed method based on the application of h-BN and SiO_2 gratings is capable of improving the PL of WS_2 monolayers. In the next step, we will find the optimum grating parameters to obtain the maximum PL enhancement.

Nanophotonics and Plasmonics Applications

Transfer Learning for the Design of a Composite Metasurface Unit Cell in the K_a-Band

Alexander Wolff[1], Lukas Mueller[1], Steffen Klingel[1], and Marco Rahm[1]

Abstract: Training data is a sparse resource when designing neural networks to describe the scattering parameters of metamaterials based on their geometry. Using transfer learning, we have reduced the necessary training data for a neural surrogate model of a tunable composite metasurface unit cell by more than an order of magnitude.

Neural networks have been shown to accelerate the design process of artificial electromagnetic materials (AEM) by several orders of magnitude [1]. Yet, training an accurate neural network requires a substantial amount of training data to be obtained beforehand. This training data is typically specific to a particular set of geometrical and material parameters of the described AEM. However, transfer learning allows us to generalize training data to other AEM-problems [1, 2].

We apply transfer learning to the design of a metasurface unit cell for the use in 5G and 6G wireless communication. In this context, metasurfaces can improve the signal-to-noise ratio of a mobile user by redirecting and focusing an electromagnetic wave onto the user area [3]. To decrease side lobes, it is beneficial to tune the phase of the reflected wave from the metasurface between 0° and 360° while keeping the reflectivity invariant. A composite structure of two varactor-tunable dipoles, as illustrated in Figure 1 (left), can achieve these requirements when tuned correctly [4]. The structure comprises two metallic dipoles of different length on top of a FR-4-substrate. The bottom layer of the PCB is covered entirely by a ground plane. The bias circuitry for the varactors was neglected in the coarse design phase to accelerate the training data generation. The goal was to investigate whether transfer learning could reduce the number of simulations of the dipole-dipole structure as inherently needed to train a direct model of the structure in Fig. 1. This was examined by comparing the required simulations for training a direct model to those needed when first training a model on a single dipole and then applying a transfer model to learn the coupling between two dipoles, ultimately describing the same structure.

The objective of the transfer learning process was to train a model to accurately characterize the S_{11} parameters of a single dipole, before feeding them into a transfer model designed to learn the coupling effects between two dipoles to describe the S_{11} parameters of the structure shown in Fig. 1. For this purpose, we first simulated and extracted the S_{11} parameters of a single dipole dependent on the four parameters {D, L_i, H, C_{var}}. Based on this data, we trained a multi-layer perceptron (MLP) to output the S_{11} parameters of a single dipole in a frequency range between 18 GHz and 34 GHz. The MLP had 4 input neurons, 4 hidden layers with 200 neurons each and 706 output neurons that represented the concatenation of Re(S_{11}) and Im(S_{11}) at 353 discrete frequency samples. In order to train the transfer model regarding the coupling between two dipoles, we used the S_{11} parameters of the first model as input for a second MLP of the same size that learned the dipole-dipole coupling dependent on the distance d between the two dipoles. The second MLP was trained on simulation data previously obtained from numerically calculating the S_{11} parameters of the unit cell in Fig. 1.

In order to evaluate the benefit of this transfer learning scheme, we calculated the mean squared error (MSE) of the transfer-learned MLP over a test dataset for different sizes of training datasets. The result is illustrated by the solid red line in Fig. 1 (right). We see that the MSE reaches 0.05 with only 29 training simulations. In comparison, the solid blue line in Fig. 1 (right) represents a reference MLP of the direct model of the structure in Fig. 1. This reference network requires 583 simulations to yield a MSE of 0.05. As a result, the transfer-learning scheme decreased the number of training samples of the composite unit cell by more than an order of magnitude.

Although transfer learning requires additional simulations to train the single dipole, these simulations are typically faster due to the smaller and less complex geometry. Furthermore, the simulations of the single dipole can be recycled for composite unit cells with different coupling geometries between the dipoles.

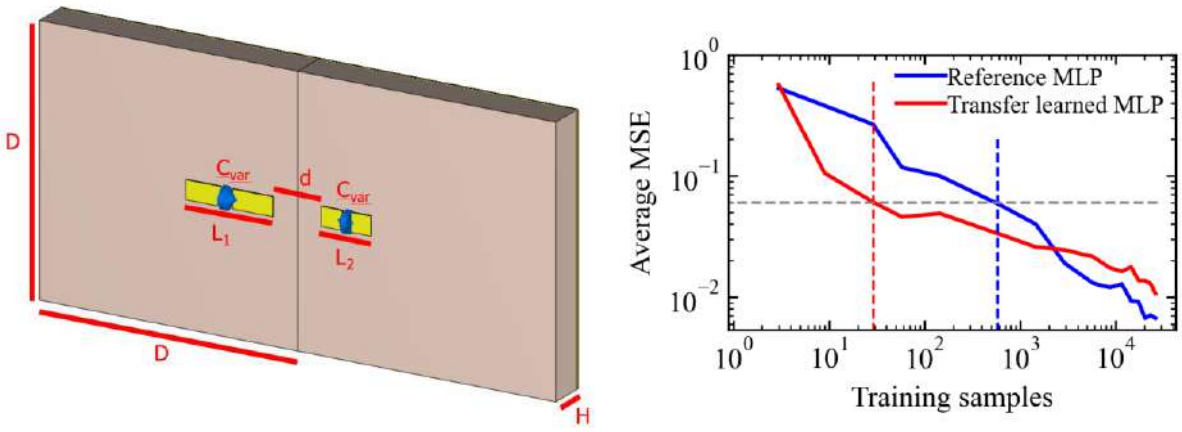

Figure 1

(left) Composite unit cell for a tunable metasurface with high reflection phase shift. The dipoles are split in the middle and the gap is bridged by a varactor diode. The backside of the FR-4 substrate is covered with a ground plane.

(right) Test set average mean squared error of the multi-layer perceptron (MLP) for different training sample sizes in the case of the transfer-learned network (red) and the reference direct network (blue). The transfer-learned MLP requires an order of magnitude fewer training data of the coupled dipole structure than the reference MLP.

Broadband Field Prediction via Parameter-Efficient Electromagnetic Surrogate Solver

Abstract

We propose a parameter-efficient electromagnetic surrogate solver that predicts broadband field distributions from discrete wavelength data. Using wave-informed multiplicative encoding and Fourier group convolutional shuffling, our approach reduces parameters by 74% and improves the accuracy of untrained wavelength prediction by 80.5%, outperforming state-of-the-art models.

1 Introduction

Electromagnetic simulations based on Maxwell's equations are essential for photonic device design but are computationally intensive [1]. For electric field prediction, traditional surrogate solvers that are trained under fixed conditions struggle to generalize across a continuous wavelength spectrum [2]. To overcome this limitation, we introduce two key method Wave-Informed Multiplicative Encoding (WIME) and Fourier Group Convolutional Shuffling (FGCS) which together enable efficient and accurate prediction of electric fields over a broad spectrum while drastically reducing parameter complexity.

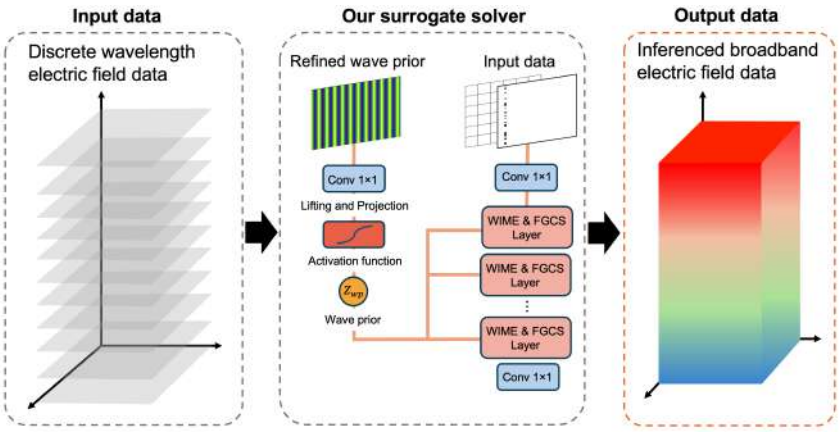

Figure 1: Schematic illustration of the proposed overall framework.

Our approach overcomes the high computational cost and limited generalization ability of traditional methods by integrating two key components. First, WIME extracts condition embeddings from a refined wave prior defined as $\mathcal{W}_x = e^{j\frac{2\pi}{\lambda}x\mathbf{1}^T\Delta l_x}$ and $\mathcal{W}_z = e^{j\frac{2\pi}{\lambda}\mathbf{1}z^T\Delta l_z}$ where x and y are the coordinates. Δl_x, Δl_z, and λ are the simulation step sizes and wavelength, respectively. These embeddings are processed with shallow 1×1 convolution layers and injected into every network layer via element-wise multiplication, adaptively modulating feature maps

to account for wavelength variations. Second, the FGCS operator efficiently reduces parameters by factorizing the Fourier transform along horizontal and vertical dimensions [3]. By leveraging weight sharing and channel shuffling, it achieves a compact yet expressive representation while preserving essential spectral features.

Our surrogate model thus approximates the mapping from material properties to field distributions, enabling fast inference over continuous wavelengths. Figure 1 illustrates the overall architecture of our surrogate solver, where WIME and FGCS are integrated to condition the model and reduce parameters effectively. Figure 2 compares our method with a state-of-the-art surrogate solver [2], demonstrating a 74% reduction in parameters and enhanced prediction accuracy for wavelengths not observed during training.

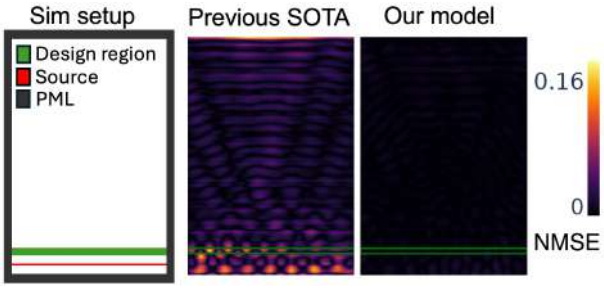

Figure 2: Model error evaluation at 410nm, the unobserved wavelength with maximal error.

Our surrogate solver achieves state-of-the-art performance by accurately predicting broadband electromagnetic fields from a limited set of discrete wavelength data. The proposed WIME and FGCS enable robust generalization to unseen wavelengths while significantly reducing computational burden, paving the way for faster and more efficient photonic device simulation.

Abstract: Experimental demonstration of superscattering is among the long-standing challenges in electromagnetic theory. We will present several strategies to design superscatterers with the aid of generic optimization and demonstrate their state-of-the-art performances experimentally. A solution to an emerging problem of small UAV tracking and monitoring with radar-visible superscatterers will be demonstrated.

The presentation is based on our recent works [1-8] and on a large set of new unpublished data. On top of our published results, we will demonstrate novel extremely broadband superscatterers, fabricated with the aid of additive technologies, and all-angle all-polarization corona-virus-like devices, whose operation encompasses both resonant phenomena and constructively interfering creeping wave interactions. The results will be supported with experimental data, considering both indoor and outdoor demonstrations.

Electromagnetic scattering on subwavelength structures has always been a subject of extensive investigations owing to fundamental challenges and applied rewards, related to its maximization or suppression. The maximal possible scattering into a single multipole is called a channel limit. A dipolar single channel limit (the maximal scattering cross-section, which a small resonant lossless dipole can approach) is $3\lambda^2/(2\pi)$, where λ is a free space wavelength. Subwavelength structures, bypassing the single channel limit, are called super-scatterers. While there is no fundamental upper bound on a scattering cross section, quite a few theoretical limits, with Cho-Harrington being the most commonly used, have been proposed to account for possible practical aspects. Bypassing those limits requires accommodating several resonant multipoles, constructively interfering at nearly the same frequency. In this case, a significant near-field accumulation in the vicinity of lossy materials, accompanied by an extremely low fabrication tolerance, are the main known factors limiting the practical demonstration of super-scatterers. Regardless of their particular realization, they all share the same design principles. The first one is the choice of a material platform. Since high near-field accumulation necessarily implies having high Ohmic losses, constitutive components should be carefully chosen. The second criterion is the capability to perform extensive electromagnetic optimization. In the case of compact structures, internal resonances tend to repel each other, opening frequency gaps. In this contribution, we will demonstrate several conceptually different strategies to design and experimentally demonstrate superscattering. The following sections survey our results. Novel and conceptually different architectures will also be demonstrated at the conference. A strong emphasis will be placed on practical outdoor demonstrations, related to tagging small radar cross-sections (RCS) with super scattering devices. Those will be shown to play a dramatic role in the detection, rendering initially weakly detectable objects to highly visible targets, subject to convenient and reliable radar-based monitoring.

Abstract

We present a probabilistic, data-driven surrogate model for predicting the radiative properties of nanoparticle embedded scattering media. The model uses conditional normalizing flows, which learn the conditional distribution of optical outputs, including reflectance, absorbance, and transmittance, given input parameters such as the absorption coefficient, scattering coefficient, anisotropy factor, and particle size distribution. We generate training data using Monte Carlo radiative transfer simulations, with optical properties derived from Mie theory. Unlike conventional neural networks, the conditional normalizing flow model yields full posterior predictive distributions, enabling both accurate forecasts and principled uncertainty quantification. Our results demonstrate that this model achieves high predictive accuracy and reliable uncertainty estimates, establishing it as a powerful and efficient surrogate for radiative transfer simulations.

1. Introduction

Monte Carlo (MC) simulations, are a foundational tool in modeling radiative transfer through scattering and absorbing media, with widespread applications in thermal engineering [1], biomedical optics [2], and in materials science [3]. The Monte Carlo for Multi-Layered Media (MCML) algorithm by Wang et al. [4], originally developed for biological tissues, has been extensively adapted for other types of layered media.

In previous work [5], we applied the MC method to study the optical properties of a particle-containing layer at low volume fractions. This method involves launching a large number of photons at normal incidence into the layer, where they are either transmitted, reflected, or absorbed. Despite advances in GPU-based parallel processing, MC simulations remain computationally expensive for high-throughput applications. In this work, we combine the MC method with Mie theory to model radiation transport in layers with low particle volume fractions.

While MC simulations are accurate and physically grounded, they remain computationally intensive, especially when repeated across a high-dimensional input space of wavelengths, particle sizes, and material properties. Despite the efficiency gains achieved through parallel processing on GPUs, large-scale or repeated simulations continue to be computationally prohibitive in high-throughput applications such as design optimization or inverse scattering problems.

To address this limitation, surrogate models have been introduced to approximate the forward mapping from physical parameters to optical responses, enabling significant cost reduction while preserving accuracy [6, 7]. Fully connected neural networks (FCNNs), in particular, have demonstrated strong performance in learning deterministic relationships from Monte Carlo-generated data. With sufficient training data, neural networks can approximate complex functions and provide fast, accurate predictions [8]. Such networks have been successfully applied to surrogate modeling tasks, including the design of thin-film photovoltaic cells and other optical systems [7].

Deterministic neural networks lack the capacity to quantify uncertainty—an essential feature for applications such as photonic material design and uncertainty-aware simulations [9]. We propose a probabilistic surrogate model based on Conditional Normalizing Flows (CNFs), which transform a simple base distribution (e.g., standard Gaussian) into a complex target distribution through invertible transformations [10, 11, 12]. By conditioning this transformation on physical input parameters (e.g., μ_a, μ_s, g, and ρ), CNFs learn the conditional distribution $p(\mathbf{x} \mid \mathbf{y})$, where $\mathbf{y}$ denotes the input parameters and $\mathbf{x}$ represents the radiative spectral outputs. To overcome the computational burden of radiative transfer in scattering media, we generated training data using Monte Carlo simulations executed on a high-performance server at Aalto University.

The proposed CNF framework enables the generation of diverse and physically consistent outputs for a given input, thereby capturing the inherent uncertainty in radiative transfer simulations. It produces posterior predictive distributions, allowing for both mean predictions and associated confidence intervals—an essential feature for uncertainty-aware modeling. By maintaining consistency with Monte Carlo-generated training data, the framework ensures physical interpretability and robustness. To validate its effectiveness, we train a RealNVP-based CNF model on MC-simulated datasets. The model successfully predicts full spectral profiles of reflectance, absorbance, and transmittance with high accuracy while also providing well-calibrated uncertainty estimates. Model performance is

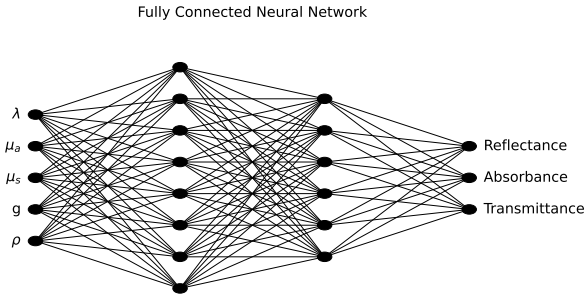

Figure 1: A schematic representation of the fully connected neural network.

rigorously assessed through cross-validated posterior sampling and comparisons against deterministic neural network baselines.

2. Methods

The proposed surrogate modeling framework is structured around two main components: data generation via Monte Carlo simulations and probabilistic modeling using CNFs. We begin by providing an overview of this framework and its rationale. Subsequent subsections describe the data generation process, the architecture of the CNF model, the training objective, and the inference procedure in detail.

2.1. Data Generation and Preprocessing

To train the CNF model, we generated a comprehensive dataset using Monte Carlo radiative transfer simulations, specifically designed for layered media embedded with nanoparticles. Each simulation corresponds to a folder containing detailed input parameters and the resulting output spectra.

The input parameters include the wavelength-dependent absorption coefficient (μ_a), scattering coefficient (μ_s), anisotropy factor (g), and the particle size distribution function (ρ). These parameters represent the key physical and optical properties that influence light transport within the medium.

For each simulation, the Monte Carlo method outputs the spectral properties of the system, including total reflectance (computed as the sum of specular and diffuse components), absorbance, and transmittance.

All input features are preprocessed by stacking and reshaping them into a unified feature vector representing each sample. The corresponding outputs are vectorized in a similar manner, resulting in a structured dataset compatible with neural network training. A schematic overview of the network architecture used for modeling is provided in Figure 1.

2.2. Conditional Normalizing Flow Architecture

We employ a CNF framework to model the conditional distribution of radiative spectral outputs given input physical parameters. The CNF is based on a Real-valued Non-Volume Preserving (RealNVP) transformation, which provides a scalable and invertible mapping between a simple latent distribution and a complex target distribution [13]. In our case, the target distribution corresponds to spectral quantities such as total reflectance, absorbance, and transmittance, conditioned on high-dimensional input features extracted from the optical and material properties.

Starting from a standard Gaussian latent variable $\mathbf{z} \sim \mathcal{N}(\mathbf{0}, \mathbf{I})$, where $\mathbf{z} \in \mathbb{R}^D$ is a latent vector of the same dimensionality as the output and $\mathbf{I}$ is the identity covariance matrix, we define an affine mapping:

$$\mathbf{x} = \exp\big(\log s(\mathbf{y})\big) \odot \mathbf{z} + t(\mathbf{y}),$$

where $\log s(\mathbf{y})$ and $t(\mathbf{y})$ are the log-scale and shift vectors produced by a conditioner neural network, and $\odot$ denotes element-wise multiplication. This structure ensures that the transformation is differentiable and invertible, making it suitable for both sampling and likelihood estimation. Here, the functions $s(\mathbf{y})$ and $t(\mathbf{y})$ are parameterized by neural network weights ψ.

To compute the conditional likelihood $p(\mathbf{x} \mid \mathbf{y})$, we apply the change-of-variables formula. Due to the affine nature of the transformation, the Jacobian determinant simplifies to the sum of log-scale terms:

$$\log p(\mathbf{x} \mid \mathbf{y}) = \log p(\mathbf{z}) + \sum_{j=1}^{D} \log s_j(\mathbf{y}),$$

where $p(\mathbf{z})$ is the log-density under the standard normal prior. This formulation enables the model to learn expressive conditional distributions and supports principled uncertainty quantification via posterior sampling. For a full derivation of the conditional log-likelihood, see Supplementary Material, Section 5.

2.3. Training Objective

The CNF model is trained to maximize the likelihood of the observed output data given the input features. This is achieved by modeling the conditional distribution $p(\mathbf{x} \mid \mathbf{y})$ using a bijective transformation applied to a latent variable sampled from a standard multivariate normal distribution. Specifically, we learn a mapping from latent space to data space through neural networks that output data-dependent shift and scale parameters.

Given a training pair $(\mathbf{y}^{(i)}, \mathbf{x}^{(i)})$, the model first computes the inverse transformation to recover the corresponding latent variable:

$$\mathbf{z}^{(i)} = g_\psi^{-1}(\mathbf{x}^{(i)}, \mathbf{y}^{(i)}) = (\mathbf{x}^{(i)} - t(\mathbf{y}^{(i)})) \oslash \exp(\log s(\mathbf{y}^{(i)})),$$

where $t(\mathbf{y})$ and $\log s(\mathbf{y})$ are the shift and log-scale vectors predicted by the conditioner neural network with parameters ψ, and $\oslash$ denotes element-wise division.

The conditional log-likelihood is then computed using the change-of-variables formula derived earlier:

$$\log p_\psi(\mathbf{x}^{(i)} \mid \mathbf{y}^{(i)}) = \log p(\mathbf{z}^{(i)}) + \sum_{j=1}^{D} \log s_j(\mathbf{y}^{(i)}),$$

where $\log p(\mathbf{z}^{(i)}) = -\frac{1}{2}\left(\|\mathbf{z}^{(i)}\|^2 + D\log(2\pi)\right)$, since $\mathbf{z}^{(i)} \sim \mathcal{N}(\mathbf{0}, \mathbf{I})$.

To train the model, we maximize the total log-likelihood over the dataset. Equivalently, the training objective is to minimize the negative log-likelihood loss:

$$\mathcal{L}(\psi) = -\frac{1}{N}\sum_{i=1}^{N} \log p_\psi(\mathbf{x}^{(i)} \mid \mathbf{y}^{(i)}).$$

This objective is minimized using stochastic gradient descent with the Adam optimizer. By learning parameters ψ that maximize the likelihood of the observed data, the model captures the full conditional distribution and generates accurate, uncertainty-aware predictions of spectral responses.

2.4. Training Procedure

The model is trained using stochastic gradient descent with the Adam optimizer to minimize the negative log-likelihood objective. Training is conducted over 20,000 epochs using mini-batches. At the beginning of each epoch, the training data is shuffled to promote generalization and to avoid learning spurious patterns. For each mini-batch, the conditioner network computes the shift and log-scale parameters, defines the transformed distribution, evaluates the loss, and updates the model weights via backpropagation.

To ensure robust evaluation and reduce variance in performance estimates, we employ 5-fold cross-validation. The dataset is partitioned into five subsets, and training is repeated five times, each time using a different subset for validation and the remaining subsets for training. This yields five independently trained models. Model checkpoints are saved at the end of each fold to facilitate ensemble predictions and uncertainty estimation. The key steps of the training process are summarized in Algorithm 1.

Algorithm 1 Conditional Normalizing Flow Training

Require: Dataset $\{X, Y\}$, epochs number T, batch size B
Ensure: Trained conditioner network

```
Initialize the conditioner network and Adam optimizer with learning rate 10^-4
for epoch = 1 to T do
    Shuffle the training data {X, Y}
    Partition the data into mini-batches of size B
    for each mini-batch (x_batch, y_batch) do
        (shift, log_scale) ← conditioner_net(x_batch)
        Define transformed distribution:
        p(y_batch | x_batch) = N(shift, exp(log_scale))
        Compute loss: L = − log p(y_batch | x_batch)
        Update conditioner network via backpropagation
    end for
end for
return Trained conditioner network =0
```

2.5. Inference and Sampling

After training, the CNF model is used to generate probabilistic predictions for new, unseen input configurations. Each input, represented by a high-dimensional vector of physical parameters, is passed through the conditioner network to compute the corresponding shift and log-scale vectors. These parameters define an affine transformation applied to latent samples drawn from a standard normal distribution, producing samples from the output distribution.

Specifically, given a new input $\mathbf{y}_{\text{new}}$, the conditioner network outputs $t(\mathbf{y}_{\text{new}})$ and $\log s(\mathbf{y}_{\text{new}})$. A set of latent vectors $\mathbf{z} \sim \mathcal{N}(\mathbf{0}, \mathbf{I})$ is sampled and transformed into output predictions $\mathbf{x}$ using the mapping:

$$\mathbf{x} = \exp(\log s(\mathbf{y}_{\text{new}})) \odot \mathbf{z} + t(\mathbf{y}_{\text{new}}),$$

where $\odot$ denotes element-wise multiplication. This procedure is repeated across all models obtained from cross-validation, enabling ensemble sampling from the posterior predictive distribution.

The resulting samples are aggregated to compute the posterior mean and standard deviation for each spectral quantity. These statistics yield the predicted response along with its associated uncertainty. A 95% confidence interval is computed as $\hat{x}_{\text{mean}} \pm 1.96 \cdot \hat{\sigma}$, providing interpretable and calibrated probabilistic forecasts of total reflectance, absorbance, and transmittance for previously unseen physical inputs.

2.6. Model Evaluation and Predictions

Model evaluation is performed using the negative log-likelihood (NLL) computed on the validation sets during cross-validation. This metric quantifies how well the predicted conditional distributions align with the observed spectral responses and serves as a principled objective that is consistent with the training loss. Lower NLL values indicate higher model confidence and better agreement with the data.

To assess predictive performance, we compare the posterior means of the predicted outputs with the ground-truth spectral values across the wavelength domain. Additionally, the model provides standard deviations and confidence intervals, enabling uncertainty quantification for each prediction. These intervals offer valuable insights into the model's reliability, particularly in the context of noisy or underdetermined physical systems.

In the following section, we present detailed comparisons between the predicted and true values, including graphical analyses with uncertainty bands. These evaluations underscore the model's ability to generalize to unseen inputs and to provide well-calibrated probabilistic forecasts across a variety of optical configurations.

3. Results and Discussion

To evaluate the performance of our trained CNF model, we perform predictive inference on previously unseen data. The test input consists of wavelength-dependent optical properties—namely, the absorption coefficient (μ_a), scattering coefficient (μ_s), anisotropy factor (g), and particle size distribution (ρ)—which are concatenated into a single

input vector and reshaped to match the input dimensionality expected by the trained model.

Predictions are generated using the ensemble of models obtained from 5-fold cross-validation. For each fold, the corresponding trained CNF model outputs shift and log-scale vectors conditioned on the test input. These parameters define a conditional Gaussian distribution from which we draw multiple samples (10,000 per model). The generated outputs are then transformed via the RealNVP bijector to yield predictive samples of the total reflectance, absorbance, and transmittance. The predictions from all five folds are aggregated to compute the posterior mean and standard deviation across the spectral domain, enabling robust estimation of both the predicted mean and associated uncertainty.

Figure 2 presents a direct comparison between the NF-predicted mean spectra (solid lines) and the true Monte Carlo-generated values (dashed lines) for all three optical properties. The NF model achieves excellent agreement with the true values across the full wavelength range. Both reflectance and absorbance curves are accurately captured, including sharp transitions, while transmittance remains consistently modeled even in low-signal regions. This highlights the capacity of the CNF model to generalize across complex radiative behaviors in nanoparticle-laden media.

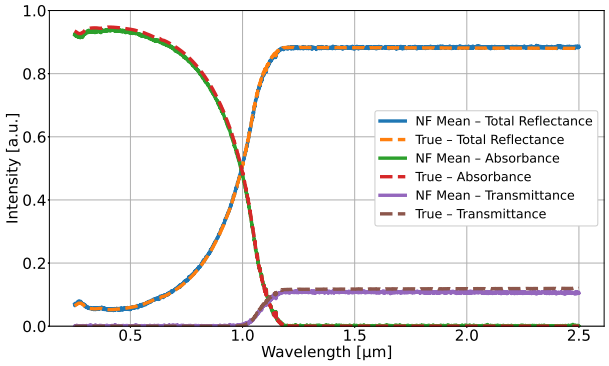

Figure 2: Comparison between conditional Normalizing Flow model predictions (solid lines) and true simulation outputs (dashed lines) for total reflectance, absorbance, and transmittance across the spectral range.

The high degree of overlap between predicted and true spectra confirms the accuracy of the CNF framework. The model remains stable in smooth spectral regions and accurately captures sharp spectral transitions. These results validate both the expressiveness of the CNF architecture and the robustness of the training strategy—including cross-validation and posterior sampling. Overall, the CNF model demonstrates strong generalization capabilities and reliability as a surrogate for fast, uncertainty-aware predictions in radiative transfer modeling.

Figures 3 present individual comparisons between the CNF-predicted spectral properties and the corresponding ground truth values for (a) total reflectance, (b) absorbance, and (c) transmittance. Each plot displays the posterior predictive mean (solid black line), the true Monte Carlo simulation output (dashed blue line), and a 95% confidence interval (shaded blue region) derived from posterior sampling. The close visual agreement between the predicted and true values highlights the model's ability to faithfully capture spectral behavior across the entire wavelength range.

The confidence intervals remain relatively uniform across most of the spectrum, reflecting high predictive certainty. Even near the sharp spectral transition around 1.1 μm, the model maintains well-calibrated uncertainty, indicating robust learning and effective generalization in data-sparse or high-gradient regions. This behavior aligns with expected uncertainty dynamics in such scenarios. Notably, the true values consistently fall within the predicted bounds, further validating the reliability of the CNF model's uncertainty estimates.

These findings confirm that the CNF model delivers both accurate point predictions and well-calibrated epistemic uncertainty quantification. Such reliable uncertainty estimates are crucial in optical modeling scenarios, where prediction confidence directly impacts experimental design, material selection, and downstream decisions. The strong performance demonstrated here suggests significant potential for extending this CNF-based approach to more complex forward and inverse problems in optical characterization.

While the conditional normalizing flow (CNF) model delivers accurate predictions and well-calibrated uncertainty estimates, it is worth noting that, in certain regions, the 95% confidence intervals occasionally extend into negative values. Although mathematically permissible within the probabilistic framework of the model, such negative bounds are physically non-interpretable for radiative properties like reflectance, absorbance, and transmittance, which are inherently non-negative. This outcome highlights a known limitation of the current modeling approach. As part of our future work, we plan to enhance the model structure and incorporate additional constraints to ensure that both the predictive means and the corresponding confidence intervals remain consistent with physical reality.

4. Conclusions

This work introduced a probabilistic surrogate modeling framework based on Conditional Normalizing Flows (CNFs) to predict the spectral radiative properties—total reflectance, absorbance, and transmittance—of nanoparticle-embedded scattering media. Trained on synthetic data generated via Monte Carlo simulations combined with Mie theory-derived optical parameters, the model provides a fast, data-driven alternative to computationally expensive simulations.

The CNF framework successfully captures complex, wavelength-dependent optical behavior across a broad spectral range. Through 5-fold cross-validation and detailed uncertainty quantification, we demonstrated its abil-

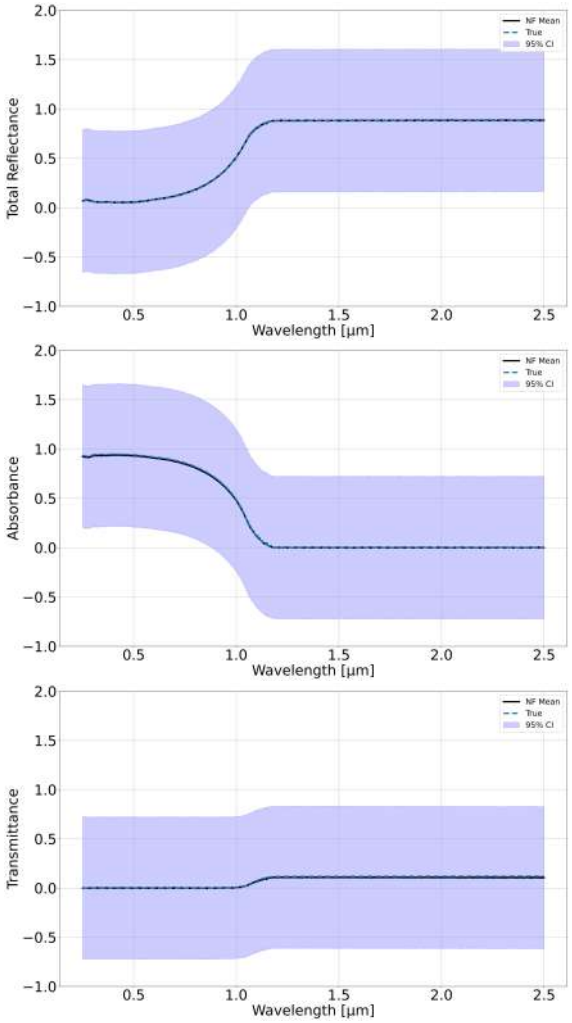

Figure 3: Posterior predictions of (a) Total Reflectance, (b) Absorbance, and (c) Transmittance obtained from the CNF model. The solid black line indicates the predictive mean, the dashed blue line represents the true simulation output, and the shaded region denotes the 95% confidence interval computed from posterior samples.

ity to generalize to unseen inputs while producing well-calibrated posterior distributions. These predictive distributions enable interpretable confidence intervals and support robust, uncertainty-aware inference.

Our findings establish CNFs as powerful tools for forward modeling in optical and materials science. The probabilistic nature of the model is particularly advantageous in scenarios where predictive confidence is essential, including optical device design, inverse scattering, and experimental planning. Future extensions could explore support for more diverse particle geometries, higher concentrations, or multilayer systems—thereby broadening the relevance of the method in advanced photonics and nanomaterials research.

Finally, we acknowledge that the model's confidence intervals can occasionally extend into negative values, which—although mathematically valid within the probabilistic framework—may be physically non-interpretable for radiative properties. Addressing this limitation is an important direction for future model development, ensuring that both predictive means and confidence intervals remain consistent with the underlying physics.

5. Supplementary Material: Derivation of the Conditional Log-Likelihood in CNF

Latent Variable and Forward Mapping: Let $\mathbf{z} \in \mathbb{R}^D$ be a latent variable drawn from a standard multivariate Gaussian distribution:

$$\mathbf{z} \sim \mathcal{N}(\mathbf{0}, \mathbf{I}),$$

where $\mathbf{I} \in \mathbb{R}^{D\times D}$ is the identity matrix. We define an affine transformation to generate the observed variable $\mathbf{x} \in \mathbb{R}^D$ conditioned on an input $\mathbf{y}$:

$$\mathbf{x} = \exp\big(\log s(\mathbf{y})\big) \odot \mathbf{z} + t(\mathbf{y}),$$

where $\log s(\mathbf{y}) \in \mathbb{R}^D$ is the log-scale vector output by the conditioner network, $t(\mathbf{y}) \in \mathbb{R}^D$ is the shift vector from the same network, and $\odot$ denotes element-wise (Hadamard) product. This transformation is invertible and differentiable, making it suitable for both sampling and density estimation.

Change of Variables Formula: Given the invertible transformation $f_\psi : \mathbf{z} \mapsto \mathbf{x}$, the conditional log-probability $p(\mathbf{x} \mid \mathbf{y})$ is computed using the change-of-variables formula:

$$\log p(\mathbf{x} \mid \mathbf{y}) = \log p(\mathbf{z}) - \log \left|\det \left(\frac{\partial \mathbf{x}}{\partial \mathbf{z}}\right)\right|.$$

Jacobian Determinant: The Jacobian matrix $\frac{\partial \mathbf{x}}{\partial \mathbf{z}}$ is diagonal because the transformation is element-wise. Each diagonal entry is given by:

$$\frac{\partial x_j}{\partial z_j} = \exp(\log s_j(\mathbf{y})) = s_j(\mathbf{y}).$$

Hence, the determinant is:

$$\left|\det \left(\frac{\partial \mathbf{x}}{\partial \mathbf{z}}\right)\right| = \prod_{j=1}^{D} s_j(\mathbf{y})$$

$$\log \left|\det \left(\frac{\partial \mathbf{x}}{\partial \mathbf{z}}\right)\right| = \sum_{j=1}^{D} \log s_j(\mathbf{y})$$

Latent Density: The log-density of $\mathbf{z} \sim \mathcal{N}(\mathbf{0}, \mathbf{I})$ is:

$$\log p(\mathbf{z}) = -\frac{1}{2}\left(\|\mathbf{z}\|^2 + D\log(2\pi)\right).$$

Combining the two components, the final expression for the conditional log-likelihood is:

$$\log p(\mathbf{x} \mid \mathbf{y}) = \log p(\mathbf{z}) + \sum_{j=1}^{D} \log s_j(\mathbf{y}),$$

where $\mathbf{z} = f_\psi^{-1}(\mathbf{x}, \mathbf{y}) = (\mathbf{x} - t(\mathbf{y})) \oslash \exp(\log s(\mathbf{y}))$.

Optical Polarization modulation based on metasurfaces

Chen Chen*

College of Engineering and Applied Sciences, Nanjing University, Nanjing, 210093, China
*corresponding author: chenchen2021@nju.edu.cn

Abstract: We realized independent wavefront manipulation of different polarization channels including two cross-polarizations, and co- and two cross-polarizations, applications like achromatism, polarimetry and encryption were successively demonstrated.

Metasurfaces, emerging as innovative flat optical devices, facilitate the development of thin and lightweight optical elements with precisely engineered wavefronts. Benefiting from the plentiful freedoms of the anisotropic meta-atoms, flexible manipulation of polarization can be achieved.

The fundamental phase modulation method for spin light is the PB phase, which is determined by the varying orientation angles of each meta-atom, constrained by intrinsic symmetry. Unlike the global effects of the PB phase in spin light manipulation, we propose a novel local phase modulation mechanism based on planar chiral meta-atoms. This mechanism enables efficient and independent phase control for different spin lights [1]. Utilizing such two cross-polarizations modulation, we can realize a folded pancake metalens with polarized space-folding effect [2], and an achromatic metalens out of the size limitation. Considering the co-polarization light channel [3], we can realize three independent channels: one co-spin channel and two cross-spin channels. Leveraging this chiral modulation, we propose a non-interleaved single-pixel polarimetry scheme that achieves high spatial resolution through mutual interference information [4]. Applying interferometric methods to Poincaré beams, we introduce the concept of perfect high-dimensional Poincaré beams with expanded degrees of freedom. By cascading two arrayed metasurfaces, we can independently engineer more beam properties, significantly enhancing the key and encoding spaces for optical encryption, thereby achieving high security levels and large information capacities [5]. Such tri-polarization-channel wave front control can further be extended for the arbitrary polarization state [6]. We envision that such polarization manipulation based on metasurfaces could bring in more intriguing applications in the near future.

All-optical ultrafast polarization switching with nonlinear plasmonic metasurfaces

Heng Wang, Guixin Li*

Department of Materials Science and Engineering, Southern University of Science and Technology, Shenzhen 518055, China

*corresponding author: ligx@sustech.edu.cn

Abstract: We demonstrate all-optical ultrafast polarization switching of second harmonic waves with nonlinear plasmonic metasurfaces. By leveraging geometric phase controlled symmetry-selective polarization switching via second-harmonic generation, ~520 fs switching time, ~97% modulation depth and dual-channel switching are achieved. The metasurface platform offers promising applications in ultrafast optical information processing.

Optical switching has important applications in optical information processing, optical computing and optical communications. The long-term pursuit of optical switch is to achieve short switching time and large modulation depth. Among various mechanisms, all-optical switching based on Kerr effect represents a promising solution. However, it is usually difficult to compromise both switching time and modulation depth of a Kerr-type optical switch. To circumvent this constraint, symmetry selective polarization switching via second harmonic generation (SHG) in nonlinear crystals has been attracting scientists' attention. Here, we demonstrate the all-optical ultrafast polarization switching of second harmonic waves with the nonlinear plasmonic metasurfaces working in the near infrared regime. By using the concept of geometric phase, the linear polarization directions of the second harmonic waves could be well controlled by the linear polarization direction and time delay of the two pump waves. A switching time of ~520 femtoseconds and a near-unity modulation depth of ~97% were experimentally achieved. In addition, we also demonstrate the dual-channel all-optical ultrafast switching by designing the distributions of the meta-atoms. This work represents an important progress in the fields of nonlinear optics and optical information processing. The metasurface platform is easy to be scaled up and allows for the design of parallel switching channels. The metasurface platform proposed here may open new routes for developing all-optical ultrafast switches and would benefit the area of optical information processing.

Abstract: We presents a tunable nonlinearity method in synthetic temporal lattices via opto-electric feedback, experimentally demonstrating bistability-to-chaos transitions and constructing a high-entropy chaos-based encryption system. The findings enable advanced secure communication schemes within synthetic dimension platforms.

Main results:

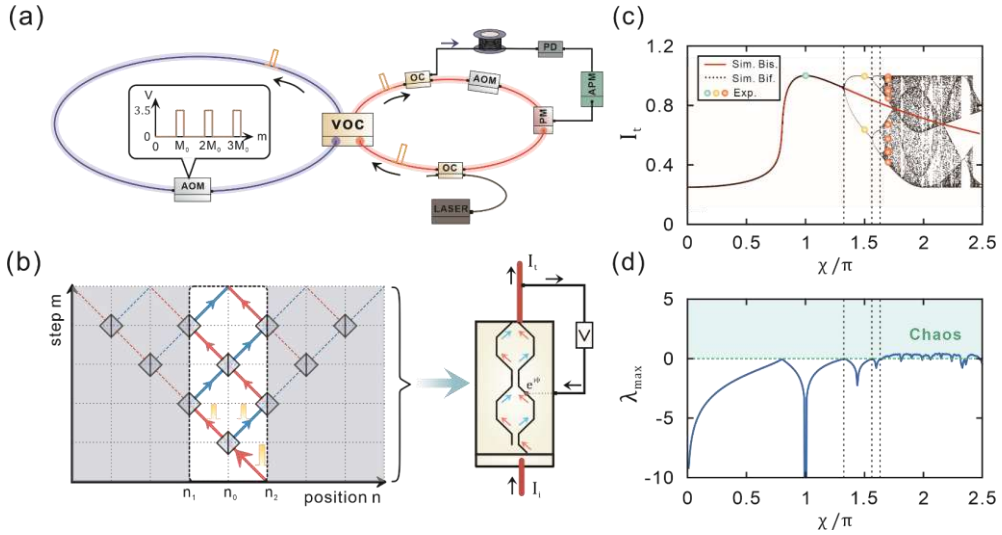

Fig. 1. a. Schematic experimental setup of temporal lattices based on two coupled fiber loops with a length difference. **b.** Schematic diagram of the synthetic temporal mesh lattice and temporal feedback system. **c.** Bifurcation diagram. **d.** The maximal Lyapunov exponent corresponding to the bifurcation diagram in **c**, the green region means chaos behavior emerge.

Based on two coupled fiber loops with difference lengths and an opto-electric circuit shown in Fig. 1a, we first construct temporal nonlinear feedback system (Fig. 1b). Assuming the temporal feedback system operates continuously, with the nonlinear phase feedback time negligible compared to the system's response time and the final output intensity stabilizing at a constant value, two functional relationships between transmittance and phase can be described as

$$T = \sin^4\beta + \cos^4\beta - \frac{1}{2}\sin^2(2\beta)\cdot\cos\phi, \tag{1}$$

$$T = \frac{\phi}{\chi I_i}, \tag{2}$$

where χ is the nonlinear feedback coefficient. This allowed us to derive a simulated bistable curve illustrating the relationship between χ and the outgoing light intensity It, as shown in Fig. 1c. Due to the discreteness of temporal

synthetic lattices underlying the temporal nonlinear feedback system, the feedback phase becomes discretized and exhibits iterative variations rather than continuous changes. Therefore, as the nonlinear coefficient increases, the lower branch of bistable curve transitions through a sequence of period-doubling bifurcations, ultimately leading to chaotic behavior. Figure 1c displays the bifurcation diagram illustrating the transition from bistable behavior to chaos as ϕ is discretized. The maximal Lyapunov exponent curve shown in Fig. 1d corresponding to the bifurcation diagram, in which maximal Lyapunov exponent λ_{max} is positive in the chaotic region and negative in region without chaos.

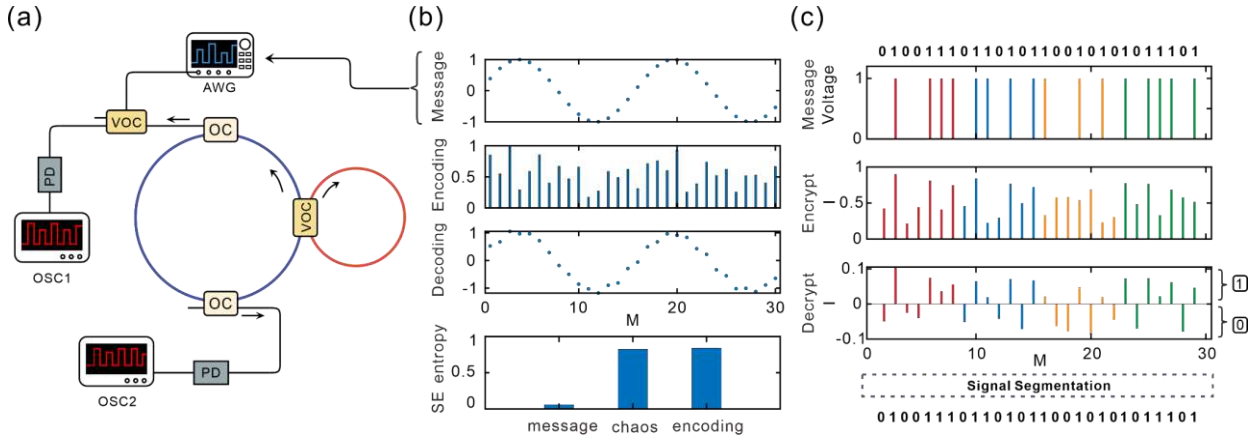

Fig. 2. a. Experimental and theoretical implementation of temporal chaotic encryption transmitter. **b.** Experimental results of chaotic encryption and decryption of waveform message. **c.** Experimental results of chaotic encryption and decryption of binary message.

Figure 2a is the experimental setup of temporal chaos transmitter. The chaotic pulse sequences generated by the nonlinear coupled fiber loops are extracted via an OC in the long loop. These sequences are modulated by a VOC, which incorporates message through an arbitrary waveform generator (AWG). The modulated chaotic signal is then detected by a photodetector (PD) and displayed on oscilloscope 1 (OSC1). The unmodulated chaotic signal is extracted using a separate set of OC and PD and recorded by OSC2. Figure 2b and 2c are the experimental and simulation results of the chaotic encryption and decryption processes of waveform he binary message.

This work represents the first experimental realization of temporal chaos in synthetic lattices and paves the way for advanced chaos-based communication with high-security encryption.

Abstract

The quantum valley Hall effect is used to arrange different topological areas with specific topological properties and customize waveguides and resonators to study enhanced light-matter interactions.

1 Introduction

Topological waveguides display novel possibilities of controlling light in on-chip structures. Here the quantum valley Hall effect is used as a foundation to design topological valley photonic crystal structures which relies on a broken inversion symmetry of the topological area. [1]
Superlattices of holes with different sizes, etched into a silicon on insulator wafer, are used to open up a bandgap in the photonic crystal slab [2]. The bandgap can be further tuned through changing hole sizes and the lattice constant. Combining two different topological areas breaks the spatial-inversion symmetry of the overall topological area and edge states arise at the interface. These edge states create one directional waveguides with tunable transmission windows and low losses as shown in Figure 1. Since silicon offers high non-linearity for light-matter interaction the topological waveguide provide a platform for tuning direction as well as wavelength range for these processes. In order to further enhance light-matter interaction within the topological structures we build triangular topological resonators which couple to the nearby topological waveguides as shown in Figure 2.

2 Figures and Tables

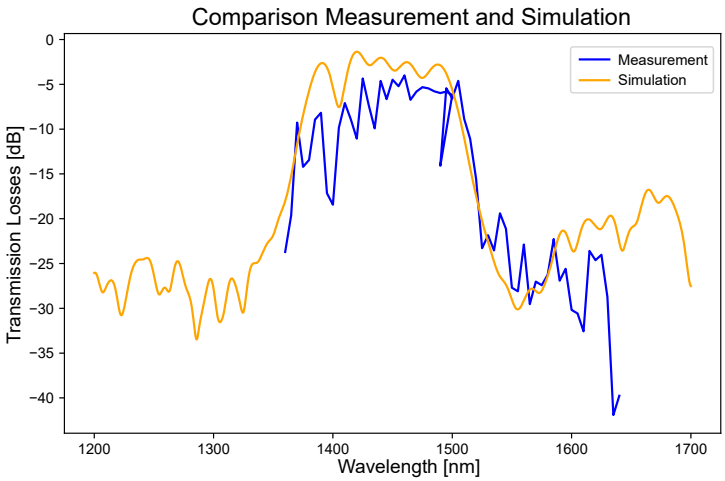

Figure 1:
The losses of a topological waveguide for wavelength between 1350 nm and 1640 nm are shown. The reduced topological losses can be recognized both in the experiment and in the simulation and are in agreement.

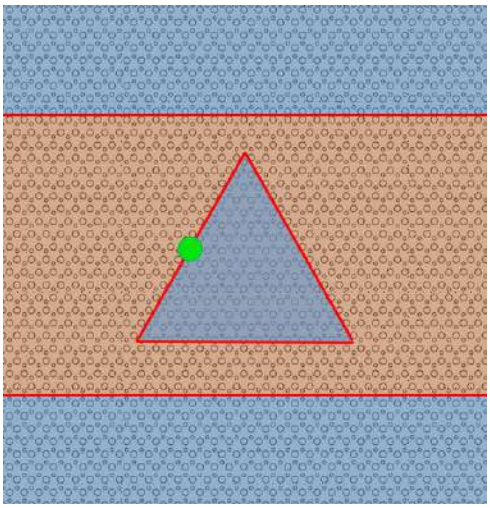

Figure 2:
The figure shows a schematic drawing of the resonator that should enhance linear and non-linear effects. The different topological areas are highlighted and the interfaces are marked red. The green dot indicates a possible position of a pump laser.

Abstract:

In this study, we present the pixelated plasmonic metasurface for detecting mid-infrared molecular fingerprints and for the chemical identification and compositional analysis of surface-bound analytes. The pixelated plasmonic metasurface successfully detected the molecular fingerprints of glucose (1 nM) in the wavenumber range of 1000 cm^{-1} to 1800 cm^{-1}.

Plasmonic metasurfaces are two-dimensional arrays of metallic nanoantennas (meta-atoms) with subwavelength thicknesses and spacings and spatially varying phase responses. Plasmonic metasurfaces promise a paradigm shift in optics by replacing traditional bulky optical elements, e.g., beam deflectors, lenses, waveplates, vortex generators, and holograms, with ultrathin, lightweight, and easy-to-integrate two-dimensional optical interfaces [1,2]. Furthermore, plasmonic metasurfaces have an ultrathin thickness on the order of tens of nanometers, are easy to fabricate, support field confinement beyond the diffraction limit, and have the potential to respond on the timescale of a few femtoseconds. These properties are unparalleled in traditional optical elements, which makes them a promising candidate for sensing applications, especially in the mid-IR range. However, because of the mismatch between mid-IR wavelengths and dimensions of molecules, the sensitivity of mid-IR spectroscopy is limited when detecting signals from nanometer-scale samples.

This drawback can be addressed by exploiting the strong near-field enhancement of the plasmonic metasurfaces. If the metasurface resonance is spectrally overlapped with the absorption fingerprints of the molecule, the enhanced molecule-resonator coupling can lead to a change in either the frequency or the strength of the resonance, from which the molecular fingerprints can be extracted [3]. The idea of pixelated metasurfaces helped to tune the resonance wavelength and the electromagnetic field enhancement at specific wavelengths. In this study, we successfully fabricated plasmonic metasurfaces with reflectance resonances in the molecular fingerprint region (Figure 1) from 1000 cm^{-1} to 1800 cm^{-1}.

Figure 1(a) shows the schematic illustration of the fabricated pixelated plasmonic metasurface according to different scaling factors (S), and it can be inferred that the resonances of each pixel (shown in Figure 1(b)) covered the molecular fingerprint region entirely. Upon the addition of glucose (1 nM) on top of the plasmonic metasurface, specific changes can be observed in the frequency or intensity of the resonances (Figure 1(b, middle row)), which can be attributed to the absorption fingerprint of glucose. These reflectance differences were translated to a 2D map using a Python code from which the signature of the glucose molecule can be seen clearly. As can be inferred, this platform can enhance, detect, and differentiate the absorption fingerprints of glucose (as a model) without the need for complex instrumentation.

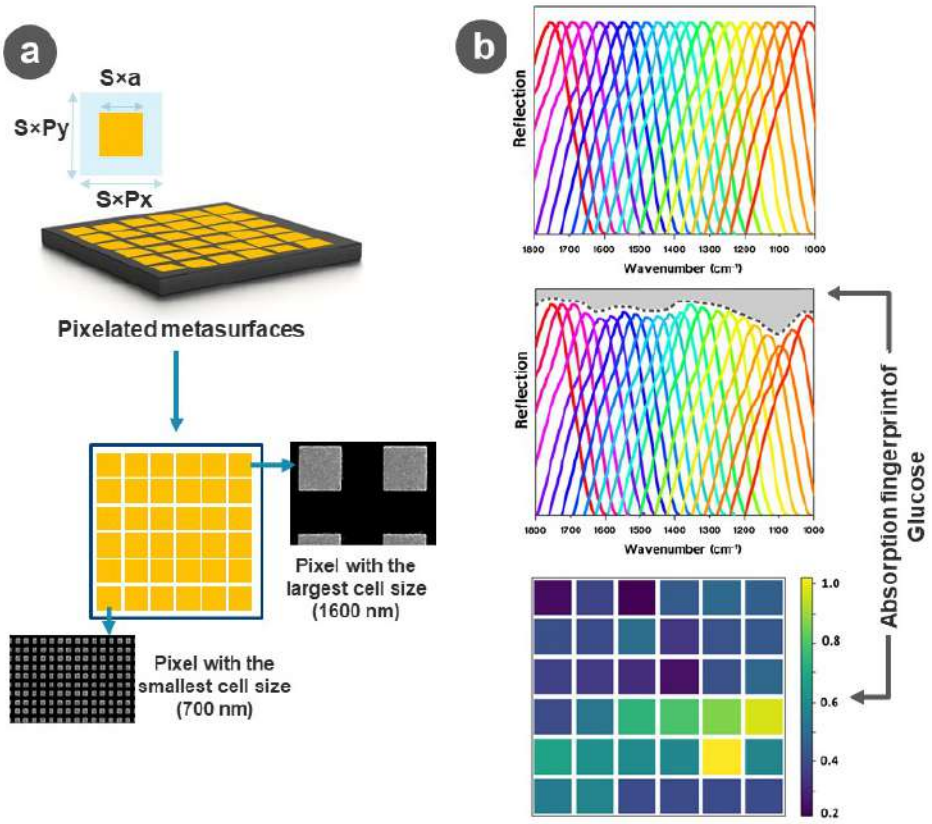

Figure 1. (a) Schematic illustration of the fabricated plasmonic metasurfaces containing 36 pixels with different cell sizes according to the scaling factor (S). (b) Resonance spectra of each pixel before (top row) and after (middle row) the addition of the analyte (Glucose (1 nM) in this case). The bottom row shows the 2D barcode-like map of reflectance difference.

This concept showed promising applications for detecting mid-infrared molecular fingerprints for the chemical identification and compositional analysis of surface-bound analytes. We aim to use the developed barcode-like sensor to detect different molecules and realize the multiplexed sensing in the mid-IR range.

Abstract

We discuss a sharp increase in photon number noise in bosonic chains with off-diagonal disorder. This "noise avalanche" occurs under coherent excitation of a bosonic mode, leading to super-thermal photon bunching in the lattice. Single-photon excitation of an another mode can quench the avalanche, while classical excitation only slows it.

1 Introduction

Study of coupling between closely situated waveguides often discusses an influence of coupling randomness on field propagation through waveguides. This randomness eventually leads to an asymptotically equal field energy distribution between the waveguides, regardless of the initial states. This phenomenon was shown to be common in systems with noisy coupling (i.e., the so-called 'off-diagonal disorder') [1]. Here we report an counterintuitive phenomenon that can arise in coupled bosonic systems with random off-diagonal disorder: a noise avalanche.

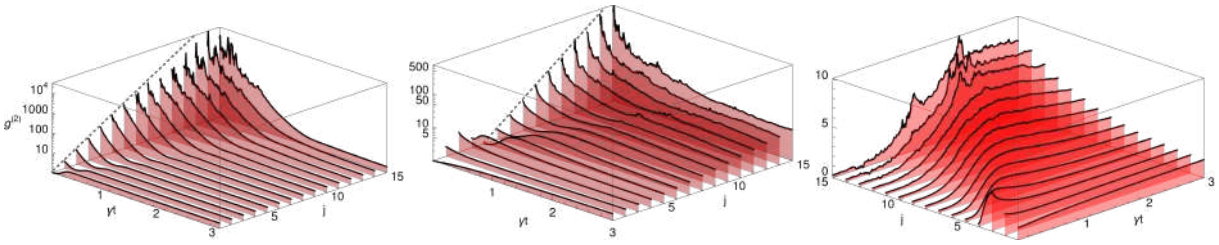
2 Model and the noise avalanche demonstration

The chain model can be considered as a generalization of the much discussed Su–Schrieffer–Heeger [2] (SSH) and is described by the Hamiltonian $H = H_0 + V(t)$, where the time-independent non-random part H_0 describes the unitary SSH chain of $N+1$ resonant coupled bosonic modes:

$$H_0 = \sum_{j=1}^{N}(v_j a_j^\dagger a_{j+1} + v_j^* a_{j+1}^\dagger a_j), \quad V(t) = \sum_{j=1}^{N}(\mu_j(t) a_j^\dagger a_{j+1} + \mu_j^*(t) a_{j+1}^\dagger a_j), \tag{1}$$

with $a_j^\dagger$ and a_j being bosonic creation and annihilation operators for the j-th mode of the chain; v_j are the interaction constants. The off-diagonal random disorder affecting the chain we take as described by the random addition to the Hamiltonian $V(t)$, where $\mu_j(t)$ are random zero-mean classical variables $\langle \mu_j(t) \rangle_c = 0$, where $\langle \ldots \rangle_c$ denotes classical averaging over the noise realizations. We assume that noises between each pair of modes are independent,

$$\langle \mu_j(t)\mu_k(\tau)\rangle_c = \langle \mu_j(t)\mu_k^*(\tau)\rangle_c = 0, \quad \forall j \neq k.$$
$$\langle \mu_j^*(t)\mu_j(\tau)\rangle_c = \gamma_j \delta(t-\tau), \quad \langle \mu_j(t)\mu_j(\tau)\rangle_c = \kappa_j \delta(t-\tau).$$



We concentrated our attention on the peculiar phenomenon arising for just one mode initially excited in the coherent state with other modes initially in the vacuum state [3]. This phenomenon is a sudden jump of the photon number noise in the initially empty modes at the very early

stages of dynamics. For long chains of coupled modes this jump turns to the avalanche: the normalized second-order correlation function grows exponentially. However, an additional single-photon excitation quenches the avalanche [3].

We found a simple analytical estimate at the initial time point for the avalanche growth and differences in dependence on the character of noise. For real κ_j one has

$$g^{(2)}_{j+1}(0) \approx \left(2 + \frac{\kappa_j^2}{\gamma_j^2}\right)^j . \tag{2}$$

We have performed numerical Monte-Carlo (MC) simulation demonstrating the effect, particular case is shown in Figure 1.

(a) (b) (c)

Figure 1: Normalized second order correlation functions of a system (1) for j-th mode is calculated via MC simulation with the number of realization is $K = 3 * 10^5$ and the number of time sub-intervals is $M = 300$ (see details in [3]). (a) The first mode is initially excited in a coherent state with the amplitude $\alpha_1 = 10$ and $v = 5\gamma$, $\nu = 0.5$; (b) the first mode is in a coherent state with the amplitude $\alpha_1 = 10$ and the fifth mode is in the amplitude $\alpha_5 = 1$ and $v = 0$, $\nu = 1$; (c) the first mode is in a coherent state with the amplitude $\alpha_1 = 10$ and the fifth mode is initially excited in the single-photon Fock state; all other unmentioned modes are initially in the vacuum state. Dashed lines show a curve (a) 2.36^{j-1} and (b) 2^{j-5} as limit case (2) for $t = 0$.

3 Conclusions

An obvious use of the considered systems with random off-diagonal disorder might be for generation of bunched and super-bunched states in well-defined spatial modes. Such sources are of high demand nowadays for ghost imaging, LIDAR ranging based on intensity correlations or quantum tomography [4, 5]. Additionally, the considered phenomena can be useful for breeding sub-Poissonian states from a combination of a single-photon and coherent inputs.

PEEM based near-field imaging of plasmonic topological Harper nanochains

Qiuchen Yan[1*], Boheng Zhao[2], Xiaoyong Hu[1], and Qihuang Gong[1]

[1]Peking University, China
[2]Tsinghua University, China

Abstract: We propose a novel approach to regulate coupling intensity by integrating gold nanodisks with connecting waveguides. The topological properties of Aubry-André-Harper configuration are directly characterized using photoemission electron microscopy. This work provides direct in-situ measurements of topological states at nanoscale, advancing the practical applications of integrated plasmonic topological photonics.

Photoemission electron microscopy (PEEM) with ultrahigh spatial-temporal resolution can be a good platform to measure the plasmonic modes in the near field and the time field[1]. We have successfully explored the near-field mode distributions and the topological dynamic responses of topological edge states (TESs) in the Aubry-André-Harper (AAH) nanochains. The wavelength-dependent mode distributions of AAH chains are well demonstrated by PEEM instruments, which provides a reliable approach for the multidimensional regulation of TESs and explains the dynamic evolution process of TESs from a fundamental physics perspective.

Here, we report a novel strategy of weaving gold nanodisks with waveguides to realize an ultracompact on-chip-integrated plasmonic topological insulator with an AAH configuration[2]. The on-chip plasmonic topological insulator is constructed by gold nanodisks that are connected by short gold waveguides with different widths, meeting the extremely strict precision requirement of coupling parameters for sample nanofabrication and suppressing the influence of plasmon hotspots. Furthermore, we discover a transition between symmetric and asymmetric boundary modes of the plasmonic topological nanodisk chains with increasing nanochain length, corresponding to variations in the value of parameter ϕ of AAH model. This work advances the foundational research and practical applications of controlling synthetic dimensions in optical micro/nano-scale AAH models, providing robust support for the development of plasmonic topological photonics. By addressing the challenges in this field, the work lays a foundation for the development of advanced photonic devices and information processing chips, enabling further exploration and innovation in the realm of topological photonics.

Slot Mode Optomechanical System for Mass Sensing

C. Thrideep[1], M. Belov[2], and W. Hiebert[1,2*]

[1] Department of Physics, University of Alberta, Edmonton, Alberta, Canada T6G 2E1

[2] Nanotechnology Research Centre, National Research Council Canada, 11421 Saskatchewan Dr NW, Edmonton, Alberta, Canada T6G 2M9

Abstract: Optomechanical systems have demonstrated their significance in sensing applications. We study a slot mode optomechanical system where in a THz optical mode from a Photonic Crystal (PhC) cavity is coupled to a MHz mechanical mode of the cantilever to construct an effective mass sensitive device specifically operating at low-frequency region.

Improving ultimate mass sensitivity in resonant NEMS is achieved by the best combination of smallest mass resonator (m_{eff}), highest signal-to-noise-ratio (SNR) and largest mechanical quality factor Q represented by the figure of merit:

$$\frac{\delta f}{f} = \frac{m_{eff}}{QSNR} \tag{1}$$

The primary tension in this figure of merit comes from the fact that shrinking device size tends to lose both readout signal and drive efficiency and thus diminishes SNR. In previous work using a cantilever coupled to a racetrack optical resonator [1], it was shown that drive efficiency has a maximum for an optimum optical quality factor and that larger optomechanical coupling provides larger amplitude. It was further shown [2] that readout laser frequency could be tuned for cancellation of optomechanical nonlinearity potentially allowing relatively large driven amplitude. Shrinking the device to improve mass sensitivity would quickly diminish the optomechanical coupling value (G) which would endanger SNR in both the ability to resolve noise floor and the ability to drive a large peak amplitude. While adding optical power could partially mitigate SNR losses, this path is not available due to two-photon absorption nonlinearity limitations in the silicon system. The critical improvement required to solve this problem is one of increasing G in this system, even while maintaining or reducing coupled mass. This drives our present motivation for methods to increase G between a cavity and a low mass mechanical element. For a slot-mode system, the redistribution of energy into the slot should allow an increase to G per unit volume of coupling mechanical element, due to the increased sensitivity of the mode to the surface position boundary conditions. The use of a PhC better localizes the mode energy to the cantilever region also increasing G. Further, the mode energy in the slot may allow slightly higher optical powers due to reduced two photon absorption. Altogether, this motivates the choice of PhC with slot waveguide for best mass sensitivity.

In slot-mode optomechanical devices, the coupling of photonic and phononic beams is utilized to enhance the optomechanical coupling strength beyond what is achievable in single nanobeam crystals. We consider the integration of Silicon PhC with cantilevers on either side which essentially behave as a slot mode optomechanical system. A modified inline coupling technique in reflection mode is used to couple light into the cavity by manipulating losses at the mirrors [3]. To achieve this, the coupling end of the waveguide is provided with only 1 to 5 holes to access different coupling regimes. We utilized COMSOL to model our slot-mode optomechanical system, considering both photonic and phononic bandgap. The PhC- cantilever system was fabricated, and the

chip underwent testing through a pump and probe system to evaluate the device's mass sensitivity. We were able to realize a mass sensitivity of 51zg despite the encountered temperature fluctuation noise. This aligns with the notion that our shorter cantilever demonstrated an improved G of 0.12 GHz/nm, as compared to the value achieved by our research group for a longer cantilever coupled to a racetrack resonator.

Incoherent Dielectric Tensor Tomography for Robust 3D Birefringence Imaging Using Non-Interferometric System

Juheon Lee[1], Herve Hugonnet[1], Chulmin Oh[1], YongKeun Park[1,*]

[1] Department of Physics, Korea Advanced Institute of Science and Technology (KAIST), Daejeon, Republic of Korea

Abstract: We present an incoherent dielectric tensor tomography (DTT) technique for robust three-dimensional birefringence imaging of anisotropic materials. Unlike conventional DTT methods that rely on temporally coherent light and interferometry—making them vulnerable to mechanical vibrations and speckle noise—our system utilizes temporally incoherent illumination and a non-interferometric architecture.

Birefringence is an optical property observed in anisotropic materials, where the refractive index (RI) varies depending on the polarization of incident light. This polarization-dependent RI arises from the internal molecular alignment and structural anisotropy of the material. Consequently, three-dimensional (3D) birefringence imaging has become a valuable tool in both industrial and biomedical fields for analyzing the internal orientation and organization of target samples [1,2].

Recently, dielectric tensor tomography (DTT) has emerged as a powerful technique for 3D birefringence imaging, offering a more comprehensive characterization of anisotropic structures by reconstructing the full 3×3 dielectric tensor at each spatial position [3,4,5]. Unlike conventional holotomography, which measures a scalar RI value per voxel, DTT captures the vectorial nature of light–matter interactions by accounting for both the local molecular orientation and the polarization state of light. This tensorial approach provides fundamentally richer information on anisotropic optical behavior within the sample.

However, conventional DTT systems typically rely on interferometric setups with temporally coherent illumination, making them prone to mechanical vibrations and speckle-induced artifacts. To overcome these limitations, we propose a novel incoherent DTT framework based on a non-interferometric imaging system combined with modulated illumination.

Our system employs two temporally incoherent LED light sources and a spatial light modulator (SLM) to control both the incident wavefront and polarization states. A polarized beam splitter is used to direct the modulated light onto the sample, which is sequentially illuminated with a series of polarization-encoded wavefronts. For each illumination condition, the resulting 2D diffraction patterns are recorded at the image plane.

To reconstruct the full 3×3 dielectric tensor, we compute polarization-dependent optical transfer functions using the known input and analysis polarization states. Because a single measurement cannot capture all tensor components, multiple acquisitions with varied SLM modulation patterns and polarization configurations are performed, enabling comprehensive tensor recovery [3].

For validation, we experimentally measured a liquid crystal droplet with a well-known radial molecular alignment. The reconstructed orientation field closely matches the expected structure, and the resulting birefringence tomograms clearly reveal a positive uniaxial anisotropy within the droplet.

In addition, we applied our method to thick biological tissue samples from colon cancer patients. The 3D birefringence information of the collagen network within the tumor microenvironment was accurately reconstructed and quantitatively analyzed, demonstrating the applicability of our approach to complex biological

specimens.

These results demonstrate that our incoherent DTT framework provides a robust and noise-resilient approach for high-fidelity 3D birefringence imaging of anisotropic samples. By eliminating the need for interferometry and coherent illumination, the system significantly enhances experimental stability and reduces speckle artifacts, enabling reliable tensor reconstruction even in challenging biological and material contexts. The ability to retrieve the full dielectric tensor in a label-free and quantitative manner opens new avenues for investigating molecular alignment and structural anisotropy in diverse applications ranging from soft matter physics to cancer pathology.

3D Strain Tensor Analysis in micro-indented glass via Dielectric Tensor Tomogram

Juheon Lee[1], YongKeun Park[1,*]

[1] Department of Physics, Korea Advanced Institute of Science and Technology (KAIST), Daejeon, Republic of Korea
[*]corresponding author: yk.park@kaist.ac.kr

Abstract: Dielectric tensor tomography (DTT) enables 3D visualization of strain in materials through optical birefringence. Applying the stress-optic law, we determine principal strains and orientations in micro-indented glass, revealing density variations and crack propagation. Our findings highlight DTT's potential for non-destructive strain analysis and characterization of complex strain distributions.

Assessing mechanical stress and strain is essential for optimizing mechanical components and preventing failures. Optical birefringence, which is sensitive to molecular alignment induced by mechanical stress, serves as a valuable tool for studying stress and strain in materials. A recently developed technique, dielectric tensor tomography (DTT), enables the reconstruction of 3D optical anisotropic structures.[1] In this study, we employ DTT to visualize the 3D strain tensor in micro-indented glass samples. By applying the stress-optic law, we determine the principal strains and their orientations, uncovering variations in density and crack propagation patterns. Our findings demonstrate the potential of DTT for non-destructive strain analysis and its effectiveness in characterizing complex strain distributions in materials.

Abstract: Here we propose a generic approach to design ultra-thin and high-efficiency metasurfaces for multiple holographic images' generation. Utilizing high-efficiency reflective meta-atoms exhibiting incident-spin-delinked reflection phases governed by geometric and resonant mechanisms, distinct holographic images can be generated by the metasurface with the thickness ~ 1/4 λ and efficiencies ~ 48.08%.

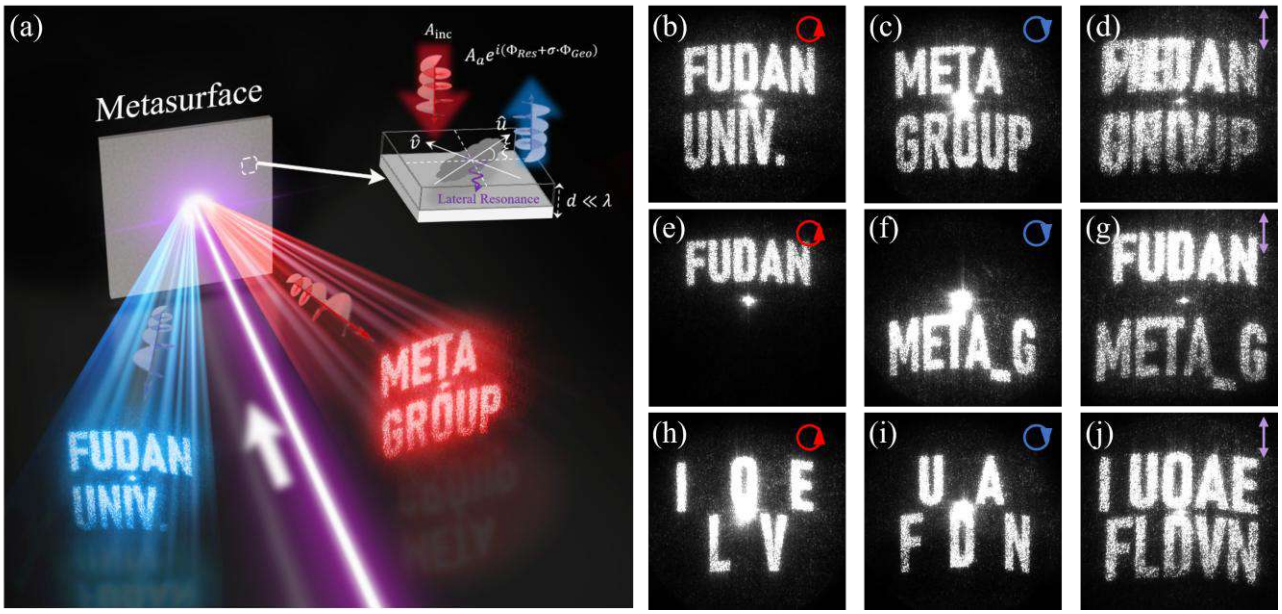

Fig. 1 Bifunctional holography generation based on metasurface. (a) The schematics of bifunctional holography generation with ultra-thin and high efficiency metasurfaces. Experimental demonstrations of varied kinds of bifunctional holography generation at incidences of different polarizations: (b) full-screen bi-functional meta-hologram; (c) split-screen bi-functional meta-hologram; (d) information-encrypted bi-functional meta-hologram.

Generation of holography has garnered increasing interests for its broad applications in modern photonics[1]. However, conventional generation technology requires complex setups, unfavorable for on-chip photonics

applications. Though employment of metasurface in holography generation have been studied recently, meta-holograms realized so far still suffer from imbalances between device thickness and working efficiency/ performance[2].

In this work, designing a series of meta-atoms in MIM configuration exhibiting reflection phases governed by both resonant and geometric mechanisms, we construct bi-functional meta-holograms based on phase distributions retrieved from two distinct holographic images[3]. Suppressing the undesired normal mode by:

$$A_n = |r_{uu}+r_{vv}|/2 = 0 \tag{1}$$

Under the condition of which, the reflected wave of the meta-atom can be expressed by $\boldsymbol{R}|\sigma\rangle = A_a e^{i(\Phi_{Res}+\sigma\cdot\Phi_{Geo})}|\text{-}\sigma\rangle$, containing both a spin-*independent* resonant phase $\Phi_{Res} = (\Phi_u+\Phi_v)/2\text{-}\pi/4$ and a spin-*dependent* geometric phase $\sigma\cdot\Phi_{Geo}$. With the GS algorithm, the reflection-phase distributions to generate distinct holographic images can be retrieved as $\Phi^{m}_{tar,|+\rangle}(\vec{r})$ and $\Phi^{m}_{tar,|-\rangle}(\vec{r})$, Thus with $\Phi^{m}_{tar,|\sigma\rangle}(\vec{r}) = \Phi_{Str}(\vec{r})+\sigma\Phi_{Geo}(\vec{r})$, we have

$$\begin{cases} \Phi_{Str}(\vec{r}) = \dfrac{\Phi^{m}_{tar,|+\rangle}(\vec{r})+\Phi^{m}_{tar,|-\rangle}(\vec{r})}{2} \\ \Delta\Phi(\vec{r}) = \pm\pi \\ \xi(\vec{r}) = \dfrac{\Phi^{m}_{tar,|+\rangle}(\vec{r})-\Phi^{m}_{tar,|-\rangle}(\vec{r})}{4} \end{cases} \tag{8}$$

Which provides an explicit guidance for metasurface design. Following this design strategy, we design and experimentally realize three different kinds of bi-functional meta-holograms. As shown in Fig. 1 (b,c), the first metadevice displays two different full screen patterns on the imaging plane at left circular polarized (LCP) and right circular polarized (RCP) incidences respectively, and simultaneously displays both components at the linear polarized (LP) incidence[Fig. 1 (d)]. Similar bifunctional holographic images exhibit for the split-screen meta-hologram as demonstrated in Fig 1 (e-g). The third metadevice can be applied to information encryption. Carefully arranging the two groups of desired character patterns, we find that while effective information (i.e., “I LOVE” and “FUDAN”) can be correctly displayed as the device is shined by LCP and RCP light beams [Fig. 1(h,i)], respectively, no meaningful information can be obtained as the incident light changes to the LP beam [Fig. 4(j)]. The efficiencies are evaluated to be ~35% in experiments and ~48% in numerical calculations.

In conclusion, we propose a generic strategy to realize bi-functional meta-holograms and experimentally verify the concept with three different metadevices including an information-encrypted one in the telecom frequency domain. The proposed meta-platform can find many applications in future integration photonics.

Theoretical Analysis of Recoil Force Generated by Stimulated Emission of Higher-Order Optical Vortices

Y. Umekawa[1*], T. Horai[1], M. Ashida[1], and H. Ishihara[1,2]

[1] Graduate School of Engineering Science, Osaka Univ., Japan

Abstract: The mechanical recoil force generated in a material by stimulated emission occurs in the direction opposite to the propagation of light. In this study, we theoretically elucidate the rotational motion of nanoparticles induced by recoil force from higher-order optical vortices, considering nonlinear optical responses.

Optical manipulation has been studied since Ashkin's discovery in 1970 as a technique for the non-destructive manipulation of microscopic materials [1]. In particular, resonant optical manipulation, which significantly enhances optical forces, is effective for manipulating nanomaterials [2]. Recently, we proposed an optical manipulation method based on stimulated emission, focusing on the fundamental optical property of luminescence [3]. Stimulated emission induces a recoil force in the direction opposite to light propagation, which overcomes the conventional limitation due to absorption saturation, and this has been quantitatively demonstrated theoretically [4]. Furthermore, this method has been verified experimentally [5][6]. However, photobleaching from prolonged high-intensity laser irradiation remains a challenge, hindering long-distance recoil force observation. Therefore, in this study, we focus on fluorescent nanodiamonds (NV-NDs), which are resistant to photobleaching. Additionally, by employing optical vortices with orbital angular momentum (OAM) as the light source, we explore novel light-matter interactions. Optical vortices propagate with a helical wavefront and are known to induce rotational motion in materials. We previously proposed that stimulated emission induced by optical vortices could reverse the rotational force on dye molecules [7], but its experimental demonstration has been challenging. In this study, we theoretically analyze the reversal of the rotational direction of NV-NDs in room-temperature water and demonstrate that rotational motion can be controlled. Furthermore, we discuss the effects of higher-order optical vortices on rotational motion. While the relationship between higher-order OAM and optical vortices has been previously discussed [8], this study rigorously examines the nonlinear optical response and elucidates the relationship between recoil force from stimulated emission and OAM, providing new physical insights into optical manipulation through optical vortices.

The optical force is evaluated using the time-averaged Lorentz force [9]:

$$\langle \mathbf{F} \rangle = \frac{1}{2} \Re \left[\sum_{\omega} \int \mathrm{d}\mathbf{r} \{ \nabla \mathbf{E}^{*}(\mathbf{r}, \omega) \} \cdot \mathbf{P}(\mathbf{r}, \omega) \right], \tag{1}$$

where, $\mathbf{E}(\mathbf{r}, \omega)$ is the incident electric field and $\mathbf{P}(\mathbf{r}, \omega)$ is the polarization. The incident electric field is modeled as a Laguerre-Gaussian (LG) beam, which is a paraxial eigenmode of the Helmholtz equation.

The resonant polarization is determined through non-perturbative solutions of the density matrix equation of motion. This enables the precise calculation of the nonlinear optical response of the material. The non-resonant polarization is evaluated using the Clausius-Mossotti relation, since the target material is an NV-ND with a 50 nm diameter. In the computational model, an NV-ND is modeled as a five-level system. The assumed experimental

setup involves two excitation LG beams propagating in the same direction, along with an additional stimulated LG beam. The excitation LG beams are configured so that their rotational forces almost cancel each other out, with their wavefronts rotating in opposite directions and their output power adjusted accordingly. Additionally, to prevent interference, the wavelengths of the two excitation LG beams are tuned within the absorption range of the NV-ND. As a result, the rotational force induced by the stimulated LG beam becomes dominant. Finally, room-temperature water is considered as the solvent. The motion of the nanodiamond in the solvent is analyzed using the Langevin equation.

Since p and l represent the radial and azimuthal mode indices, respectively, this study first considers a simple system with (p,l)=(0,1). As a result, the analysis reveals a significant difference in the rotational motion of the NV-ND and an undoped nanodiamond (undoped-ND) within just 0.1 seconds of laser irradiation. Specifically, it is demonstrated that the NV-ND can overcome thermal fluctuations and rotate opposite to the optical vortex, even in room-temperature water. Furthermore, this study examines the resonant and non-resonant components of the rotational force on the NV-ND as the OAM varies. The results are shown in Figure 1. As the orbital angular momentum increases, the ring radius expands, while the rotational force remains nearly constant. The trends observed in these computational results are also consistent with previous studies. The insights from this study advance the understanding of optical vortex–nanomaterial interactions and open new possibilities for optical manipulation.

Abstract: Photonic computing offers a promising platform for accelerating highly parallel tasks, including neural networks. We present a computing metalens array scheme for programmable quantum algorithms and complex-to-complex DFT. The scheme incorporates error correction through multi-focal point focusing and phase reconstruction. Experimental results demonstrate accuracy with random inputs amplitude and phase.

The growing demand in machine learning and artificial intelligence has brought focus into research of more energy efficient alternatives to traditional electronic computing frameworks. Photonic computing emerges as a promising platform, offering advantages such as higher speed, larger bandwidth, lower power consumption, and enhanced parallelization capabilities [1]. Due to their inherent ability to achieve parallelization at the physical level, photonic computers excel in tasks requiring high degrees of parallelism.

Metasurfaces – two-dimensional arrays of nanostructures, is a promising platform for free-space photonic computing, which offers higher bandwidth and greater parallelism compared to on-chip methods [2]. However, free-space approach is often susceptible to errors due to misalignment of the optical elements. To addresses this issue, we adopt a metalens array approach to generate multiple focal points. This approach localizes the output field, which embeds redundancy and allows error correction.

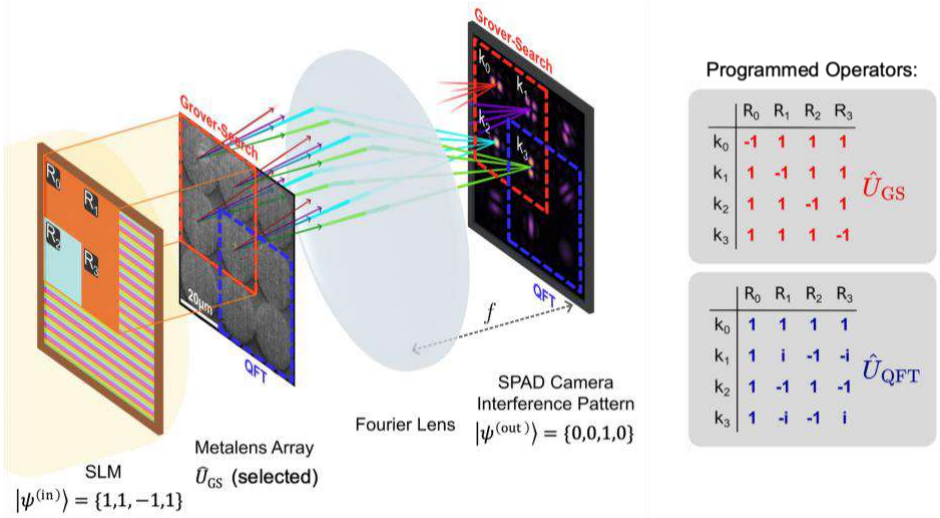

Fig 1 Computing metalens array for programmable quantum algorithms. An SLM selectively excites the metalens array to select the algorithm and prepares the two-qubit input state $|\psi^{(in)}\rangle$. Each metalens diffracts the beam into four directions, with amplitude and phase modulated by the U-matrix. The interference patterns of the diffracted beams in the same direction are projected onto the Fourier plane, where the intensity profile yields the output state $|\psi^{(out)}\rangle = \hat{U}|\psi^{(in)}\rangle$ by decoding constructive/destructive interference feature.

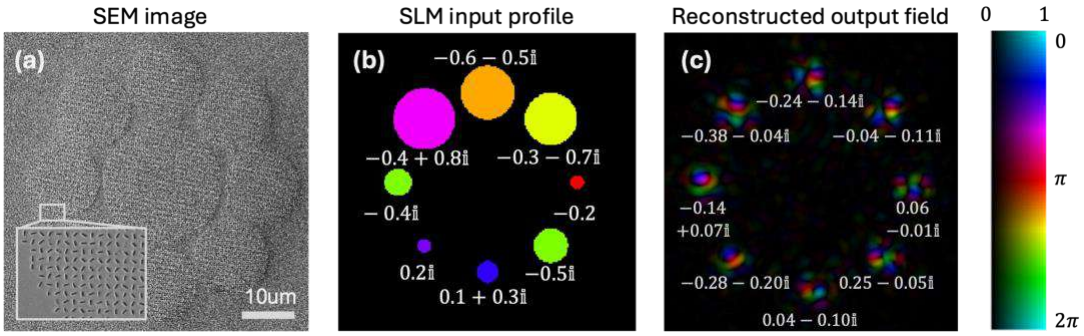

Fig 2 Computing metalens array for complex-to-complex DFT. (a) SEM image of eight circumferential signal metalenses and an additional central reference metalens. Each signal metalens is designed to focus light on 8 focal points, which phase delay designed according to DFT_8 matrix. The reference metalens is used to reconstruct the complex phase of the field at the focal plane. **(b)** A typical input vector encoded as complex illumination profile, with arbitrary input amplitude and phase. The amplitude is proportional to illumination radius (black region indicates no illumination), while the phase will be set directly by the SLM phase (represented as hue in the plot). **(c)** Reconstructed output field, experimentally obtained by combining four camera images with varying reference metalens incident phases $\phi_R = \{0°, 90°, 180°, 270°\}$. The output vector can be extracted by reading the complex value of the pixel at the center of each complex interference pattern.

Here, we highlight two examples on the same metalens-array platform for matrix-vector-multiplication (MVM). Our scheme encodes the input vector as the illumination profile using a spatial light modulator (SLM), and the matrix as the metasurface transmission profile. The output vector is decoded from the interference pattern, which is imaged at the focal plane of the metalens array. The first example demonstrates programmable quantum algorithms at countable photon regime [3], as shown in Fig. 1. The programmability comes from the selective excitation of the SLM and selective observation of the interference pattern. The second work extends this framework for complex-to-complex computation, demonstrating discrete Fourier transform (DFT) [4]. Typically, reconstructing the complex phase necessitates additional optical elements or computation. Our design addresses this by incorporating a built-in reference metalens, where phase reconstruction can be performed by iterating four phases of incident light on the reference metalens. Consequently, we experimentally demonstrate DFT with O(n) time complexity and effective error control, as shown in Fig. 2

Single-shot optical imaging of plasmonic nanoparticles: orientation, polarization anisotropy, aspect ratio

P. Bouchal[1], P. Dvořák[1], M. Hrtoň[1], K. Rovenská[1], V. Křápek[1*], R. Chmelík[1], T. Šikola[1], and Z. Bouchal[2]

Abstract

We demonstrate single-shot wide-field optical imaging of plasmonic nanoparticles visualizing their orientation and aspect ratio, in conventional far-field methods hidden below the diffraction limit. The capability of the method is demonstrated in the time-resolved imaging of the electrophoretic deposition process or the Brownian motion imaging using plasmonic nanorods.

Plasmonic nanoparticles can be used to shape (confine, enhance, and direct) the light at the nanoscale, building upon their ability to support localized surface plasmons and making them suitable optical probes for sensing and imaging. The most common shapes are nanospheres and nanorods. The nanorods offer the benefit of anisotropic optical properties, which makes them suitable for orientation sensors in the conformation and dynamics studies of biological systems as well as for novel plasmonic-based nanoimaging devices [1]. The orientation imaging of the nanorods is thus highly desirable, although it is significantly hindered by their deeply subwavelength dimensions. An overview of available methods is provided in Ref. [2].

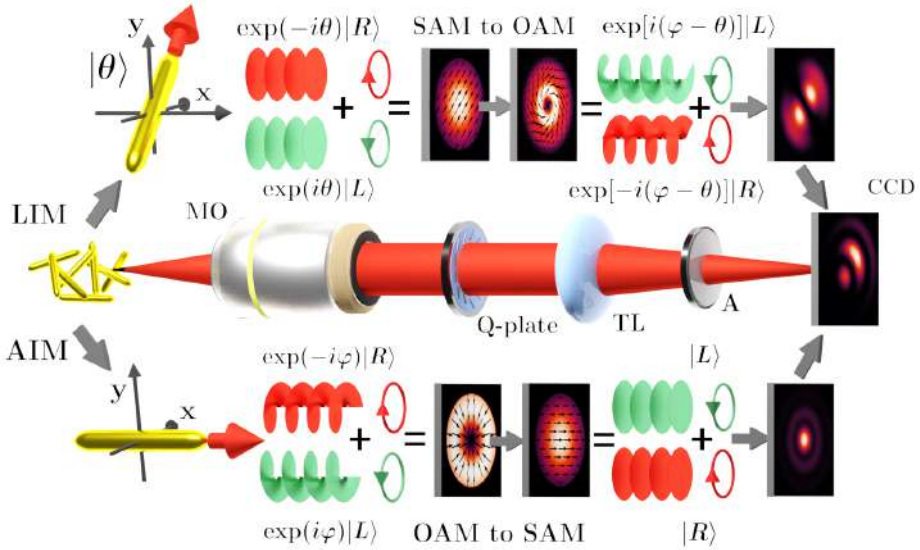

Figure 1: Left to right: A plasmonic nanorod either in LIM (top) or in AIM (bottom) scatters the light field with a specific spin and orbital angular momentum, transformed by the Q-plate to form characteristic PSF in the image plane. For a general nanorod orientation (middle), both LIM and AIM fields propagate independetly through the optical column (due to orthogonal polarization) and interfere in the image plane after polarization projection by the analyzer (A).

In our contribution, we report a new method for single-shot three-dimensional orientation imaging of plasmonic nanorods. We utilize a dark-field transmission optical microscope with an add-on imaging module that exploits a Q-plate for conversions between spin and orbital angular momentum of the light scattered by the nanorods. In this way, the orientation of nanorods is imprinted into the polarization and geometric phase of the scattered light and transformed into characteristic point spread functions (PSF), which are detected and utilized to retrieve the orientation angles of the nanorod. The principle of the method is visualized in Fig. 1. We consider two specific modes: the lateral imaging mode (LIM) with the nanorod perpendicular to the optical axis and the axial imaging mode with the nanorod parallel to the optical axis. In both cases, the spin or orbital angular momentum of the scattered light is shaped by the optical system to produce characteristic PSF: double helix PSF for LIM and the Airy disk for AIM. For a general nanorod orientation, the resulting image is formed by the interference of both specific components of the light fields. A calibration measurement comparing the orientation image of the nanorods to a reference scanning electron microscopy image allowed us to estimate the accuracy of the method by a standard deviation of 2.5° [2]. We have also developed an extension that allows to characterize the polarization anisotropy of the nanorods which can be related to their aspect ratio [3]. Our orientation imaging method can be generalized to other dipole light sources, e.g., quantum emitters.

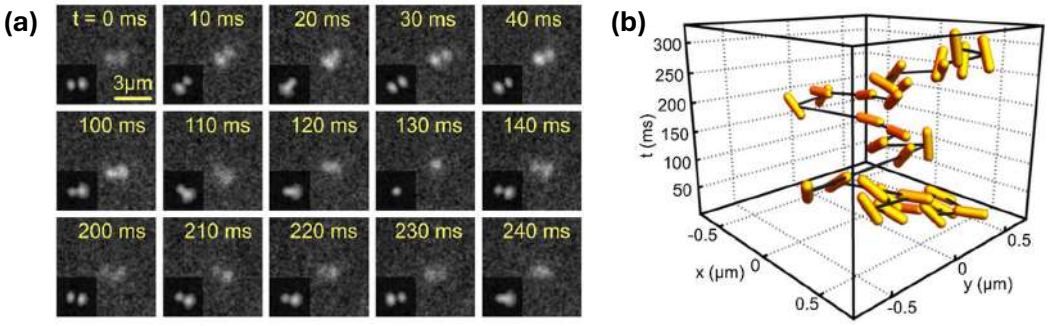

Figure 2: 3D orientation imaging of nanorods moving by Brownian motion. (a) Gradual variations in the axial and polar angles of a single nanorod are reflected in variations in the detected image patterns taken with a time step of 10 ms. (b) Reconstruction of the single nanorod 3D orientation during its Brownian motion.

To demonstrate the capability of the orientation imaging we present in Fig. 2 a study of a Brownian motion of a nanorod (length 71 nm, diameter 25 nm) dispersed in a water droplet. The method was also successfully applied in the time-resolved imaging of the electrophoretic deposition process [3] or the live cell imaging using plasmonic nanorods [2].

Abstract

We have developed tungsten doped VO_2-Au switchable material with needle-like morphology through hydrothermal synthesis and post growth thermal annealing method. Structural studies confirm the grown samples are mixture of various polymorphs of VO_2 (VO_2 (M), VO_2 (B) and VO_2 (R)) which is further supported by vibrational studies using Raman spectroscopy.

The metal-to-insulator (MIT) transition of VO_2 close to room temperature (~68°C) makes it a prominent candidate for various applications, such as, reflective/transmissive smart windows, photonic and optoelectronic switching devices, sensors and actuators design, energy storage and conversion, and more [1]. However, utilizing VO_2 for devices operating around room temperature is considerably challenging due to its high critical temperature. Research on lowering down its critical temperature and high differential reflection/transmission is required. Present work explores an effective way of manipulating structural, optical and thermochromic properties of tungsten (W) doped VO_2 in the presence of plasmonic gold.

Pristine VO_2 and W doped VO_2 (VO_2:W, at different weight percent (wt%) % of W: 1.5%. 3%, 4.5% and 6%) are prepared using hydrothermal synthesis (at 200°C ± 10 °C) and high temperature thermal annealing method (at 500°C ± 15 °C) in the presence of argon gas. Subsequently, VO_2:W and gold (Au) are mixed at different wt % (ratio of VO_2:W and Au), such as, 1:1 (sample A), 5:1 (sample B) and 10:1 (sample C). All these samples are thermally annealed at 300°C ± 15 °C.

Structural studies using X-ray diffraction (XRD) show doped samples contain three polymorphs of VO_2 (VO_2(B), VO_2(M) and VO_2(A)) (JCPDS card no. 01-082-0661, 00-009-0142, 01-081-2392 and 01-079-1655) (Figure-1). Also, dominance of VO_2 (B) is indicated in pristine VO_2 which decreases with increasing dopant concentration. Dominance of VO_2 (M) is evident too. Considering the peak at 2θ=25°, crystallite size for 1.5% W doped sample is larger than pristine VO_2, which surprisingly decreases with increasing W% (Table-1).

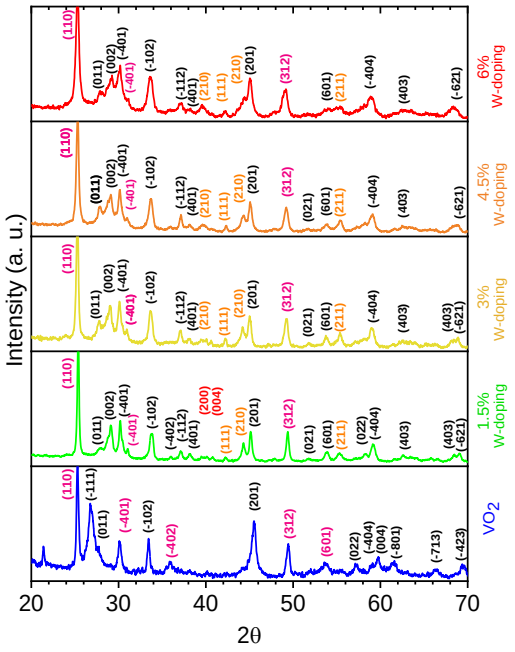

Fig. 1 XRD spectra of different W doping percentage (Black- VO_2(M), Pink- VO_2(B), Red- VO_2(A) and Orange- VO_2(A)).

Table. 1 Change in crystallite size with W doping percentage

Doping %	K	λ (nm)	θ (Radian)	β	D (nm)
Pure VO_2	0.94	0.154	12.65	0.27	29.97
1.5% W-VO_2	0.94	0.154	12.685	0.25	32.37
3% W-VO_2	0.94	0.154	12.635	0.31	26.11
4.5% W-VO_2	0.94	0.154	12.650	0.33	23.12
6% W-VO_2	0.94	0.154	12.645	0.46	18.39

Raman spectroscopic measurements show samples corresponds to polymorphic phases of VO_2 as observed from XRD measurements (Figure-2). XRD and Raman measurements on VO_2:W in the presence of gold show no change in characteristic peaks correspond to polymorphs of VO_2. These observations indicate the retainment of switching characteristics of VO_2 polymorphs intact. Needle-like structure (as observed from scanning electron microscope (SEM)) can be used for further investigation of MIT transition temperature (using differential scanning calorimetry (DSC)), resistive switching and optical/thermal switching characteristics for optoelectronic applications.

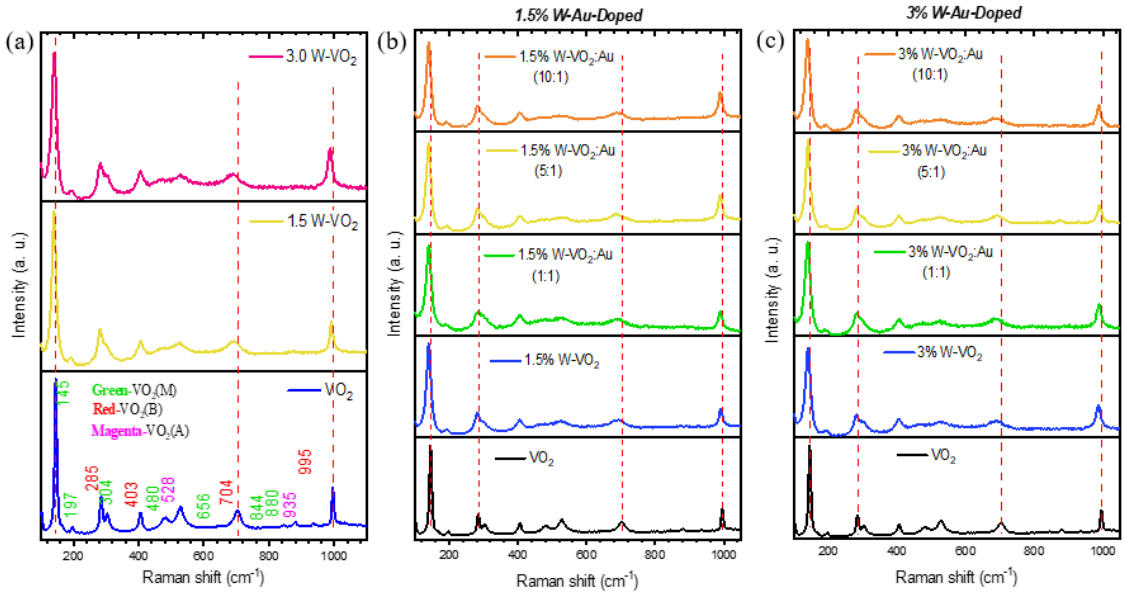

Fig. 2 Raman spectra of (a) pure VO_2 when compared with 1.5% and 3% W-doped VO_2 (VO_2:W), (b) 1.5% VO_2:W when compared with VO_2:W-Au, and (c) 1.5% VO_2:W when compared with VO_2:W-Au.

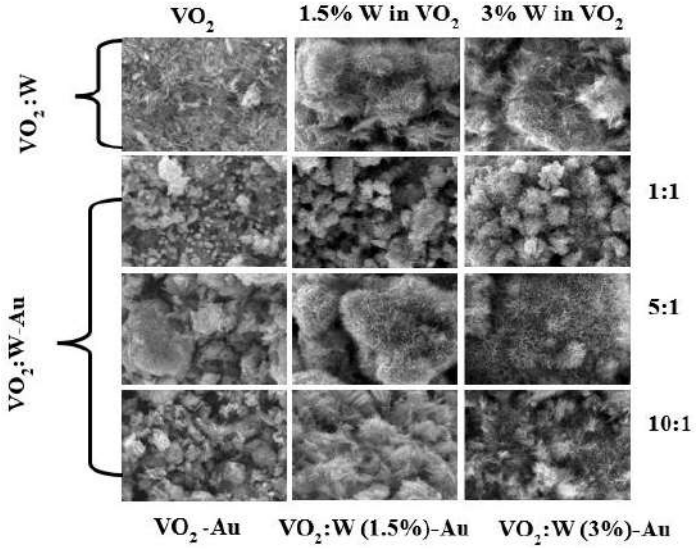

Fig. 3 SEM images of VO_2:W (top row) and VO_2:W-Au (second row: (1:1), third row: (5:1) and bottom row (10:1)). Scale bar is 2 μm for all the images.

Strong coupling of chiral light with chiral matter: a macroscopic study

Abstract: We studied the strong coupling of chiral light with chiral material by incorporating the Lorentz pole into macroscopic chirality parameter: dielectric permittivity, magnetic permeability, and chirality coefficient. Our study demonstrates significantly distinct behaviors between the material's enantiomers, offering a promising approach for their detection and selective differentiation.

The detection and selection of chiral organic molecules with different handedness are critical for numerous applications in pharmacology, biology, and chemistry. Due to their similar size and chemical structure, the most promising approach is to exploit subtle differences in their optical responses when interacting with an electromagnetic field. Consequently, enhancing the interaction between chiral light and chiral matter is essential for developing advanced techniques that enable handedness-selective optical detection of chiral molecules. One effective strategy to achieve this involves creating resonators that support photonic modes with non-zero electromagnetic handedness, allowing differential interaction with left- and right-handed chiral molecules [1,2]. Recent studies have investigated chiral polaritons—strong couplings between chiral light and individual chiral molecules at the microscopic scale [3]. However, when chiral molecules are introduced into resonator hotspots, their electric and magnetic transition dipole moments significantly influence the overall system. This effect becomes particularly pronounced at high molecular concentrations.

In this study, we investigate the interaction between a chiral medium and photonic modes within a resonator from a macroscopic perspective. Specifically, we examine a Fabry-Perot resonator featuring dielectric mirrors that preserve handedness. These mirrors are engineered using a combination of dielectric Bragg mirrors and a one-dimensional photonic crystal slab, creating a layer with high artificial anisotropy. They are optimized to achieve near-unity reflection while maintaining the handedness of light over a broad spectral range. This design enables the Fabry-Perot cavity to support photonic modes with high electromagnetic chirality for both handednesses. Notably, these modes become distinct when the rotational angle between the upper and lower mirrors deviates from integer multiples of π [4]. To describe the resonant medium inside the cavity, we introduced macroscopic parameters to model the chiral material. Rather than focusing on individual molecules, we represented the medium using effective properties: dielectric permittivity, magnetic permeability, and a chirality coefficient. The chirality coefficient, also known as the Pasteur parameter, quantifies the medium’s macroscopic chirality and establishes a coupling between the electric and magnetic fields in the constitutive relations. Materials with opposite signs of the Pasteur parameter correspond to media composed of enantiomers with opposite handedness.

Our results demonstrate that using a chiral medium with a constant macroscopic chirality parameter enables the separation of modes with different electromagnetic chirality, even when the rotational angle between the mirrors equals πn. Furthermore, introducing a resonant chiral medium—modeled by incorporating a Lorentz pole into its macroscopic parameters—leads to the emergence of chiral strong light-matter coupling. Furthermore, the mode

splitting near the resonant wavelength varies depending on the value of the chirality parameter.

A particularly intriguing regime occurs when the chirality coefficient satisfies the condition $|\chi|=\varepsilon^{1/2}/2$. In that case materials with opposite values of chirality coefficient would be in different light and matter coupling regimes. Under these circumstances, media with opposite chirality coefficients exhibit distinct light-matter coupling regimes. For instance, a medium with positive chirality may exhibit strong coupling between the chiral electromagnetic field and the medium, while a medium with negative chirality remains in a weak coupling regime. This behavior reverses for modes of the opposite handedness.

These findings offer exciting prospects for developing advanced methods to detect chiral molecules with different handedness, even in high-concentration conditions where molecular resonance significantly influences cavity modes.

Integrated Spectral Sensitivity as Physics-Based Figure of Merit for Spectral Transducers in Optical Sensing

F. L. McCluskey[1*], A. van Klinken[1], and A. Fiore[1]

[1]Eindhoven University of Technology, Netherlands
[*]corresponding author: f.l.mccluskey@tue.nl

Abstract:

We introduce Integrated Spectral Sensitivity, a novel figure of merit for optical sensors, derived from the Cramér–Rao lower bound. This metric quantifies transducer performance across various readout methods, improving sensor design. We apply it to two transducer types, offering insights into optimizing spectral sensing systems for enhanced precision.

Optical sensors which use spectral transducers play a very important role in mapping a physical, chemical or biological phenomena or change in environment. Traditional figures of merit which aim to aim estimate the performance of these transducers are often independent of the readout system used in combination with these transducers. This creates practical challenges since different transducers achieve optimal performance with varying types of readout systems. A new physics-based figure of merit, the Integrated Spectral Sensitivity, is introduced to take into account both parts of the system and is used as a framework to enable a more appropriate transducer design and optimisation.

The sensing system in the paper consists of a spectral transducer that converts changes in the target measurand into spectral shifts, which are detected using a readout system. The study analyses different transducer types and readout methods, comparing their performance using the newly introduced Integrated Spectral Sensitivity metric. This Integrated Spectral Sensitivity is derived from the already known Cramér Rao lower bound, which sets a limit on measurement precision of sensing systems based on spectral transduction, but has no assumption on the data analysis method. This simple FoM is applied to two different types of transducer responses, namely a single peak spectrum (ie. a photonic crystal resonance) and a multipeaked response (achieved with a Fabry-Pérot).

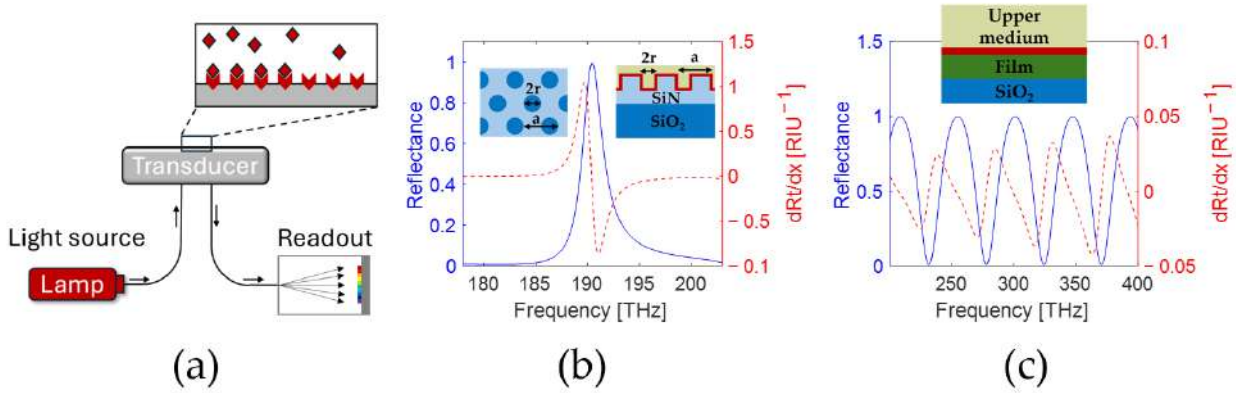

Figure 1. (a) Schematic representation of the sensing system. Reflectance spectrum (blue) of (b) a photonic crystal (insets) and (c) a Si/SiO_2 multilayer (inset) and its derivative with respect to the measurand (red).

From the analytical expression of the CRLB, we can derive a more general FoM based on certain assumptions, which allows us to implement the type of readout used. It is defined as an integral of the squared sum of the reflectance derivative times the transmission functions of the readout channels, thus incorporating both parts of the sensing system. The mathematical formulation of Integrated Spectral Sensitivity is given by:

$$S_{\int ¿} = \frac{1}{\Delta \nu} \sqrt{\sum_{i=1}^{n} \left(\int_{\nu_{min}}^{\nu_{max}} \frac{\partial R_t(\nu)}{\partial x} T_i(\nu) d\nu \right)^2} \quad ¿ \quad (1)$$

Where R_t represents the reflectance function of the transducer, derived as a function of x which is the parameter of interest, T_i is the response functions of the readout channels chosen and $\Delta \nu$ is the spectral range.

This now more general FoM is then used as a comparison of performance for both types of transducers, with more specific assumptions made on the characteristics of the readout. This introduces the concepts of spectrometric and ideal readouts, as two different examples of approaches to assess performance. The spectrometric readout is a description of different closely spaced frequency bands in space or in time, which commonly represents an array of filters or photodetectors. The ideal readout assumes that all available spectral information is optimally used without being constrained by practical limitations such as detector noise or resolution. This gives the maximum achievable precision in determining the measurand based on the transducer's spectral response, and not on the data analysis method.

The application of $S_{\int ¿¿}$ to single-resonance transducers, such as photonic crystal resonators, reveals that optimal performance is achieved when the transducer linewidth matches the readout system resolution, which contradicts the common assumption that narrower linewidths always improve sensitivity. The framework is also applied to multi-resonance transducers like Fabry-Pérot cavities, which demonstrates a decrease in performance compared to photonic crystals.

From these two cases of readout methods, simpler expressions of $S_{\int ¿¿}$ can be derived depending on the method used. Thanks to these new expressions, we can analyse the impact of the design parameters of the transducers on its overall performance and evaluate the performance of different transducer types in a specific label-free biosensing application, demonstrating that the proposed method offers novel insights and highlights new possibilities for transducer design.

Abstract: We report hierarchically porous Au nanostructures fabricated via nanotransfer printing to achieve sub-10 nm gaps and ultradense hotspots on flexible substrates. These structures showed a 9.6-fold SERS enhancement over flat Au nanowires using 4-mercaptobenzoic acid. The results demonstrate the significance of structural design in plasmonic systems [1,2].

1. Introduction

Surface-Enhanced Raman Spectroscopy (SERS) enhances molecular signals through localized surface plasmon resonances, where sub-10 nm gaps generating dense hotspots that greatly improve sensitivity [3].

2. Fabrication and SERS Performance

Figure 1 shows the morphology of Au NWs and P-Au NWs. Figure 2 illustrates the stacking process and SERS results. The porous structure forms nanogaps with an average spacing of 10.22 nm. Single-layer P-Au NWs exhibited 9.6-fold higher SERS intensity than Au NWs using 4-mercaptobenzoic acid, with a markedly steeper increase observed for P-Au NWs.

3. Conclusion

The integration of porous nanostructures and nanotransfer printing increases contact areas, promoting strong plasmonic coupling at cross-junctions, and enables high-performance SERS substrates on flexible platforms. Our P-Au NWs with ultradense nanogaps demonstrate enhanced signal amplification and strong potential for applications in flexible sensing, catalysis, and photonics.

Abstract: We introduce and experimentally demonstrate, for the first time, metasurface-driven dynamic focusing arrays designed to accurately transport multiple microparticles along customized routes. By exploiting interference between polarization-multiplexed holographic images, our method enables simultaneous, precise movement of optically trapped microparticles.

Here, we propose metasurface-enabled dynamic focusing arrays capable of precisely transporting multiple microparticles along arbitrary trajectories. Optical forces have been widely investigated for particle manipulation in various fields, including nanophotonics, biomedical sciences, laser optics, and microfluidics, enabling functionalities such as optical sorting, tweezing, and conveying. Although spatial light modulators (SLMs) have previously enabled dynamic optical field control to transport particles along arbitrary pathways by applying phase gradients, precise particle manipulation through an optical trap array remains challenging [1]. Prior metasurface studies aiming to form optical trap arrays have either been limited to static focusing arrays or discrete holographic field state changes without demonstrating experimental trapping or dynamic particle transport [2, 3, 4].

Our work experimentally demonstrates dynamic, precise control of multiple optical traps generated from polarization-multiplexed metasurfaces. We achieve continuous and precise movement of optical focusing spots along user-defined trajectories by overlapping and dynamically interfering two polarization-dependent states. This capability allows multiple microparticles to be simultaneously trapped and conveyed with high precision over substantial distances, overcoming previous limitations. Our experimental validation confirms the reliable and precise transport of microparticles along trajectories, demonstrating significant potential for applications in microfluidic channels, particle sorting systems, and biomedical devices.

This research advances optical particle manipulation by integrating the unique advantages of metasurface-based focusing arrays with dynamic optical field control, enabling sophisticated micro-manipulation tasks previously unattainable with conventional SLM-based or static metasurface approaches.

Spectrally tailored surface-enhanced Raman spectroscopy (SERS) with polarization-sensitive metasurface

J. Lövgren[1] and A. Xomalis[1*]

[1] Nanoscale Spectroscopies Group, Department of Electronic Systems,
Norwegian University of Science and Technology, Trondheim, Norway

Abstract: While SERS is a powerful sensing technique with single-molecule resolution, plasmonic SERS antenna arrays lack precise spectral control. Here, we present a metasurface with polarization-dependent optical resonances designed to overlap with individual vibrational modes of a molecule. Spectrally tailored SERS has applications in biosensing, molecular optomechanics and plasmon-based nano-optics.

I. INTRODUCTION

SERS utilizes plasmonic resonances to enhance the intrinsically low Raman scattering of molecules, providing a versatile spectroscopy method [1]. However, the optical linewidth of typical plasmonic array resonances is far greater than the vibrational resonances (Raman modes) of molecules, prohibiting plasmon-enhanced sideband-resolved spectroscopy. Recent configurations for spectrally tailored SERS comprise either photonic crystal cavity-antenna structures [2] or hybrids of antennas coupled to Fabry-Perot microcavities [3]. While these approaches offer tunable spectrally tailored Raman mode enhancements, they demand advanced nanofabrication and layering of nanophotonic structures, limiting widespread use. Here we demonstrate an approach for spectrally tailored molecular SERS based on polarization dependent resonances of a single-layer metasurface.

II. STRUCTURE DESIGN AND FABRICATION

A 100 nm thick Au film was deposited on a Si substrate by E-beam evaporation (K.J. Lesker, PVD 200). Quadratic holes in a rectangular lattice were patterned into the Au film using focused ion beam milling (FIB, FEI Helios G4 UX). Two samples with rectangular hole arrays are presented here, both with holes of dimensions 250x250 nm^2 and periodicity 750 nm in the x direction (see Figure 1a for definition of x and y directions). The periodicity in the y direction of the two samples is different: 780 nm and 800 nm, respectively.

III. OPTICAL MEASUREMENTS AND SIMULATION

White light reflectance nanoscale measurements were performed in an in-house built setup capable of both broadband reflectance measurements and Raman spectroscopy. Each metasurface is shown to have different resonance features when illuminated with light polarized along the x and y directions (Figure 1b, c), with the resonance being redshifted for larger periodicities. Comparing the two demonstrated metasurfaces, we see that the resonance emerging for y polarized light can be shifted independently of the resonance for x polarized light. The resonance of the metasurface can be shifted to the spectral position of selected Raman peaks of biphenyl-4-thiol (BPT) on demand (Figure 1d). The experimental results are supported by finite-difference time-domain (FDTD Ansys Lumerical) simulations (dashed lines, Figure 1b, c).

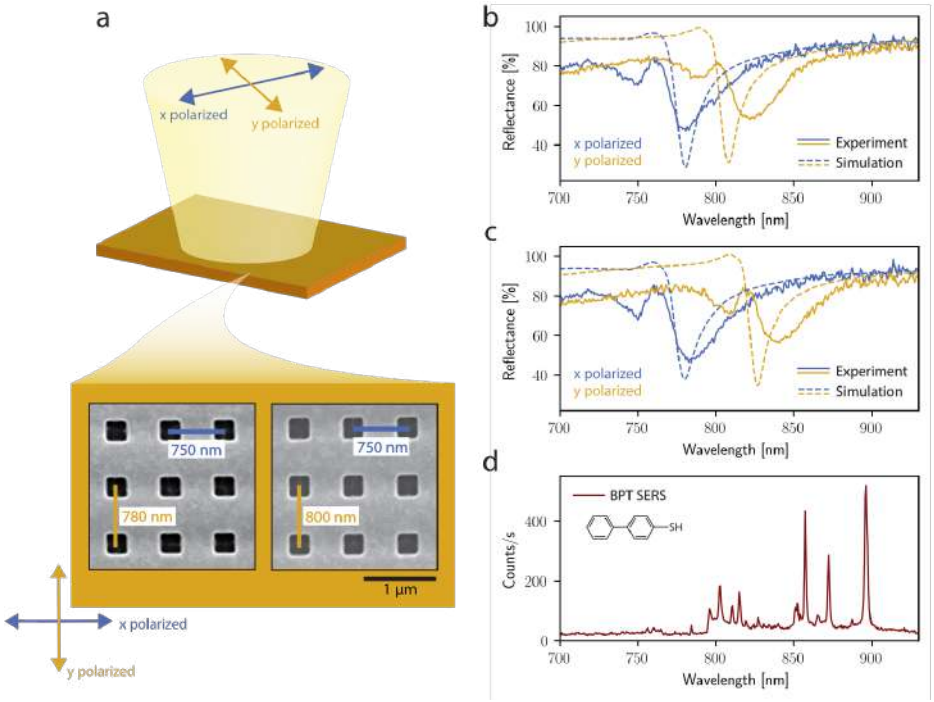

Figure 1. (a) Schematic of excitation of the metasurface by x (blue) and y (yellow) polarized light and SEM images of the two evaluated metasurfaces. **(b,c)** Broadband reflectance measurements (solid) and simulations (dashed) of metasurfaces with periodicity 780 nm (b) and 800 nm (c) in the y direction, using x (blue) and y (yellow) polarized light. Both metasurfaces have a periodicity of 750 nm in the x direction. **(d)** Standard surface-enhanced Raman spectroscopy (SERS) of biphenyl-4-thiol (BPT), using a 785 nm laser for excitation.

IV. CONCLUSION

Utilizing a polarization sensitive metasurface, we show how to perform spectrally tailored SERS otherwise challenging with conventional plasmonic nanoconstructs. Here we design, fabricate and experimentally characterize such metasurfaces, demonstrating resonances promising for spectrally tailored and sideband-resolved SERS. Our results are in good quantitative agreement with full-wave simulations, indicating the quality of the fabricated metasurfaces.

Strong light-matter interaction of Chlorophyll-a molecules on plasmonic arrays

Yadav Rohit Umashankar, Parinda Vasa*

Department of Physics, Indian Institute of Technology Bombay, Mumbai, India

Abstract

Here, we demonstrate strong exciton-photon coupling between photosynthetic light-harvesting complexes i.e., Chlorophyll-a molecules, and a surface lattice resonance of periodically patterned Silver nanodisk arrays. The high-quality factor and delocalized field modes of lattice resonances enable efficient studies of optical responses and energy transfer in strongly coupled photosynthetic pigments.

1. Introduction

Strong light-matter coupling provides a sophisticated and effective approach to altering the energy landscapes of excited states in organic semiconductors[1]–[3]. This interaction allows for the tuning of their chemical and photophysical properties without requiring any chemical modifications to the material itself. Noble metal nanoparticles have been extensively studied for their remarkable optical properties, particularly their ability to support localized surface plasmon resonances. These resonances exhibit strong optical field confinement and are highly sensitive to changes in the surrounding environment, making them valuable for various applications[4]–[6]. The disadvantage of a single nanoparticle resonance in studying strong interaction is, it shows relatively broad and localized resonance which requires the organic molecules to be close to nanoparticles and hence it limits the coupling strength as well as signal strength from coupled molecules. However, when these nanoparticles with certain shapes and sizes are arranged periodically, they can support lattice resonances with much higher quality factors and delocalization of the electric field, known as surface lattice resonances (SLR)[7]. As these lattice resonances are more distributed between the nanostructures, it allows a greater number of organic molecules to interact and couple to these open cavity modes. Chlorophyll-a is a key photosynthetic pigment located in the light-harvesting antenna of plants, where it plays an essential role in absorbing light energy and efficiently transferring excitation energy to the reaction center.[8]. Thus, Chlorophyll-a molecules offer significant potential for artificial photosynthesis research, serving as a versatile biomolecular platform to explore optical responses, energy transfer mechanisms, and their applications in photovoltaics, light-harvesting systems, and photosensors.[9]–[11]. Here, we showed the strong radiative interaction between molecular excitations of chlorophyll-a molecules and delocalized optical fields of silver nanodisk arrays. Our observations indicate that strong coupling enhances the absorption of chlorophyll-a and introduces tunability across a broad spectral range, and more importantly the coupled systems made of open plasmonic cavities and organic semiconductors are more suitable for device applications and further study.

2. Materials and Experimental Method

The photosynthetic chlorophyll-a material, with 85% purity extracted from spinach, was purchased from Sigma Aldrich. The stock solution of chlorophyll-a was prepared by dissolving 1 mg in 1 mL of Ethanol. The experimental solution was prepared by mixing 70 µL of the stock solution with 20 µL of a 15 mg/mL PVA solution in deionized water, which served as the matrix. The reflectance spectrum obtained from the 50 nm silver film coated with the prepared solution at 1500 rpm reveals distinct absorption bands characteristic of chlorophyll-a molecules. The absorbance spectrum had been fitted with the Lorentz dispersion model to obtain the absorption peaks. It shows the strongest peak at 660 nm $Q_y(0\rightarrow0)$ corresponding to the pure electronic transition from the ground vibronic state to the ground vibronic state of the first excited electronic state. Other vibronic transitions are shown at 618 nm $Q_y(0\rightarrow1)$ and 572 nm $Q_y(0\rightarrow2)$. Figure 1 shows the fitted absorbance data, showing the corresponding absorption peaks.

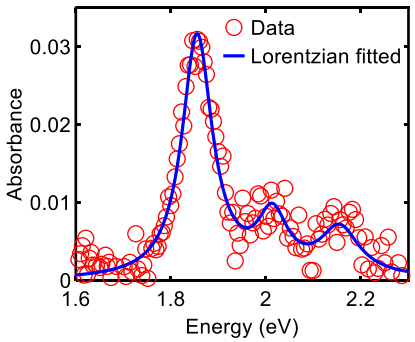

Figure 1: Absorption spectrum of Chlorophyll-a fitted with Lorentz dispersion model.

Nanodisk arrays were fabricated through electron beam lithography using Raith 150 Two. Rf sputtering of 15 nm ITO was done on the fused silica substrates to reduce the charging effect because of e-beam exposure during lithography. Bilayer resists Polymethyl Methacrylate (PMMA) of 495K A4% and 950K A2% have been used as e-beam resist. The size of the arrays was kept at 25 µm x 25 µm. The nanodisk diameter (120 nm–160 nm) and period (280 nm–410 nm) were adjusted to maintain a constant filling factor, which is

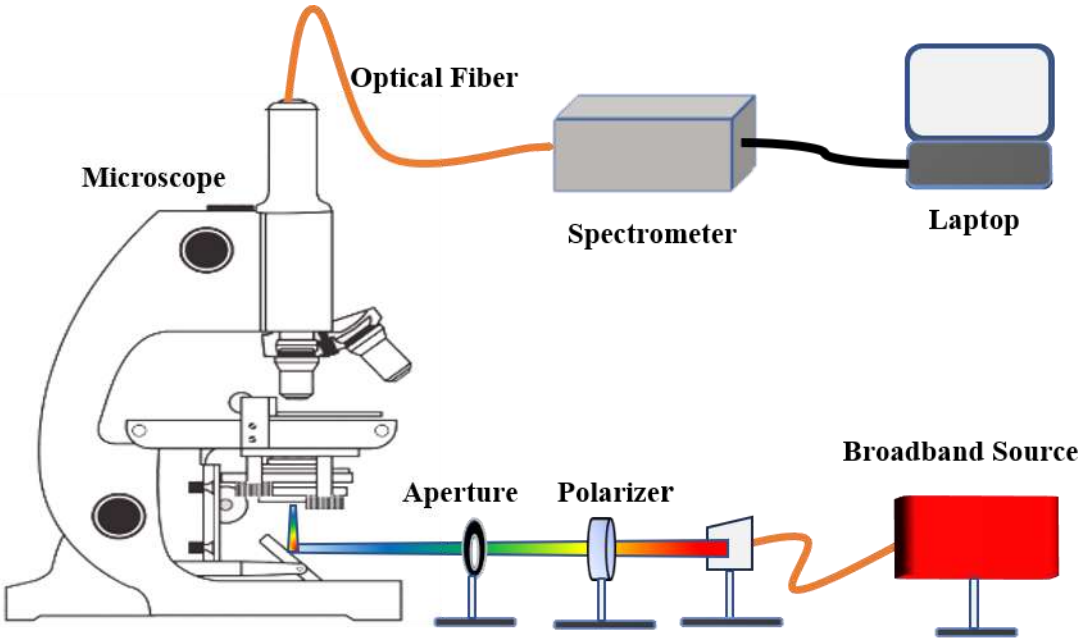

Figure 2: Schematic diagram of the experimental setup

ratio of nanodisk area to unit cell area of 13% across all arrays. Metallization of 70 nm silver has been done through an e-beam evaporator. Figure 3 shows the scanning electron microscope (SEM) image of the fabricated nanostructures.

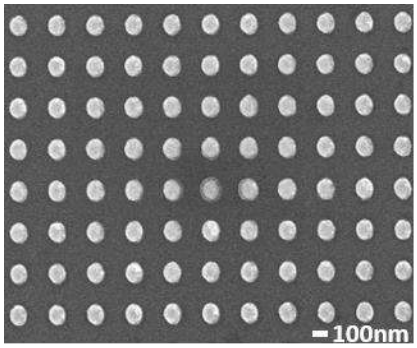

Figure 3: Scanning electron microscope (SEM) image of the fabricated silver nanodisk.

Optical transmission measurements were performed on the nanodisk arrays both before and after coating with chlorophyll-a. The schematic diagram of the experimental setup is presented in Figure 2. It comprises an Energetic-99X LDLS broadband light source, a linear polarizer, an aperture for beam shaping, a mirror, a microscope-based sample mounting and collection system, and a spectrometer connected to a laptop for data acquisition. The collimated light from the source is first passed through the polarizer to control the polarization state of the incident beam. The aperture ensures that only the central portion of the beam is used, improving spatial coherence. The beam is then directed by the mirror towards the microscope, which focuses the light onto the sample placed on a mechanical stage with micrometer-resolution movement. The transmitted light is collected through a high numerical aperture objective and guided via optical fiber to the spectrometer, where the transmission spectrum is recorded. This setup enables precise, polarization-resolved optical characterization of the nanostructures.

3. Results and Discussion

3.1. Measuring the dispersion relation

Transmission measurements performed on the nanodisk arrays, prior to chlorophyll-a coating, reveal that the array resonance energies shift from 1.7 eV to 2.1 eV as the array period increases from 280 nm to 410 nm. Since the filling factor is maintained at a constant 13%, the nanodisk diameter scales proportionally with the period. This tunability highlights the strong dependence of the plasmonic resonance on the lattice geometry. Figure 4 shows the transmittance spectrum of a few arrays.

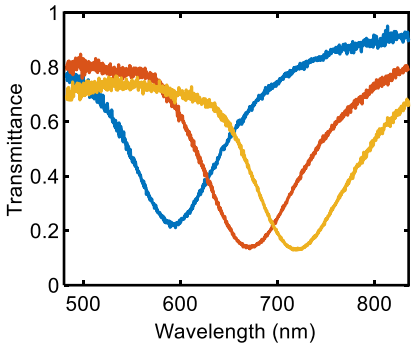

Figure 4: Transmittance spectrum of arrays having diameters and periods as d=125 nm p=300 nm (blue curve), d=145 nm p=355 nm (brown curve), d=165 nm p=405 nm (yellow curve).

To obtain the dispersion relation of these array resonances, the transmittance spectrum was fitted with the Fano line shape function[12]–[14]. The general expression for the line-shape function is given as:

$$R(w,\phi) = \sum_{i=1}^{m} \left| a_i + \frac{b_i * e^{i*\phi_i} * \Gamma_{radi}}{w - w_{0i} + i * \Gamma_{radi}} \right|^2 \qquad (1)$$

The array resonances obtained through fitting the transmittance spectrum were employed in getting the dispersion relation. Figure 5a shows the Fano-fitted transmittance spectrum of an array having a diameter of 125 nm and a period of 300 nm. Whereas, Figure 5b shows the obtained dispersion relation showing the variation of resonance energies of different arrays as a function of the array period.

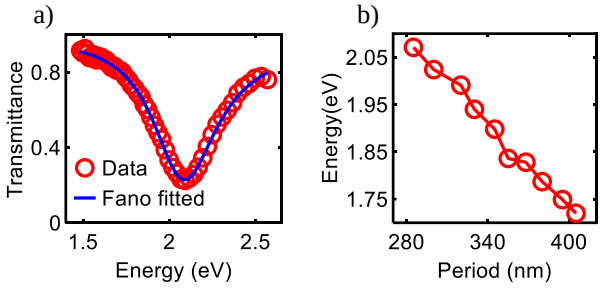

Figure 5: (a) Fano-fitted transmittance spectrum of a nanodisk array with 125 nm diameter and 300 nm period, having a fitting error of 2–3 meV. (b) Extracted dispersion relation illustrating the variation of resonance energy with array periodicity.

Transmittance spectra of the strongly coupled system were recorded after coating the sample with the chlorophyll-a solution. The dispersion relation of the coupled system was extracted by fitting the transmittance spectra with a Fano lineshape function, revealing the characteristic anti-crossing behavior at the excitonic resonance. Figure 6a shows the transmittance spectrum of the coupled system fitted with the Fano lineshape, while Figure 6b presents the extracted dispersion relation, obtained using the fitted resonance positions of the upper and lower polaritonic branches.

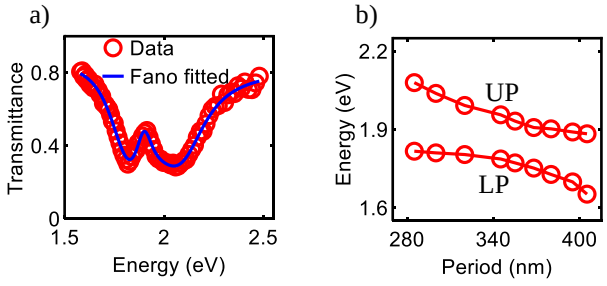

Figure 6: a) Fano-fitted transmittance spectrum of the nanodisk array with 125 nm diameter and 300 nm period, forming a strongly coupled system. (b) Dispersion relation showing the upper (UP) and lower (LP) polaritonic branches.

To model the observed anti-crossing behavior, the extracted dispersion relation was fitted using a coupled oscillator framework. This quantitatively describes the light-matter interaction.

3.2. Modeling the dispersion relation

When molecular aggregates undergo strong coupling with surface lattice resonances (SLR), they form hybrid polaritonic states that exhibit ultrafast decay dynamics on the timescale of a few femtoseconds. The strength of the strong interaction or Rabi splitting energy between the hybrid states is given as[15]

$$\hbar\Omega_R = 2 * d * \sqrt{\frac{\hbar * w_c * N}{2 * \varepsilon_0 * V}} \qquad (2)$$

where d is the dipole moment of the oscillator, V is the mode volume, and N is the number of molecules or oscillators. The linear optical behavior of this hybrid structure can be effectively described using a coupled harmonic oscillator model, where the exciton and surface lattice resonances are represented as complex Lorentzian oscillators[16]. According to the model, the UP and LP hybrid mode frequencies are given by

$$w_{UP/LP} = \frac{w_x + w_{spp}}{2} \pm 0.5 * \sqrt{(w_x - w_{spp})^2 + 4 * \Omega_R^2} \qquad (3)$$

Where W_x and W_{SPP} represent the complex frequency of the exciton and SLR. Figure 7a shows the coupled oscillator model fitting of the extracted dispersion relation, yielding a Rabi splitting energy of approximately 180 ± 6 meV. Figure 7b presents the transmittance spectra of all nanodisk arrays, illustrating the evolution of the upper and lower polaritonic branches and clearly demonstrating the strong coupling behavior.

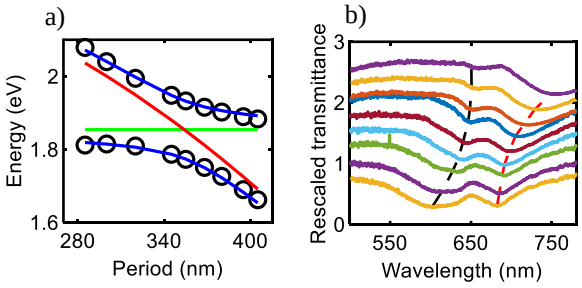

Figure 7: a) Fitted dispersion curve using the coupled oscillator model (blue line), showing a Rabi splitting energy of approximately **180 ± 6 meV**. The surface lattice resonance (SLR) dispersion is shown in red, and the excitonic absorption is represented by the green curve. b) Transmittance spectrum of different arrays in coupled form showing upper and lower polaritonic dips.

These results confirm the realization of strong coupling between the excitonic transition of chlorophyll-*a* molecules and the surface lattice resonances of silver nanodisk arrays, as evidenced by a clear anti-crossing behavior in the dispersion and a Rabi splitting energy of approximately 180 ± 6 meV. Such strong light-matter interaction offers a unique

platform to probe and manipulate the optical response of photosynthetic pigments under hybridized polaritonic states.

4. Conclusion

In summary, we have demonstrated strong coupling between chlorophyll-*a* molecules and the surface lattice resonances of silver nanodisk arrays, evidenced by a pronounced anti-crossing in the dispersion relation and a Rabi splitting of approximately 180 ± 6 meV. The coupled oscillator model effectively captures the hybridization behavior, indicating the formation of exciton–plasmon polaritonic states. This hybrid system provides a promising route to investigate the fundamental optical properties of photosynthetic pigments under modified photonic environments. By placing chlorophyll-*a* molecules in the strong coupling regime, we gain new opportunities to explore energy level modifications, polaritonic mode tuning, and potential coherence effects within biomolecular systems.

Such interaction-driven modifications can offer insights into how light-matter coupling can influence or enhance natural energy transfer pathways. Furthermore, the ability to manipulate excitonic states using nanophotonic structures may prove useful in designing artificial photosynthetic systems, sensitive bio-sensors, and low-threshold polaritonic devices. Overall, this work highlights the potential of plasmonic architectures in advancing our understanding and control of bio-excitonic systems at the nanoscale.

Abstract: Using semiconductor-metal patch cavities, we demonstrate ultrastrong coupling at room temperature between conduction sub-band states in $Si_{(1-x)}Ge_x$ heterostructures and THz cavity photons. At the resonant frequency of 3.1 THz, we observe an anticrossing splitting of 1.4 THz, corresponding to a coupling ratio in excess of 0.2.

Control and manipulation of quantum states by light are increasingly important for both fundamental research and applications [1]. This can be achieved, among other techniques, through the strong coupling between light and intersubband transitions (ISBT) in semiconductor quantum wells, typically observed at THz frequencies in integrated lithographic optical cavities [2,3]. Here, we explore the possibility of achieving ultrastrong coupling at room temperature between conduction sub-band states in $Si_{1-x}Ge_x$ heterostructures and THz cavity photons fabricated with a potentially silicon-CMOS-compliant process. Our system is based on $Si_{1-x}Ge_x$ parabolic quantum wells (PQW) [4] with a transition at $\omega_0 = 3.1$ THz embedded in THz patch-antenna microcavities array resonating between 2 and 5 THz depending on the antenna length. We realized a stack of 25 identical $Si_{1-x}Ge_x$ QWs grown by chemical vapor deposition on a Si wafer [6]. We then fabricated the cavities acting as square patch antennas with a highly doped semiconductor ground plane and etched sidewalls to improve the field confinement inside the cavity. In this first demonstration, we achieved anti-crossing at 3.1 THz with spectroscopically measured Rabi frequency $\Omega_R \simeq 0.7$ THz ($\Omega_R/\omega_0 \simeq 0.2$, i.e. ultrastrong coupling). The present group-IV semiconductor material platform can be extended to the 5−12 THz range, where these semiconductors are transparent, as opposed to the III−V compound semiconductors plagued by strong THz optical phonon absorption. Moreover, the intersubband transition in parabolic quantum wells hosted by the nonpolar $Si_{1-x}Ge_x$ crystal lattice is robust against carrier density and temperature variations, making the strength of the coupling only weakly temperature-dependent from 10 to 300 K. In Fig. 1 are visible the reflection spectra measured on two samples having different cavities array periodicity P filled with identical doped PQWs compared to an undoped sample (in grey). The spectra show the results for different cavity dimensions from 7 to 14 um. The present understanding [5] of the strong coupling

conditions in a group-IV semiconductor material may be exploited in the future to realize optoelectronics devices operating in the THz frequency range at room temperature in a fully CMOS compatible platform.

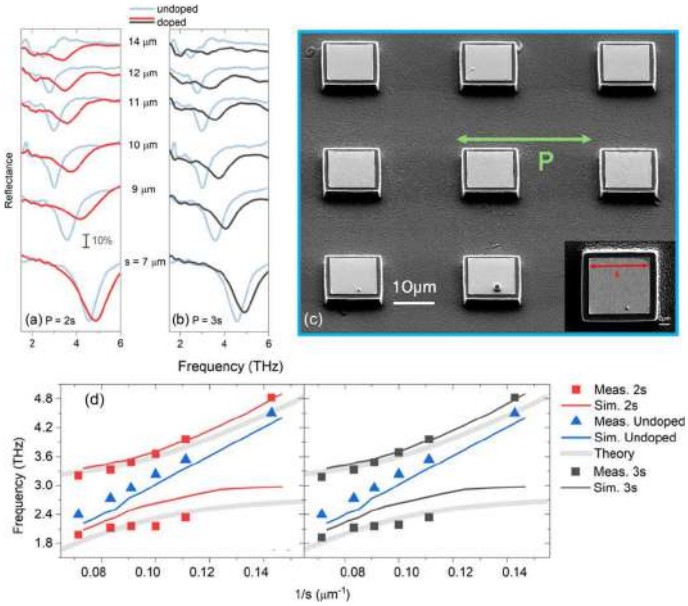

Figure1: (a) Reflection spectra of the cavity arrays with P = 2s (red curves); the gray curves are the reflection spectra of identical cavities fabricated on a sample with undoped PWQs. (b) Reflection spectra of cavities filled with identical doped PQWs but P = 3s. (c) a portion of an array of patch cavities with a unit cell dimension P = 3s; inset: detail of an individual patch cavity with s = 11 μm, where s is the width of the metallic patch.(d): Polariton dispersion as determined by a bi-Lorentzian fitting of the data in (a, b), respectively.

Abstract: We demonstrate time-resolved photoluminescence (tr-PL) mapping with sub-diffraction resolution (~150 nm) in aperture-type scanning near-field optical microscopy (a-SNOM) of $CsPbBr_3$ nanocrystals. This method allows to correlate structural and optoelectronic properties, revealing the impact of nanoscale heterogeneities on recombination dynamic and enhancing nanoscale characterization for optoelectronic applications.

Lead halide perovskites (LHPs), particularly $CsPbBr_3$ nanocrystals, have emerged as highly promising materials for optoelectronic applications [1], exhibiting exceptional optoelectronic properties, such as high photoluminescence quantum yield [2], long non-radiative recombination lifetimes [3]. However, a detailed understanding of these properties necessitates advanced characterization techniques capable of resolving spatial and temporal dynamics at the nanoscale [4].

Traditional far-field photoluminescence (PL) and tr-PL spectroscopy methods provide insights into charge-carrier dynamics and recombination mechanisms but are diffraction-limited. Consequently, they fail to resolve nanoscale heterogeneities that significantly impact the optoelectronic behavior of LHPs. This limitation underscores the necessity of a non-destructive, high-resolution optical technique for nanoscale characterization.

To address this challenge, we present an approach that integrates aperture-type scanning near-field optical microscopy (a-SNOM) with tr-PL to achieve sub-diffraction-limited resolution in the study of carrier recombination dynamics in $CsPbBr_3$ nanocrystals. Our experimental setup enables pixel-by-pixel correlation of structural topography, PL intensity, and tr-PL decay dynamics within a single scan, providing a comprehensive nanoscale characterization framework.

Using this technique, we demonstrate tr-PL mapping of $CsPbBr_3$ nanocrystals with a spatial resolution of ~150 nm. This multimodal approach allows direct visualization of charge-carrier recombination dynamics, revealing significant spatial variations in lifetime distributions, spectral shifts, and carrier diffusion. By directly correlating these findings with structural features, we gain critical insights into morphology-dependent optoelectronic behavior.

This study establishes near-field excited tr-PL as a powerful tool for nanoscale characterization of perovskites. By enabling simultaneous nanoscale mapping of topography, PL, and tr-PL dynamics, this method provides essential insights into local recombination mechanisms, paving the way for the optimization of perovskite-based devices. By advancing nanoscale characterization capabilities, our approach contributes to the broader goal of developing high-performance perovskite-based optoelectronic technologies.

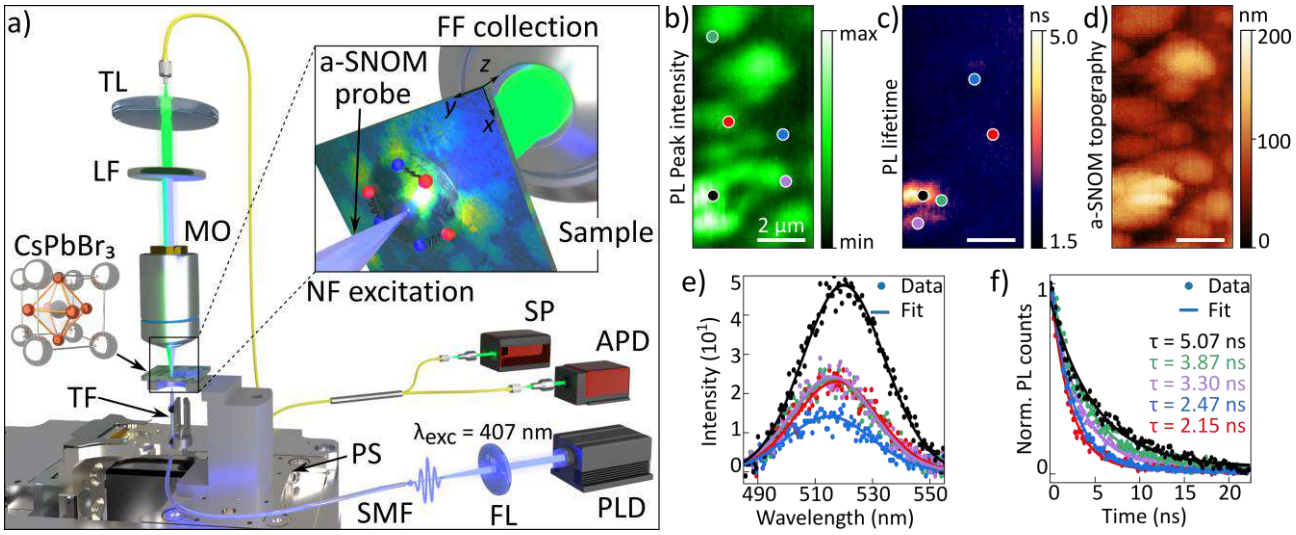

Figure 1: (a) Schematic of the experimental setup, integrating a pulsed laser diode (PLD), single-mode optical fiber (SMF), piezo stage (PS), tuning fork (TF) with an a-SNOM probe, 50× magnifying objective (MO), longpass filter (LF), tube lens (TL), avalanche photodiode (APD), and spectrograph (SP). The inset illustrates near-field (NF) excitation of photoluminescence (PL) in $CsPbBr_3$ nanocrystals. (b) NF excited PL intensity map fitted using a Gaussian function. Abstract: We present a sub-diffraction limit imaging approach using the Photonic Nanojet (PNJ) effect in tapered fibers. By analyzing the PNJ generated by upright dielectric cylinders, we achieve extended working distances without compromising resolution. This label-free method enables non-invasive nanoscale imaging, offering new possibilities for biological and material science applications.

The resolution limit of conventional optical imaging techniques, imposed by the diffraction of light, restricts the ability to observe nanoscale structures with high precision. This limitation presents significant challenges in understanding biological systems at the nanoscale, which is crucial for gaining insights into disease mechanisms and cellular processes. As a result, there is a growing need for advanced imaging techniques that go beyond the diffraction limit of traditional microscopy [1]. To address this, we utilize the Photonic Nanojet (PNJ) effect, which generates high-intensity, narrow light beams through dielectric structures under plane wave illumination [2].

We demonstrate the resolution of sub-diffraction limit grid lines using a tapered fiber, showcasing its capability in imaging nanoscale structures. Further, we explore the PNJ characteristics by illuminating upright dielectric cylinders with varying diameters (8 to 16 microns). Through experimental imaging and computational simulations, we analyze the full width at half maximum (FWHM) and working distance of the generated PNJ. Our findings indicate that while the FWHM remains relatively constant across different cylinder diameters, the working distance increases with larger diameters. This extended working distance enhances imaging versatility, particularly for applications requiring non-invasive techniques.

By optimizing the fiber diameter to balance resolution and working distance, our approach offers a label-free, sub-diffraction limit imaging solution. This method is particularly advantageous for imaging specimens sensitive to damage from electron microscopy or high-power imaging systems, opening avenues for safer and more effective nanoscale imaging in biological and material sciences.

The research reported in the manuscript was funded by Israel Science Foundation (ISF no. 2598/20).

Randomness in self-assembled photonic crystals

Duanduan Wan[1]

1 School of Physics and Technology, Wuhan University, Wuhan 430072, China

*corresponding author: ddwan@whu.edu.cn

Abstract: Randomness arising from thermal noise is almost inevitable in self-assembled colloidal crystals and is generally believed to be detrimental to photonic band gaps (PBGs). In this talk, I will present a counterintuitive example in which randomness actually enhances PBGs and discuss its effects on the width of PBGs.

Unlike top-down design, self-assembly, as a bottom-up method, offers advantages such as low cost, low energy consumption, and the ability to produce crystals over large areas. However, randomness arising from thermal noise is almost inevitable in self-assembled colloidal crystals. In this talk, we will present a counterintuitive example where randomness actually benefits photonic band gaps (PBGs) and explore the effects of particle randomness on the width of PBGs. Additionally, we will discuss the realization of chiral photonic crystals using self-assembly approaches.

Abstract: PCSEL lasers utilize a photonic crystal layer to scatter the light in the vertical direction. However, the practical etching limitations result in hole scatterers not having an ideal cylindrical shape. Using a 3D numerical method the paper investigates the impact of realistic hole shapes on PCSEL characteristics and performance.

Photonic Crystal Surface Emitting Lasers (PCSELs) are a relatively new type of surface emitting lasers that incorporate a photonic crystal layer that uses in-plane scattering to enhance optical feedback and scatters the light vertically. PCSELs that lase with a small divergence angle and CW output power of 50 W have been reported [1]. The photonic crystal pitch, size and shape of the air holes need to be engineered to optimise the Q-factor, maximise the threshold difference between the lasing mode and higher order modes and to control the far field emission pattern. In order to do this accurately full three-dimensional (3D) nature of the PCSEL unit cell needs to be accounted for and combined with the realistic model of the laser gain.

In this paper we extend the analysis of the PCSELs by investigating how the true shape of the etched holes affects the lasing spectrum of the PCSEL. Fabrication limitations mean that the vertical shape of the etched holes is not of ideal cylindrical shape and that the etching depth depends on the overall diameter of the hole, i.e. smaller holes will be etched with smaller depths than larger holes. An example of double lattice 3D PC unit cell with ideal cylindrical profile that is assumed in the theoretical analysis is shown in Fig.1a). SEM image of the fabricated sample is shown in Fig.1b) where it can be seen that the shapes of the holes are not cylindrical but of tapered design and rounded at both ends.

a) b)

Figure 1. Detail of the photonic crystal unit cell with: a) ideal cylindrical holes, b) SEM image of the fabricated photonic crystal.

PCSELs are commonly modelled using Effective Index type methods that eliminate the vertical epitaxy by approximating the 3D structure with an equivalent two-dimensional (2D) one and thus are not able to accurately characterise 3D features of PCSEL geometry. Full 3D analysis can be done using Finite Difference Time Domain (FDTD) method (FDTD) and Transmission Line Modelling (TLM) method [2]. Time-domain electromagnetic methods that deploy unstructured meshes that can tackle increasingly complex, multi-scale and multi-physics problems are being continually developed. Although not as well known as FDTD, the TLM

framework offers distinctly valuable features namely: a) no need for mass lumping in order to obtain an explicit time-stepping algorithm and, b) unlike the FDTD method, it calculates the electric and magnetic fields at the same point and at the same time step, ensuring the unconditional stability which is of particular importance for modelling of complex materials and for large scale simulations [2]. Recently, a TLM method formulated on the unstructured tetrahedral mesh has been extended to include the model of realistic laser gain by combining the polarization equation that relates carrier dynamics in the lasing media with the macroscopic Maxwell's equations [3].

As PCSELs contain many thousands of PC unit cells it is adequate to approximate it with an infinitely periodic structure using a 3D unit cell with periodic boundary conditions. The PCSEL vertical epitaxy is shown in Fig.2a) and is comprised of following layers (from top to bottom): 2040 nm thick InP cavity (n = 3.20), 185 nm thick MQW (n =3.37), spacer of 170 nm thickness (n = 3.20), infill layer of 25 nm thickness (n = 3.40), 600 nm deep photonic crystal and InP substrate of 1500 nm thickness (n = 3.20). A perfectly reflecting mirror is placed at the top of InP cavity and matched boundary conditions are placed at the bottom of the InP substrate where light escapes and constitutes the useful output of the laser. The photonic crystal is comprised of air holes (n = 1) etched into a InGaAsP slab (n = 3.40). The photonic crystal has lattice constant a = 408nm. The larger hole has a diameter of 143 nm and depth of 600 nm, the smaller hole has the diameter of 105 nm and depth of 325 nm and they are separated by 450 nm. Figure 2b) compares the lasing spectrum of the PCSEL with ideally etched holes and with a realistic hole. It can be seen that the vertical hole shape has a significant impact on the lasing frequency spectrum. Similarly to the measured lasing spectra in Fig.2c) the simulated results predict multimodal lasing output but are shifted down in wavelength. The full paper will discuss in more detail the impact of the realistic shape on the modes that are supported in the structure and the carrier dynamics.

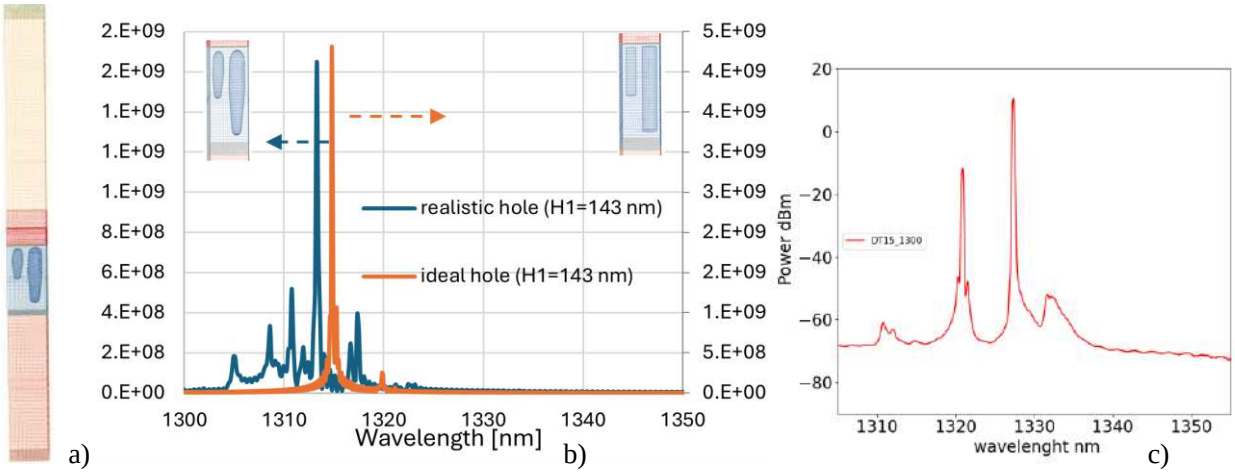

Figure 2. a) Vertical epitaxy of the 3D PCSEL unit cell with realistically etched holes and b) lasing spectrum of the PCSE with ideal cylindrical holes and realistically etched holes and c) measured lasing spectrum of fabricated PCSEL.

From Photonic Time-Crystals to Gravitational Waves

M. W. McCall and S. F. Koufidis*

Blackett Laboratory, Department of Physics, Imperial College London, London SW7 2AZ, United Kingdom
*corresponding author: steven.koufidis20@imperial.ac.uk

Abstract: Building on the band structure and optical response of synthetic photonic time crystals, we explore the temporal analogs of quasi-crystals and optical activity via coupled-wave theory. We thence extend this framework to investigate the interaction of light waves with Nature's quintessential space-time grating: the gravitational wave.

Incorporating time as an additional degree of freedom for *tripping the light fantastic* has given rise to the temporal analog of photonic crystals, which, under certain conditions, feature regions where waves are amplified rather than attenuated. The key ingredient in this parametric amplification process is the periodic modulation of the relative permittivity, akin to conventional photonic crystals but in *time* rather than space. Since these exotic modulations require pumping certain crystals, such as ITO, it hardly comes as a surprise that de-synchronizations may well occur. Thus, by treating the temporal medium as a temporal quasi-crystal—wherein the permittivity is an *almost*-periodic function of time—we observe in Fig. 1(a) that for a specific tone-spacing, almost-periodicity surprisingly outperforms perfect periodicity [1]. On the other hand, the temporal analog of optical activity—where the permittivity, permeability, and chirality are periodic functions of time—reveals that a wave traversing such a temporal slab will not only be amplified but also rotated [see Fig. 1(b)]. Moreover, the amplification is handedness-specific: two bandgaps form in Brillouin space, one for right-handed modes and one for left-handed modes [2]!

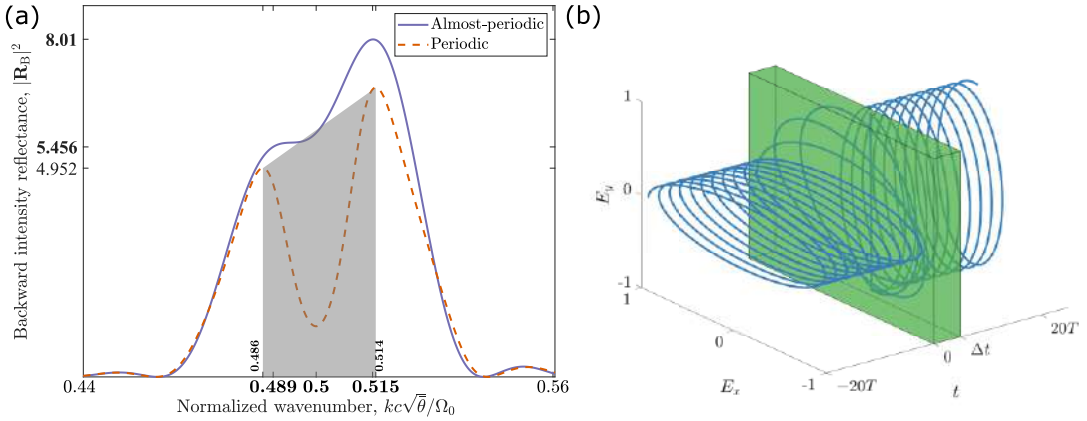

Fig. 1 (a) Optical response of an *almost*-periodic temporal slab: almost-periodicity outperforming perfect periodicity [1]. (b) As waves traverse a time-periodic chiral slab, the **E**-field is at once rotated *and* amplified [2].

Hitherto, we have been discussing purely temporal meta-media. We may now move on to spatio-temporal modulations. This category of meta-gratings has garnered significant attention in recent years, with the concept of "traveling wave modulation" and synthetic velocity in meta-optics not only promising exciting new ways of manipulating light but also proposing entirely new physical mechanisms to achieve, e.g., gain via the compression of lines of force [3]. Here, we pose the question: Are meta-media truly the only route towards realizing spatio-temporal gratings? Insofar as *synthetic* gratings are concerned, obviously yes! However, Nature has gone a step further! Indeed, one may conceptualize gravitational waves (GWs)—the fundamental spacetime perturbations—

as “luminal moving gratings” [see Fig. 2(a)]. These dynamic fluctuations induce effective refractive index modulations that interact with electromagnetic waves (EMWs), thereby providing a signature of their presence.

Within linearized gravity and in a source-free curved spacetime, the electromagnetic 4-potential satisfies a wave equation in which gravity is contained within the derivatives of the Christoffel symbols. If the metric perturbation is taken as a plane GW, and the total electromagnetic 4-potential is expressed as the sum of an incident and, say, two scattered EMWs, then fully *covariant* coupled-wave theory reveals that first-order synchronous sidebands have 4-wavevectors $k_{(+1)\mu} = k_{(inc)\mu} + K_\mu$ and $k_{(-1)\mu} = k_{(inc)\mu} - K_\mu$, wherein K_μ is the 4-wavevector of the GW, whereas $k_{(inc)\mu}, k_{(\pm1)\mu}$ those of the EMWs. These phase-matching conditions, simultaneously conserving both *energy* and *momentum*, occupy an intermediate regime between static and temporal Bragg gratings. The interaction is independent of any specific frequency and, unlike conventional Bragg scattering, does *not* support backscattering. Estimation of the interaction lengths between the EMWs’ coupling, mediated by the GW, reveals that for high-frequency, strong-field GWs, the interaction lengths shown in Fig. 2(b) appear plausible.

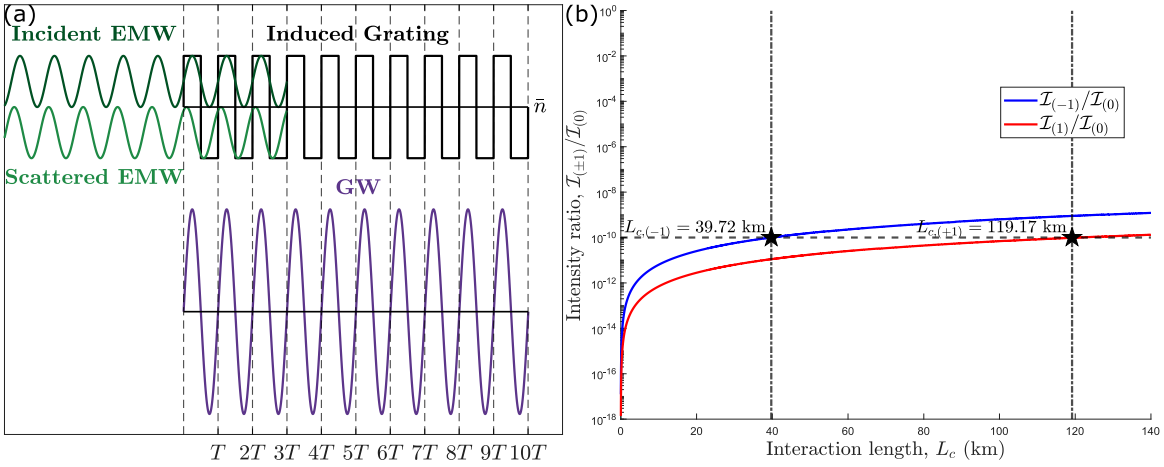

Fig. 2 (a) A luminally propagating plane GW induces a periodic spatiotemporal modulation in the refractive index. (b) Interaction lengths in the coupling process of EMWs, mediated by the scaffold formed by the GW.

Interactions between EMWs and GWs within a covariant coupled-wave framework predict observable sidebands in the electromagnetic spectrum. This direction-preserving mechanism for the indirect detection of gravitational radiation through incoherent electromagnetic sources aims to inspire an all-optical analog experiment for GW detection in laboratory settings using synthetic gratings [4].

Abstract: We experimentally demonstrate the presence of four unidirectional chiral zero modes originating from large Chern numbers in 2D gyromagnetic topological photonic semimetals. Our findings experimentally validate the intrinsic connection between the chiral zero modes and topological fermions, offering the potential to advance large-capacity and highly efficient photonic devices.

Chiral zero mode (CZM) appears as the zeroth Landau level of the quantized dispersions in the presence of a gauge field [1]. The number of chiral zero modes is dictated by the topological charge of the fermion point [2]. Despite the proposal of effective Hamiltonians to achieve multiple Chiral zero modes - which possess substantial practical applications, such as improving mode density and coupling efficiency in compact multimode waveguide devices - the realization of multiple Chiral zero modes arising from a large Chern number has remained elusive. Here, we have experimentally observed multiple unidiretional CZMs in a 2D topological photonic system with large gap Chern numbers under external magnetic fields [3]. Our findings on multiple unidirectional CZMs not only experimentally validate the index theorem on chiral Landau bands for topological semimetals [2] but also open up possibilities for the enhancement of the capacity and coupling efficiencies of wave transmission and processing devices, including large-scale topological photonic circuit with compact multimode routing.

Demonstration of a Broadband Polarization Control Device for Terahertz Waves Using Silicon Photonic Crystals

H. Yamane[1*], Y. Yamada[1], Y. Kondo[1], T. Ehiro[1], M. Fujita[2], and S. Murakami[1]

Abstract: A broadband, high-efficiency terahertz polarization converter is developed using a silicon photonic crystal with elliptical through-holes. Experimental and numerical results demonstrate its broadband half-wave plate function (0.30–0.50 THz). The device achieves high transmission with minimal loss due to biaxial anisotropy, enabling efficient terahertz polarization control using all-silicon structures.

Terahertz (THz) waves have been attracting significant attention as a promising form of electromagnetic radiation, offering new possibilities for Beyond 5G and 6G communication systems as well as biomedical imaging due to their broadband characteristics. However, practical utilization of THz waves faces challenges, including strong absorption by atmospheric water vapor and oxygen, which hinders long-distance propagation, and increased propagation losses in conventional metal-based systems as the frequency increases. To address these challenges, devices utilizing high-purity silicon as a dielectric material have gained attention. Silicon exhibits high transparency in the THz range and has a refractive index of approximately 3.4. Additionally, MEMS fabrication techniques allow for the creation of photonic crystals and metamaterials, paving the way for efficient THz optical control [1]. Polarization control of THz is essential for applications such as polarization multiplexing in communication, spectroscopy, and THz imaging. Recent developments include various metamaterial structures such as ring resonators and multilayer prism-based wave plates that demonstrate broadband performance in the THz range [2-4]. These approaches suffer from issues such as absorption losses in metal-based designs, complex fabrication processes, and challenges in miniaturization.

This study aims to create a broadband, high-efficiency polarization converter using only silicon wafers with a simplified fabrication process. To achieve broadband and uniform polarization control, it is crucial to design optical properties with appropriate frequency dispersion for each anisotropic axis, which is nontrivial. Electromagnetic response simulations were conducted to determine the size parameters, leading to the identification of a structure that functions as a broadband half-wave plate in the THz range.

Figure 1(a) shows a schematic diagram of the silicon photonic crystal half-wave plate in this study. A two-dimensional anisotropic photonic crystal is considered by periodically patterning elliptical through-holes in a rhombic lattice on a silicon substrate. The thickness of the silicon substrate is denoted as d, the short and long axes of the elliptical holes as a and b, respectively, and their periodicities along each axis as α and β. These directions are defined as the x- and y-axes, respectively. Here, using d as the unit, the parameters are set as follows:

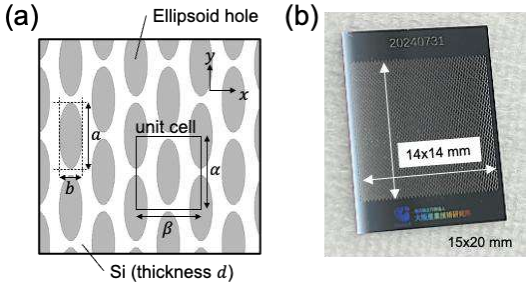

Figure 1 (a) Schematic diagram of silicon photonic crystal. (b) Photo of fabricated half-wave plate.

$$a/d = 0.160, b/d = 0.455, \alpha/d = 0.450, \beta/d = 0.500 \quad (1)$$

High-resistance silicon substrates (resistivity >10 kΩ·cm, thickness 200 μm) were used to fabricate the photonic crystal designed theoretically. Photolithography and deep reactive ion etching were employed to create through-elliptical holes in the silicon wafer. As an example, a half-wave plate was fabricated based on eq. (1) with d = 800 μm. The thickness of 800 μm was achieved by stacking four identical elements, each processed on a single 200 μm-thick silicon wafer. The element is shown in Figure 1(b).

The optical properties of the fabricated devices were evaluated using a THz time-domain spectrometer. A polarized wave tilted 45 degrees with respect to the axis of the photonic crystal was incident, and the transmitted wave was detected. Figure 2(a) shows the transmission spectrum. The red and blue lines represent the spectra of the transmitted wave with polarization parallel ($T_{\parallel}$) and orthogonal ($T_{\perp}$) to the polarization of incident wave, respectively. The solid lines indicate numerical calculations, and the dashed lines represent experimental measurements. The transmittance $T_{\parallel}$ remains close to zero over the broadband range of 0.30–0.50 THz, while $T_{\perp}$ increases to nearly 1. This is due to the photonic crystal exhibiting biaxial anisotropy along the minor and major axes of the ellipse. The phase difference for each axis is shown in Figure 2(b). The phase difference is approximately π radians over a broad bandwidth in the range of 0.30–0.50 THz.

The silicon photonic crystal polarization control device fabricated in this study demonstrates high transmission with minimal absorption loss, owing to its all-silicon composition. Unlike multilayer metamaterial structures [2, 3], it is composed solely of silicon, allowing for a simpler and more straightforward fabrication process. Compared to conventional prism-based wave plates [4], it can remain thin and compact even when scaled to a larger aperture. The desired thickness was achieved by stacking multiple thin silicon wafers, avoiding the challenges associated with high-aspect-ratio etching. The ability to batch-process multiple devices on a single thin silicon wafer significantly reduces manufacturing time and costs, thereby making this approach highly practical.

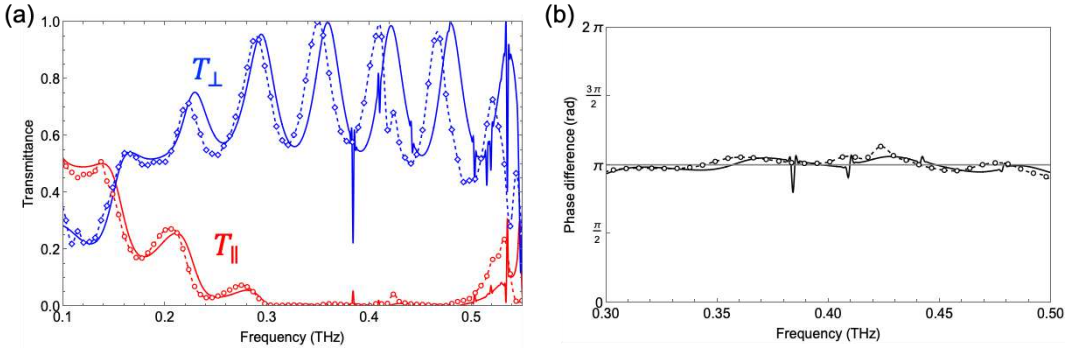

Figure 2 (a) Spectra of the transmitted wave with polarization parallel ($\boldsymbol{T}_{\parallel}$) and orthogonal ($\boldsymbol{T}_{\perp}$) to the polarization of incident wave, respectively. (b) Phase difference between polarizations along the minor and major axes of the ellipse.

Abstract: We reveal that bound states in the continuum function as robust chain points pinning together nodal lines in scattering matrices. These singularities induce observable phase vortices and persist even when symmetry is broken, providing a new framework for understanding topological protection in open photonic systems.

We present a novel framework revealing that scattering matrices of photonic systems host continuous lines of topological singularities in frequency-momentum space. While previous studies of topological photonics primarily focused on Hamiltonian matrices of closed systems, our work demonstrates that open systems characterized by scattering matrices exhibit rich topological structures with distinct properties. In lossless systems with mirror symmetry, we identify diabolic points (DPs) that form continuous nodal lines (NLs) where eigenvalues intersect linearly. Material loss transforms these into exceptional lines (ELs), where both eigenvalues and eigenvectors coalesce. Most significantly, we discover that bound states in the continuum (BICs) act as robust "chain points" that pin together nodal lines, creating nodal chain structures that persist even when mirror symmetry is broken.

The theoretical mechanism behind these phenomena emerges from the properties of reflective metasurfaces described by 2×2 scattering matrices. Mirror symmetry enforces zero inter-channel coupling when the in-plane wavevector lies in the mirror plane, creating eigenvalue degeneracies that form nodal lines in frequency-momentum space. BICs represent a special case where the resonance bandwidth approaches zero, resulting in an abrupt 2π phase jump in the eigenphase. This phase discontinuity ensures eigenvalue crossings along mirror-symmetric directions, generating nodal lines that intersect precisely at the BIC. Our theoretical analysis shows that when modifying structures to break mirror symmetry while preserving C_2 rotational symmetry, nodal chain points at BICs remain robust, while regular degeneracies disappear. This confirms a special topological protection mechanism of BIC-associated nodal chains beyond conventional symmetry requirements.

To verify these theoretical predictions, we conducted experiments using PCB-based metasurfaces operating at microwave frequencies. The experimental setup consisted of a reflective metasurface with periodic rectangular slots formed on a dielectric substrate backed by a metallic mirror. Using circular polarizers and vector network analyzers, we mapped the cross-circularly polarized reflection phase across different incident angles. These angle-resolved phase measurements revealed characteristic phase vortices at the predicted positions in frequency-momentum space, validating the presence of nodal lines converging at BICs.

The topological features we discovered have practical applications in wavefront engineering. We demonstrated the generation of spatiotemporal optical vortices using our metasurface structures, where phase vortices in the cross-polarization scattering create distinct optical signatures. More fundamentally, our work unifies previously separate concepts in topological photonics—BICs and nodal lines—through the scattering matrix framework. This connection provides new design principles for robust photonic devices that maintain functionality despite structural imperfections.

By establishing the relationship between BICs and nodal chains in scattering matrices, our research advances fundamental understanding of topological protection in open photonic systems. These findings open new avenues for exploring complex topological structures in higher-dimensional scattering matrices, non-Hermitian systems, and across different wave phenomena, potentially leading to novel approaches for designing advanced photonic devices for sensing, communications, and quantum information applications.

Abstract: We leverage the optical torque from anisotropic media for polarization control, designing ultra-compact uniaxial layered stacks that form chiral photonic crystals with >99% reflectance for one circular polarization depending on the reciprocal orientation of the extraordinary axes of neighboring layers.

We conduct a detailed theoretical analysis of the proposed device, identifying optimal conditions for a very high reflectance for one circularly polarized (CP) component and very high transmittance for the other one, according to the specific relative orientations of the extraordinary axes of neighbouring slabs and on their thicknesses. Realization of chiral metamaterials and metasurfaces exhibiting comparable characteristics involves complex, costly, and time-consuming nanoscale fabrication. Moreover, high absorption and ohmic losses limit the performance of plasmonic metasurfaces [1].

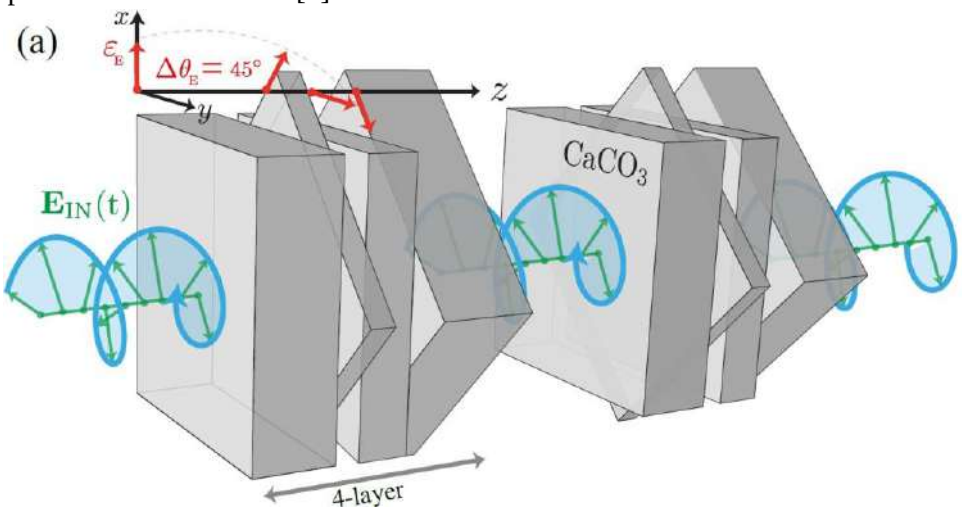

Figure 1. (**a**) Schematic of the optical system consisting of *N* four-layer stacks of uniaxial anisotropic calcite. Each layer has a defined thickness and an extraordinary axis progressively rotated relative to the *x* – axis. The mirror is illuminated by an electromagnetic field with arbitrary vacuum wavelength, incidence angle, and polarization. For simplicity, we assume circular polarization for the incident field.

We introduce a device leveraging a straightforward yet powerful physical mechanism: the optical torque density exerted by an anisotropic medium on the electromagnetic (EM) field [2]

$$\boldsymbol{\tau}_V^{EM} = -\mathbf{P}\times\mathbf{E} = -\mathbf{D}\times\mathbf{E}. \qquad (1)$$

We analyze a monochromatic plane electromagnetic wave incident at an arbitrary angle, employing the transfer matrix approach for birefringent layered media introduced by Yeh [3]. To quantify the local chirality density of the EM field, we also consider the optical chirality [4,5],

$$C = \frac{1}{2}\left[\mathbf{E}\cdot\left(\nabla\times\mathbf{D}\right)+\mathbf{H}\cdot\left(\nabla\times\mathbf{B}\right)\right]. \tag{2}$$

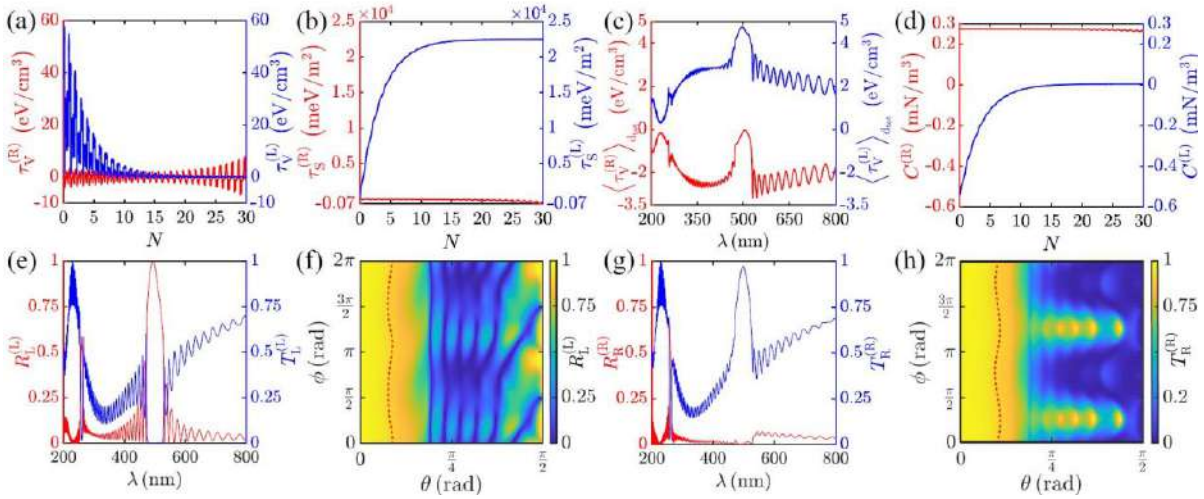

Figure 2. Normally incident EM field with λ=500 nm unless otherwise specified. (**a**) Optical torque volume density for right- and left-circularly polarized (RCP and LCP) light. For RCP, it oscillates around zero, resulting in a negligible net effect. For LCP, it is significant initially, as the device tries to force the opposite polarization, then decreases to zero. This indicates that the electric field amplitude vanishes during forward propagation, leading to near – complete LCP reflection. (**b**) Integral of the optical torque volume density along the propagation coordinate *z*. It remains near zero for RCP light but increases rapidly for LCP one until saturation. (**c**) Wavelength dependence of the length – averaged optical torque density for both normally incident RCP and LCP light. (**d**) Optical chirality for normally incident RCP and LCP light. It remains positive for RCP, while for LCP, it starts negative and increases toward zero. (**e**) Reflectance and transmittance of LCP light for incident LCP light. (**f**) Reflectance of LCP light as a function of the incidence angle. For θ values up to the red dashed line, it exceeds 0.90, and for normal incidence it is >0.99. (**g**) Reflectance and transmittance of RCP light with incident RCP light. (**h**) Transmittance of RCP light as a function of the incidence angle. For θ values up to the red dashed line, it exceeds 0.90.

This device represents a promising candidate for a new class of miniaturizable (the system characterized in Fig. 2 has a total thickness of 4.578 μm) circular polarizers, offering low – absorption, cost – effective fabrication, and suitability for applications in quantum technologies and polarization-sensitive optical detectors.

Abstract

We study thermal dissipation in optomechanical crystal geometries with monolithic silicon and hybrid silicon/silicon dioxide nanopillars. Finite-element simulations and a pump-probe technique reveal 11 MHz and 2 MHz thermal relaxation rates for monolithic and hybrid nanopillars, respectively, enabling accurate calibration of thermal effects in photonic crystal for force sensing applications.

Advances in fabrication methods have facilitated the creation of high-quality nanoscale optomechanical crystals (OMCs), integrating high-Q mechanical resonators with high-Q optical cavities [1]. Optomechanical cavities, characterized by an optical cavity created by introducing a defect within a photonic crystal functioning in the near-infrared spectrum, are notably significant within this category. Nanopillar-based OMCs offer a promising platform for on-chip sensing and photonic integration [2]. However, managing their thermal properties is vital for maintaining both stability and performance of the device. Silicon (Si) is widely used in optomechanical systems due to its high thermal conductivity, while the incorporation of silicon dioxide (SiO_2) can drastically modify thermal dissipation. In this work, we compare the thermal decay rates of monolithic silicon and hybrid silicon-silicon dioxide nanopillars through two different approaches, combining simulations and a frequency-domain pump–probe measurement.

We fabricate monolithic silicon and hybrid silicon/silicon dioxide nanopillar resonators by etching arrays of cylindrical pillars with top radii around 100 nm. The monolithic silicon nanopillars have a bottom radius 50 nm smaller than the top portion (see Figure 1a), while the hybrid nanopillars incorporate a SiO_2 segment at the base with the same radius as the top (see Figure 1b). The overall cavity structure, including periodic nanopillars and photonic crystal mirrors, is illustrated in Figure 1c.

Finite-element simulations (COMSOL) model the optical mode at telecom wavelengths and track the heat flow. By introducing an internal heating source that is subsequently switched off, we obtain the thermal decay time (τ_{th}). Figures 1d and 1e show finite-element simulations of thermal relaxation in monolithic and hybrid nanopillars, revealing respective dissipation rates of about 7.67 MHz and 2.22 MHz.

Experimentally, we employ a frequency-domain pump–probe method to evaluate the heat dissipation rate of nanostructures. The nanostructures are designed to behave as an optical cavity supporting at least two optical modes. One mode is resonantly pumped with a laser that heats the optical cavity by light absorption and the other mode is excited with a probe laser of low power that coherently detects the modulation of the spectral position of the mode due to the thermo-optic effect.

The thermal response induced by the pump laser modulation can be read on the probe laser. Figure 1f shows the measured transmission at the modulation frequency for monolithic

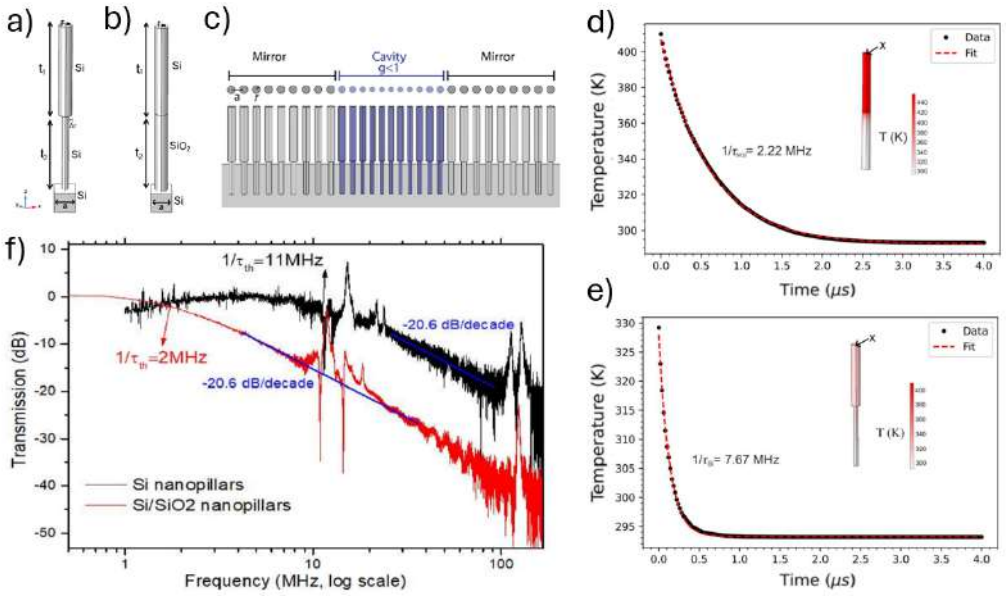

Figure 1: (a) Monolithic silicon nanopillar cross-section. (b) Hybrid silicon/silicon dioxide nanopillar cross-section. (c) Schematic of the 1D photonic crystal cavity, illustrating alternating pillars forming mirror sections and a defect region. (d) Experimentally obtained frequency-domain measurements (black/red) indicating different dissipation rates, while (e) and (f) show corresponding finite-element thermal simulations.

(black) and hybrid (red) nanopillars. By locating the cut-off (roll-off) frequency, we extract thermal dissipation rates around 11 MHz for monolithic silicon nanopillars and 2 MHz for hybrid structures, consistent with the differences in thermal conductivity ($\sim$ 1–2 $\mathrm{W\,m^{-1}K^{-1}}$ for SiO_2 vs. $> 100\,\mathrm{W\,m^{-1}K^{-1}}$ for crystalline Si) [3].

In conclusion, we have measured the thermal decay rates of monolithic silicon and hybrid silicon-silicon dioxide nanopillar OMCs, demonstrating dissipation rates of $\sim$ 11 MHz and $\sim$ 2 MHz, respectively. This dual validation—finite-element simulations and frequency-domain pump–probe measurement—enables the understanding and calibration of thermal effects on the optical and mechanical properties of these novel photonic crystal geometries. Consequently, thermal contributions from optical heating can be accurately factored into force sensing measurements.

Abstract: We demonstrate the principle of manipulating topological states towards a multi-port interferometric switch, leveraging the geometric phase degree of freedom in a silicon photonics platform with Dirac-type dispersions.

I. Introduction

The Kekulé-distorted honeycomb photonic crystal (PhC) enables a photonic quantum spin Hall effect (QSHE) [1], which offers a robust way to manipulate electromagnetic (EM) waves. This topological photonic state works across a broad frequency range, from microwaves to visible light at room temperature. Made entirely of semiconductor material, it is compatible with modern nanofabrication technology and can be integrated with existing semiconductor photonic devices.

Here, we investigate a novel scattering phenomenon in a bent topological interface based on this platform, and demonstrate both theoretically and experimentally an 2-in-2-out interferometric switching effect. We show that this switching effect can be also realized in an extended 6-way junction. The switching effect occurs within an extremely small region in the PhC ($< 1\mu m \times 1\mu m$) compared to any other existing photonic switches.

II. Interferometry switching effect of photonic topological states

In this work, we investigate the bent interface between the trivial and topological PhCs by a perturbative approach. The topological interfacial states propagating along the angle θ is described by the zero-energy Jackiw-Rebbi mode $|\theta, +\rangle = F(d)[|p_+\rangle, |d_+\rangle][1, i\exp(-i\theta)]^T$ [2, 3]. We found that a shift of the global phase $\psi(\theta)$ is induced when the topological interfacial state

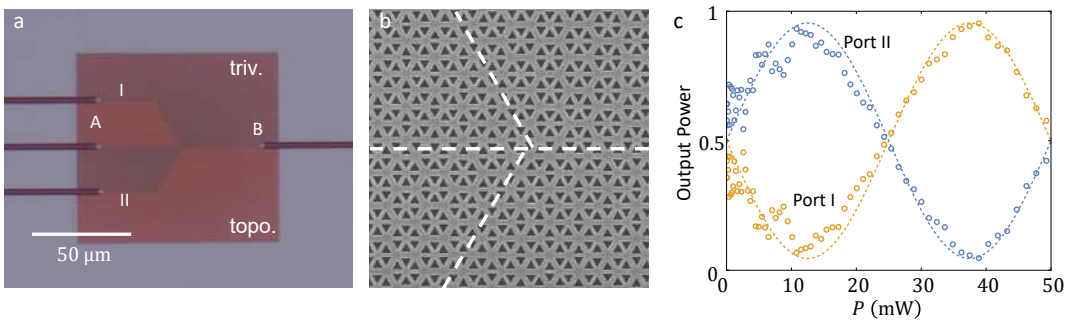

Figure 1: (a) Optical microscpe image near the PhC. (b) SEM image of the 4-way junction. (c) Experimental result of the interferometry switching effect.

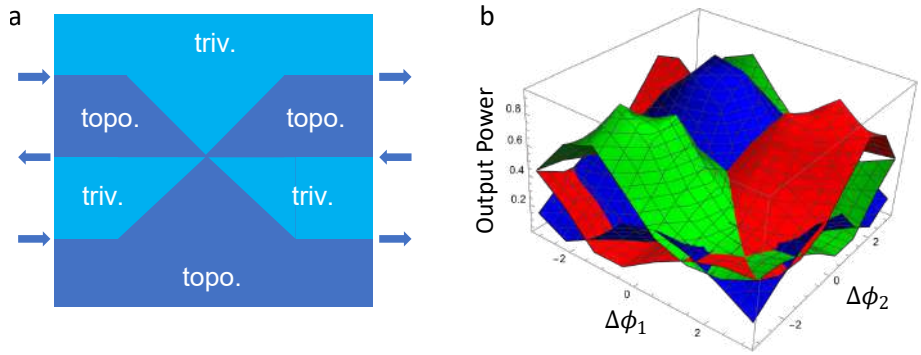

Figure 2: Interferometry switching effect of a 3-in-3-out junction.

is scattered by the bend, which is revealed as exactly half of the bending angle

$$\psi(\theta_{\text{out}}) = \psi(\theta_{\text{in}}) \exp[i(\theta_{\text{out}} - \theta_{\text{in}})/2]. \tag{1}$$

The phase shift above is understood as a geometric phase acquired by the spin-$\frac{1}{2}$ spinor wavefunction of the topolgical interface state at a bend.

We experimentally fabricate a silicon topological PhC with a 2-in-2-out structure on an SOI wafer, as shown in Fig. 1(a and b), where the two horizontal interfaces serve as the input ports. The scattering matrix of this 4-way junction can be precisely solved according to Eq. (1). By simultanuously exciting two input ports with a phase difference $\phi = \phi_{\text{A}} - \phi_{\text{B}}$, the power distribution at two output ports are evaluated as

$$P_1 = \frac{1}{2}(1 - \sin\phi), \quad P_2 \quad = \frac{1}{2}(1 + \sin\phi). \tag{2}$$

It is known from Eq. (2) that the switching effect happens at $\phi = \pi/2$ and $\phi = 3\pi/2$, where the output power is fully directed to port 2 and port 1, respectively. The experimentally measured switching effect is depicted in Fig. 1c (blue and yellow circles), which is in full agreement with the theoretical analysis (dashed lines).

We reveal that the switching effect can be also realized in an extended 6-way (3-in-3-out) junction, by controling the phase difference between the three input ports, as depicted in Fig. 2.

Abstract: This research focuses on the design and fabrication of topological photonic crystals (TPCs) using Electron Beam Lithography (EBL). Through Fourier imaging and COMSOL simulations, the study investigates the topologically protected waveguiding properties, highlighting the robustness of TPCs to defects and their potential for efficient, reliable optical applications.

Keywords: Topology, Photonic cavities, Kagome lattices, Rashba effect, COMSOL.

Introduction

Direct-bandgap monolayers of transition metal dichalcogenides (TMDs) offer promising potential for atomic scale spin-optical light sources, owing to their unique valley-dependent optical selection rules. In this study, we present a spin-valley laser incorporating a WS_2 mono- layer within a high-Q heterostructure microcavity, designed to support photonic spin-valley resonances. This Rashba monolayer laser exhibits inherent spin polarization, high spatial and temporal coherence, and symmetry driven robustness, achieving valley coherence in the WS_2 monolayer under arbitrary pump polarization at room temperature. The integration of spin-valley microcavities within monolayers expands opportunities for both classical and quantum coherent spin-optical sources, leveraging interactions between electron and photon spins.

This study presents the development of a spin-optical monolayer laser that leverages spin-valley modes generated by the photonic Rashba effect, induced through inversion symmetry (IS) breaking in a Kagome photonic crystal slab with a bound state in the continuum (Γ-BIC). By precisely tuning the orientation of anisotropic nanoholes, a photonic Rashba type spin splitting of the Γ-BIC is achieved, leading to the formation of oppositely polarized ±K spin-valley modes, which enhance spin-dependent light–matter interactions with zero group velocity. The laser's spin-valley optical microcavity is engineered by interfacing inversion asymmetric (IaS) and inversion symmetric (IS) photonic lattices, creating laterally confined resonant modes with high Q factors. This design facilitates coherent, spin-polarized emission from ±K valley excitons in the WS_2 monolayer (in Fig1), resulting in a quasi-single-mode Rashba laser with high spatiotemporal coherence and symmetry-protected robustness.

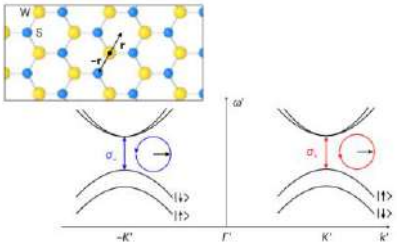

Fig:1 Valley contrasting optical selection rules of WS_2 monolayer.

Experimental Methods

In planar Kagome lattices with elliptical nanoholes were fabricated on a silicon nitride film using electron-beam lithography and reactive-ion etching techniques, followed by the integration of a highly crystalline WS_2 monolayer supported by a poly methyl methacrylate (PMMA) layer for structural stability. The Kagome lattice was chosen due to its geometric frustration properties, similar to those observed in electron spins within antiferromagnets, contributing to highly degenerate ground states with distinct chiral spin configurations. Two primary configurations were implemented: one exhibiting uniform inversion symmetry (IS) with

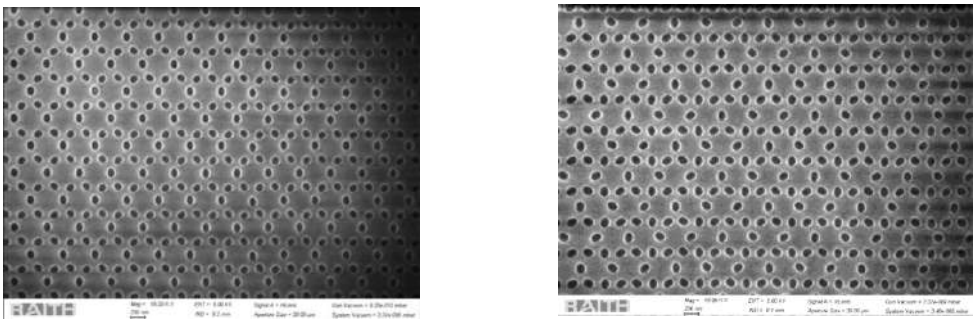

Figure 2: SEM image of IS and IaS photonic spin-like lattice**.**

q=0 and the other featuring a staggered inversion asymmetric (IaS) configuration with q=√3 × √3 chirality distributions. The orientation angles of the elliptical nanoholes within these Kagome lattices were designed to align with these two spin-like lattice configurations, as confirmed by scanning electron microscopy (SEM) images in Fig2.

Results and Discussion

COMSOL Multiphysics simulations model the band structure of optical spin-split dispersions centered around 620 nm, a wavelength optimized to align with the photoluminescence range of the WS_2 monolayer. By tuning the anisotropic nanohole dimensions in photonic spin-like lattices, coupling between nanoholes and photonic modes is enhanced, enabling effective spatial polarization control and high geometric phase efficiency via spin-orbit interaction. This interaction creates spin-split dispersions in momentum space through the photonic Rashba effect. Outside this range, geometric phase efficiency decreases sharply, causing the IS and IaS photonic spin-like lattices to converge toward a similar band structure as the Rashba effect diminishes. Future experiments will aim for Rashba monolayer lasing in the spin-valley microcavity, targeting high spatial and temporal coherence with tunable valley polarization at room temperature. By selectively pumping the WS_2 monolayer, researchers plan to achieve directional, spin-polarized emission through coherent superposition of valley excitons and to control Rashba lasing properties with pump polarization, enhancing coherence and phase correlation in the valley excitons.

Abstract

Two-dimensional (2D) photonic crystals (PhC) are fabricated from opal slabs coated with an a-Si:C:H emitting layer. The optical response of the emitting 2D PhC's near Γ-point of the Brillouin zone have been studied. A significant increase in the luminescence intensity in the visible spectral range has been demonstrated in the synthesized structures.

1 Introduction

2D PhC's are currently as considered one of the most promising dielectric media for achieving enhance light emission by increasing the probability of radiative recombination, described by the Purcell factor [1]. In this work, we studied the possibility of increasing the photoluminescence (PL) intensity of an a-Si:C:H emitting layer, resulted from interaction with the modes of a 2D PhC fabricated on the basis of an opal slab. Such interaction can be realized if the a-Si:C:H emission is located above the photonic band gap, where various radiative modes of the photonic crystal can exist within the light cone [2]. The spectral position of the PL contour can be easily varied by changing the content of carbon in the a-Si:C:H film. The full width at the half-maximum (FWHM) of the PL contour of a-Si:C:H reaches a value of 0.6-0.7 eV.

2 Results

The samples of the opal slabs being studied include opal films [2-3 monolayers (ML) of a-SiO_2 spheres of diameter 520 nm with a spread in diameter smaller than 3] grown on fused silica substrates. The a-Si_{1-x}:C_x:H layer with a thickness of 250 nm was deposited on opal film by the plasma-enhanced chemical vapor deposition (PECVD) technique in a capacitive reactor at various relative flows of silane (SiH_4) and methane (CH_4). The optical thickness of the layers was monitored in-situ by the laser beam interference pattern. Carbon content in the film is x = 0.58, which corresponds to PL peak at 1.7 eV and refractive index n = 2.2 [3].

Angle-resolved optical spectra were measured using a Fourier imaging spectroscopy technique. For PL measurements, a 405 nm laser diode illuminates the sample by the from the backside. The spectral resolution of the setup is 0.17 nm, whereas the angular resolution is not less than 0.4° [4]. Theoretical analysis of the optical response of the structure included numerical calculations of the structure's eigenmodes and angle-resolved spectra performed by a Fourier modal method in the scattering matrix form.

The experimental and theoretical angle-resolved PL spectra are presented in Fig. 2(a, b) Due to a broad PL band in the range of 500–1000 nm, the PL spectra contain many peaks resulted from interaction processes of the a-Si:C:H emitting clusters with PhC modes near Γ-point of

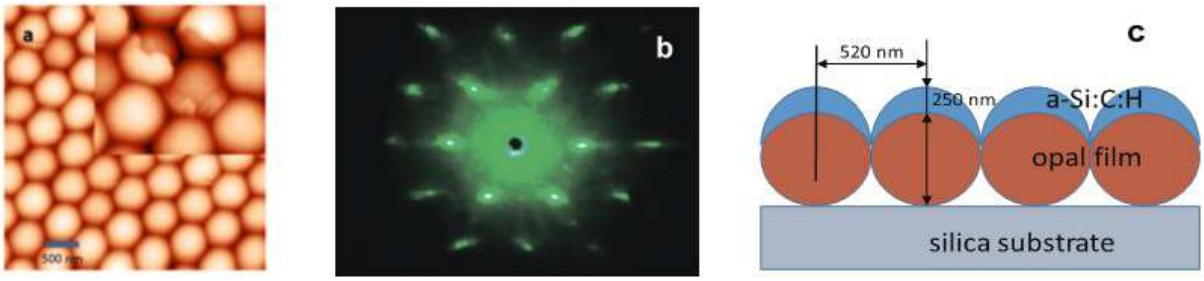

Figure 1: AFM image of the a-Si:C:H/opal slab (a). Insert: a fragment of the structure where the aSi:C:H film is partially absent and SiO2 spheres are exposed. Laser diffraction pattern of an a-Si:C:H/opal slab (b). Schematic view of the structure used in scattering matrix method calculations. Only one monolayer of SiO2 spheres is shown for simplicity (c).

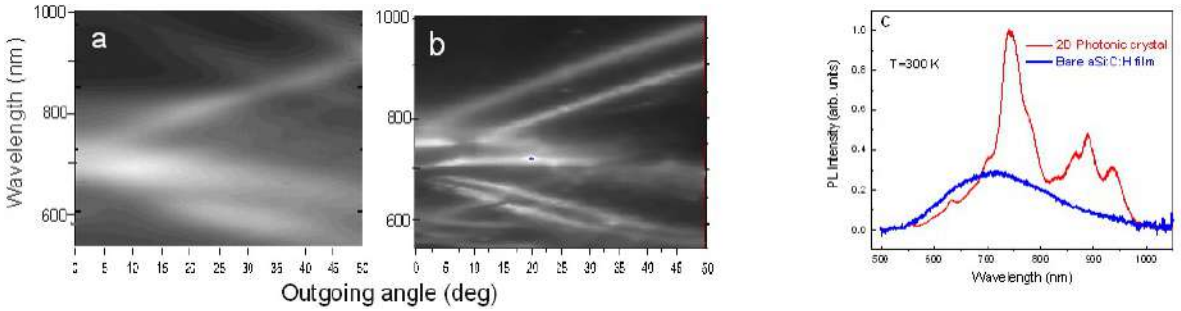

Figure 2: Experimental (a) and theoretical (b) angle-resolved photoluminescence spectra measured in p-polarization. Comparison of PL spectrum of the PhC with PL spectrum of the a-Si:C:H bare film (c).

the Brillouin zone. Figure 2c shows PL spectra from PhC slab coated with a-Si:C:H layer (a) and bare a-Si:C:H film (b) measured near Γ-point of the Brillouin zone. It is seen remarkable increasing PL intensity from PhC slab.

Finally, we have studied the angle-resolved PL spectra of 2D opal coated with a thin luminescent a-Si:C:H film. Since the measurements were carried out near the Γ-point of the Brillouin zone of the PhC, it can be assumed that the observed PL lines of different widths correspond to the interaction of the radiation of a-Si:C:H nanoclusters with PhC modes of different nature. The calculations of the PhC band diagram showed that in such structures it is possible to observe radiative modes located inside the light cone and characterized by a small group velocity, which appear in the PL spectra in the form of relatively broad, intense lines.

Abstract: Fano resonances in periodically nano-modulated thin films are known to produce narrow bandgaps in frequency and angular domains [1,2]. At resonance, the incident wave couples to the planar waveguiding mode of the film, resulting in zero transmission and 100% reflection [3]. The bandwidth of these resonances is proportional to the coupling coefficient between the incident radiation and the waveguiding mode. In this work, we demonstrate that combining two closely spaced resonances can create extremely narrow high-pass bands in transmission, with a theoretically tunable passband width that can approach zero in wavelength-angle space.

This study investigates frequency and angular filters based on Fano resonances (FR) in periodically nano-modulated thin films, which exhibit zero transmission and 100% reflection at resonance under near-normal incidence conditions. The research focuses on the coupling between incident waves and planar waveguide modes, exploring the interaction of left- and right-propagating waveguide modes. When these modes are in close proximity, a high-transmission band emerges between the resonances, achieving 100% peak transmission with a theoretically infinitely narrow bandwidth. Analytical models, derived under weak modulation ($h0 \ll dz$) and strong confinement ($n \gg 1$) approximations, describe the resonant coupling conditions and propagation wavenumbers of the modes.

The transmission resonances in the angle-wavelength can be derivated using a coupled equations for the Fabry-Perot (FP) modes of the film giving the following expression:

$$t(\theta,\lambda) = \frac{1}{1+\sum_m \frac{i\Delta\lambda_m}{\lambda-\lambda_m(\theta)}} \qquad (1)$$

Where λ_m represent the wavelength of the m-order resonance. In presence of two resonances (1) indicates that the transmission reaches unity at a particular point between the resonances and whereas being zero at resonances, θ and $\boldsymbol{\lambda}$ represents the incidence angle and wavelength of the source .

The numerical study using FDTD methods for the structures using the previously mentioned criteria (weak

modulation and strong confinement), allow us to sweep several parameters to choose the optimal design to fabricate and measure the transmission maps.

To find the best structure several simulations with one structure was performed to find the sharpest resonance, this single thin layer, was used to develop the dual configuration for this research.

Tilting these structures is possible to shift the transmission maps in the angle space allowing us to get a eye-shape filter for angle and wavelength, this is observed in figure 1, where the Numerical simulations and experimental measures are compared.

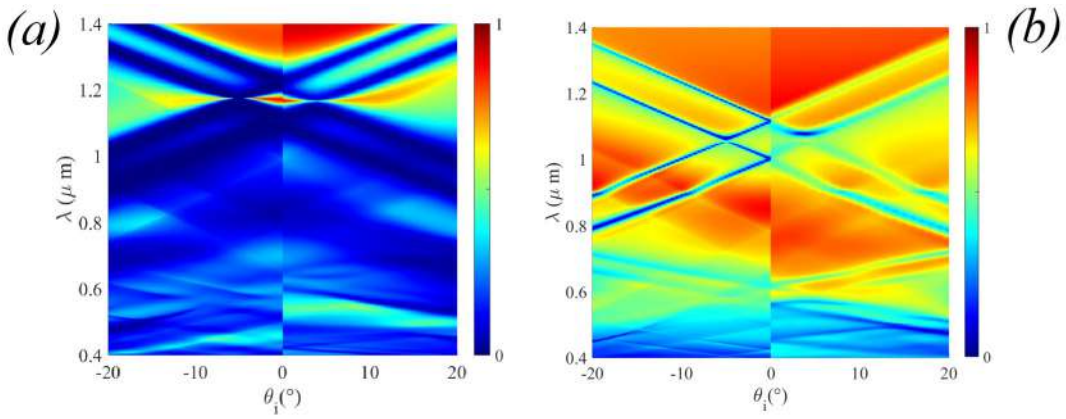

Fig. 1. Comparison of Numerical simulation (left side) and Experimental measure (right side) of this double periodical structures for (a) S polarization and (b) P polarization, tilted by 10 degrees respect each other.

This research shows the possibility of create a adaptable filter in the angle-wavelength domain by choosing the geometry of the mentioned structure, and also by changing the tilting angle between the structures, taking advantage of the Fano resonance that exist in the thin layers.

Calculation of density of states in a one-dimensional photonic biosensor

Francis Segovia-Chaves
Grupo de Física Teórica, Universidad Surcolombiana, Neiva-Huila. Colombia
Corresponding author: francis.segovia@usco.edu.co

Abstract: Using Green's functions we calculate the local density of states in a one-dimensional photonic biosensor. The insertion of a cavity with a refractive index of four types of cells: Normal, Jurkat, PC12, and MCF-7. By increasing the dielectric constant, we observe that the localized mode shifts to shorter frequencies.

In a scattering system described by a dielectric constant $\epsilon(\overrightarrow{r})$, the dyadic Green's function $\mathbf{G}(\overrightarrow{r}, \overrightarrow{r}')$ in real space satisfies:

$$\overrightarrow{\nabla} \times \overrightarrow{\nabla} \times \mathbf{G}(\overrightarrow{r}, \overrightarrow{r}') - k^2 \mathbf{G}(\overrightarrow{r}, \overrightarrow{r}') = \widehat{I}\delta(\overrightarrow{r} - \overrightarrow{r}') \tag{1}$$

In Eq. (1), $\overrightarrow{k}$ and $\widehat{I}$ represent the wave vector and the unit dyad, respectively. Using the Fourier expansion method, $\mathbf{G}(\overrightarrow{r}, \overrightarrow{r}')$ is given by:

$$\mathbf{G}(\overrightarrow{r}, \overrightarrow{r}') = \frac{1}{2\pi} \int e^{i\overrightarrow{k}_{\parallel} \cdot (\overrightarrow{\rho} - \overrightarrow{\rho}')} \mathbf{g}(\overrightarrow{k}_{\parallel}, z, z') d\overrightarrow{k}_{\parallel}, \tag{2}$$

$$\mathbf{g}(\overrightarrow{k}_{\parallel}, z, z') = \int e^{-i\overrightarrow{k}_{\parallel} \cdot (\overrightarrow{\rho} - \overrightarrow{\rho}')} \mathbf{G}(\overrightarrow{r}, \overrightarrow{r}') d(\overrightarrow{\rho} - \overrightarrow{\rho}') \tag{3}$$

where $\mathbf{g}(\overrightarrow{k}_{\parallel}, z, z')$, $\overrightarrow{k}_{\parallel} = (k_x, k_y)$, $\overrightarrow{\rho}$ is the transverse coordinate, and $\overrightarrow{r} = (\overrightarrow{\rho}, z)$. By substituting Eq. (2) into Eq. (1), the wave equation in the reciprocal space for the dyadic Green's function is:

$$\begin{bmatrix} -k^2 - \partial_z^2 & 0 & ik_{\parallel}\partial_z \\ 0 & k_{\parallel}^2 - k^2 - \partial_z^2 & 0 \\ ik_{\parallel}\partial_z & 0 & k_{\parallel}^2 - k^2 \end{bmatrix} \begin{bmatrix} g_{nxx} & g_{nxy} & g_{nxz} \\ g_{nyx} & g_{nyy} & g_{nyz} \\ g_{nzx} & g_{nzy} & g_{nzz} \end{bmatrix} = \widehat{I}\delta(z - z') \tag{4}$$

Fig. 1 illustrates the heterostructure consists of alternating polymer layers: layer A (PS) and layer B (PMMA). The polymer thicknesses are quarter-wavelength, $d_A = \frac{an_B}{n_A + n_B}$ and $d_B = \frac{an_A}{n_A + n_B}$. Fig. 2 shows the calculated LDOS for normal (Fig. 2(a)), Jurkat (Fig. 2(b)), PC12 (Fig. 2(c)), and MCF-7 (Fig. 2(d)) cells, with dielectric constants of 1.822, 1.932, 1.946, and 1.962, respectively. In the PBG region, we see that the appearance of confined photonic modes accompanied by a maximization of the LDOS, implying an elevated spontaneous emission rate within the cavity. PCs are sensitive to increases in the dielectric constant within the cavity, causing a shift of the confined mode to lower frequencies, as shown in Fig. 3. The results indicate an LDOS increase from 0.834 for the normal cell to 1.477 for the Jurkat cell, 1.471 for the PC12 cell, and 1.464 for the MCF-7 cell. The effects of pressure on the LDOS for our biosensor are presented in Figure 3.

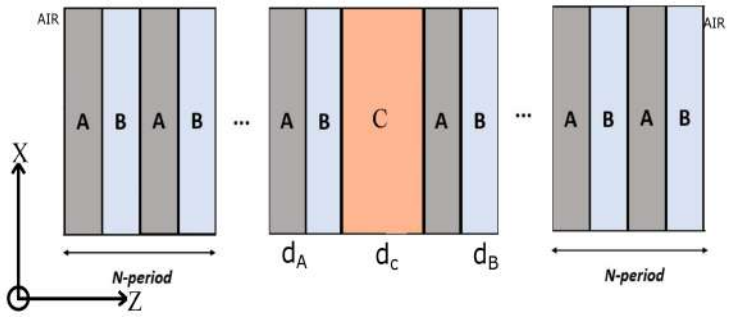

Figure 1: Representation of a 1D-PC with a cavity surrounded by N layers of materials A and B.

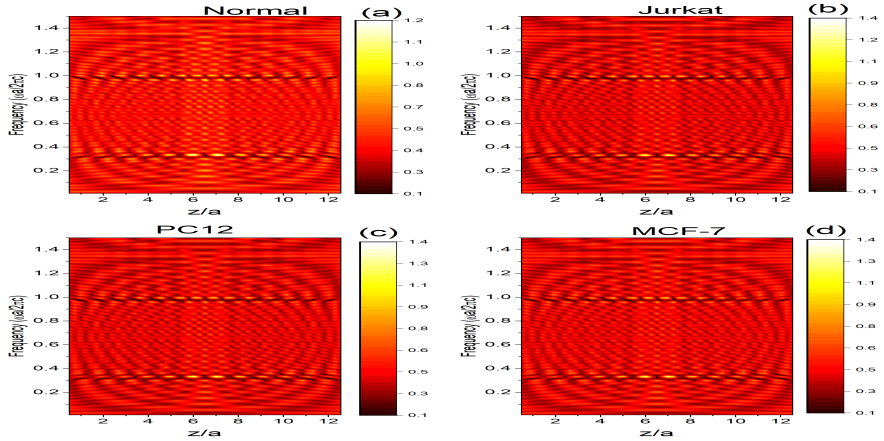

Figure 2: LDOS as a function of frequency for cells: a) normal, b) Jurkat, c) PC12, and d) MCF-7.

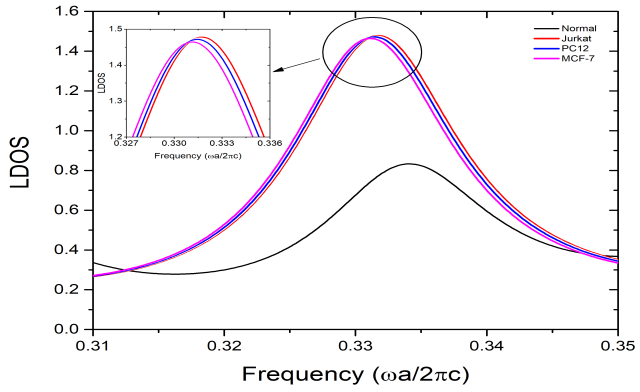

Figure 3: LDOS for different types of cells infiltrated into the cavity.

Confined mode shift in a photonic crystal with a cavity infiltrated by CHIKV cells

F. Segovia-Chaves
Grupo de Física Teórica, Universidad Surcolombiana, Neiva-Huila. Colombia.

*corresponding author: francis.segovia@usco.edu.co

Abstract: We calculate the transmittance spectrum in a defective one-dimensional photonic crystal. The cavity is filled with CHIKV-infected cells. We find a resonant peak inside the photonic band gap. Increasing the pressure decreases the confinement of the defective mode due to the decrease in quality factor.

The total transfer matrix for the defective structure $Air/(AB)^N C/(AB)^N/Air$, is given by.

$$M = \begin{pmatrix} M_{11} & M_{12} \\ M_{21} & M_{22} \end{pmatrix} = D_0^{-1}[M_A M_B]^N M_C [M_A M_B]^N D_0 \quad (1)$$

where D_0 is the dynamic matrix of the air. The transmittance T is calculated with the matrix elements M_{11} of Eq. (1), $\mathbb{T} = \left|\frac{1}{M_{11}}\right|^2$. Using the transfer matrix method, we calculate the transmittance spectrum.

Fig. 1 shows in two panels the behavior of the transmittance spectrum with increasing external pressure for normal plasma cells, keeping both temperatures constant (T=4.2K).

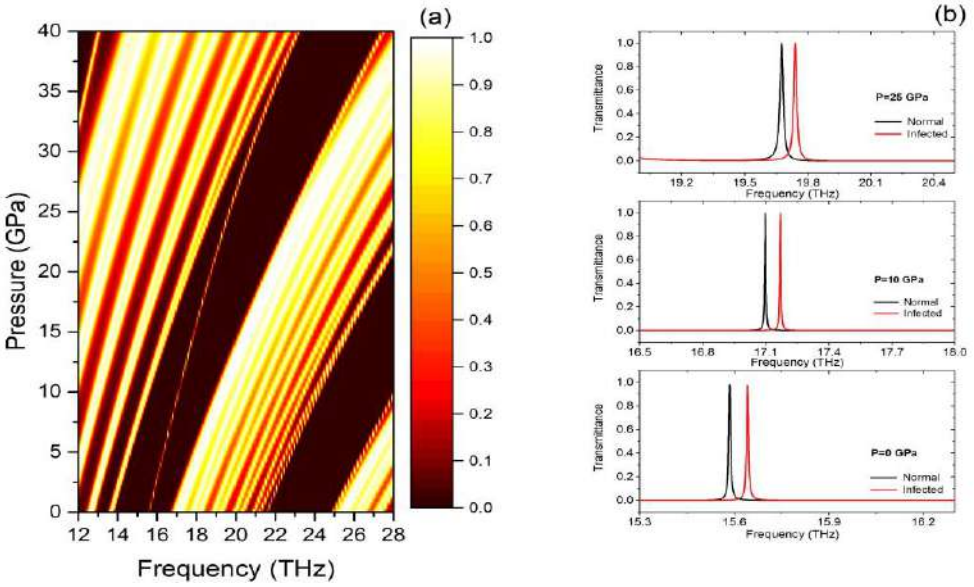

Figure 1. a) Transmittance spectrum as a function of applied pressure in a defective 1D-PC with a cavity infiltrated by normal plasma cells. b) Transmittance spectrum for normal (black line) and CHIKV-infected (red line) plasma cells for three different values of hydrostatic pressure.

The transmittance spectra for normal and infected cells of platelets (see Fig. 2 (a)) and uric acid (see Fig. 2 (b))

are shown in Fig. 2. For platelets, the maximum confined energy in the cavity is reached for 6GPa, where the quality factor is 3015.56 and 3011.79 for normal and infected cells, respectively. The energy stored in the cavity is quantified by the quality factor (Q), determined by the ratio of a resonant cavity frequency to the linewidth of the cavity mode. The energy decreases for pressures higher than 6GPa, as shown in Fig. 2(c).

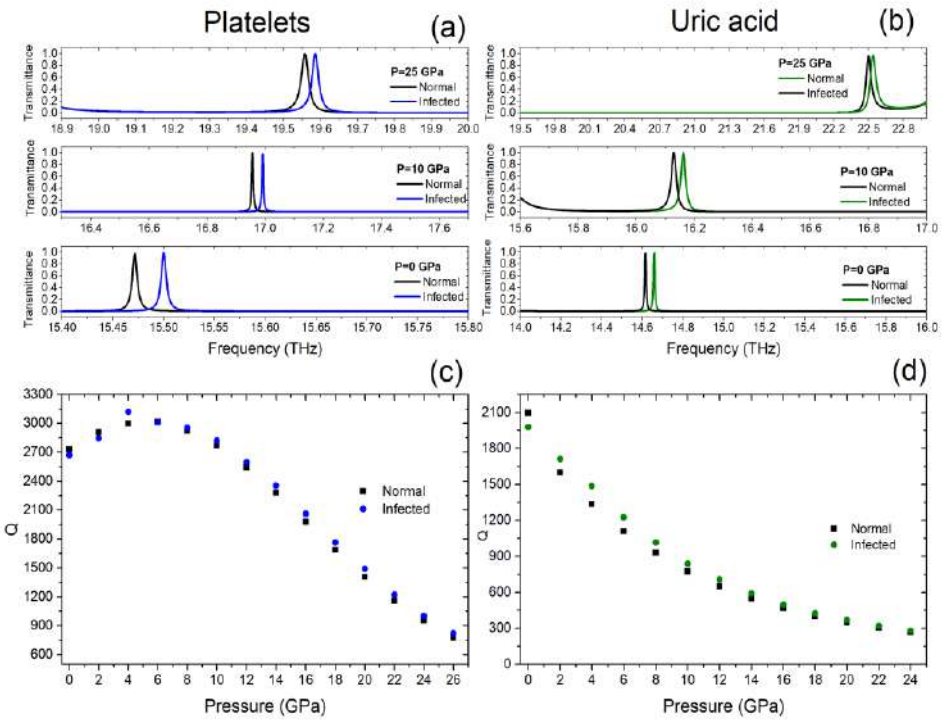

Figure 2. Transmittance spectrum for three values of applied pressure in a cavity infiltrated by cells: a) normal (black line) and infected (blue line) platelets, and b) normal (black line) and infected (green line) uric acid. Quality factor as a function of applied pressure for (c) platelets and (d) uric acid.

Abstract: Topological waveguides have demonstrated their potential to enable the design of photonic circuits without scattering from defects such as sharp bends. In this work the routing of information using multiple inputs at a 6-port topological valley junction is investigated by calculating the scattering that defines the proposed structure.

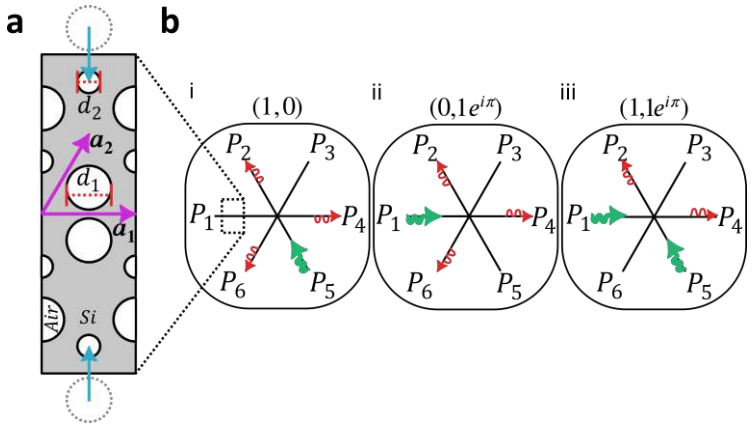

Figure 1. (a) Schematic of the center of a VPC waveguide. (b) Schematic of the routing performance at a 6-port VPC junction for three input logical combination pairs (port 1, port 5).

Valley photonic crystals (VPCs) can be used to design topological waveguides (VPC waveguides) with high transmission while being resilient to sharp turns or defects/obstacles [1–4]. Multiple VPC waveguides can be connected to form junctions. It has been shown that signals incident from one VPC waveguide will be restricted to be coupled only to other waveguides with the same valley type [5]. This property has been exploited to design four port junctions that emulate linear computing operations [6]. VPC waveguide junctions can also be represented by a scattering matrix so that they may be studied analytically [7,8]. In this communication we push forward the ideas in previous work from our group in the context of linear computing with parallel plate [9–13] and rectangular [14] waveguide junctions and move towards a solution that may function at higher frequencies using topologically protected waveguides [7]. To do this, we make use of a numerically extracted scattering matrix to investigate the possible linear routing operations that a 6-port junction may support with two or more inputs.

A schematic of the VPC waveguide is included in Figure 1a with the hexagonal unit cell vectors labeled as $\boldsymbol{a_1}$ and $\boldsymbol{a_2}$ respectively. The VPC waveguide is designed with a lattice constant, $a = 340$ nm, with a silicon (Si) background (grey) and two Air (white) holes each with different diameters of $d_1 = 0.24a$ and $d_2 = 0.12a$ respectively (labelled in Figure 1a). To design the 6-port junction, five additional VPC waveguides were rotated around a central point by $\pi/3$ radians. A frequency dependent scattering matrix, $\boldsymbol{S}$, was then extracted following [7,8]. The scattering of two input signals at the 6-port junction was then represented by a vector of phasors in the form, $\boldsymbol{X}_{\text{input}} = [x_1, 0,0,0, x_5, 0]$, where x_1 and x_5 were changed through three input combination pairs of

$(x_1, x_5) = (1,0), \left(0,1e^{i\pi}\right), (1,1e^{i\pi})$ respectively. Then, for each pair the resulting output signals were calculated using, $\boldsymbol{X}_{\text{output}} = \boldsymbol{S}\boldsymbol{X}_{\text{input}}$. This calculation produced $|\boldsymbol{X}_{\text{out}}|^2 \approx [0,0.33,0,0.33,0,0.33]$ for the first two input combinations shown in Figure1b(i-ii) and $|\boldsymbol{X}_{\text{out}}|^2 \approx [0,1.00,0,1.00,0,0.00]$ for the third input combination shown in Figure1b(iii). In this configuration, it can be observed that at port 6 the output signal can emulate an XOR gate (when defining the low/high classification threshold within the range $0 < |x_6|^2 < 0.33$). Additionally, when the output is observed at ports 2 and 4 (and considering a classification threshold $0.33 < |x_n|^2 < 1,\ n = 2,4$) the output signal can emulate an AND gate. During the conference the full details of the 6-port VPC waveguide design, the extraction of the scattering matrix and evaluation of its computing operation will be fully discussed. This will include numerical simulation of each input combination as well as different configurations such as a three-input case and a study of the performance of the junction with holes removed.

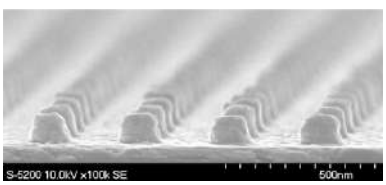
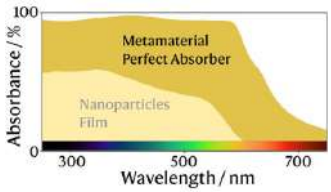
Near-unity Index Meta-surfaces and Design of Thermally Emitting Meta-surfaces for Catalysis

Joel Y.Y. Loh[1]

[1] Department of Electrical and Electronic Engineering, University of Manchester, Manchester, M13 9PY
E-mail: joel.loh@manchester.ac.uk



Abstract: A metamaterial of index <1 achieves near-perfect absorption over 400nm range in visible, enhancing CO_2 adsorption through broadband plasmonic fields and angular invariance. Further, adjoint optimization of thermal metamaterials enable coupling with CO_2 vibrational modes. Atomic simulations confirm the enhanced gas absorption due to CO_2 activation energy barrier decrease to 0 eV.



Summary

The absorption of gas-sensing metals and dielectrics offers a breakthrough in conventional material-based engineering. This approach involves meticulously engineering the electric permittivity (ε) and magnetic permeability (μ) by arranging and shaping meta-atoms, creating a meta-surface with desired properties. This surface can achieve several electromagnetic effects, including optical impedance matching and peak absorption spectrum matching of vibrational modes.

Figure 1 shows the cross-sectional microscopy of 90nm copper on a gold layer [1] (**Figure 1a**). The optical absorption spectrum of the meta-surface is wider and higher than that of a film of nanoparticles (**Figure 1b**). For a randomly distributed nanoparticle film, most absorption is due to internal scattering of incident light, with a copper plasmonic absorption edge at 600nm. For the meta-surface, the edge is extended to 650nm.

To show the difference in the underlying EM mechanism, we show the results associated with the conventional effective medium theory and the boundary sheet theory. **Figure 1c** shows the real component of the index, and the calculated absorption spectrum of the meta-surface nano-cube array and periodicity, using the MG effective medium theory. The absorption spectrum is similar to that of the nanoparticle film but not the meta-surface, and while the refractive index is close to 1, it is still high enough to induce reflection. A different refractive index theory is needed. Using the boundary sheet theory, we calculated that the meta-surface has an index real component below 1 (**Figure 2a**). This means that the metamaterial scatters or reflects minimal light because light effectively does not see any scattering medium. This is revealed by the electric field intensity spectrum (**Figure 2b**), which showed that while a nanoparticle film only shows strong plasmonic fields at the resonance wavelength of ~600nm, the plasmonic field in the meta-surface covers 350nm to 650nm. Such a range of plasmonic energies can likely enhance the adsorption of gas molecules through an energy ladder of charge injection. The in-situ FTIR spectroscopy showed a large increase in absorption in the 1050−1220 cm^{-1} band under 1 sun illumination (**Figure 2c**), which is associated with adsorbed methoxy (*CH_3O) or gaseous CH_3OH species. By contrast, the particle film showed relatively small absorption changes in the same band. This separate hydrogenation pathway suggests an additional indirect charge transfer that is present in the meta-surface, even though the nanoparticle film should also exhibit plasmonic effects.

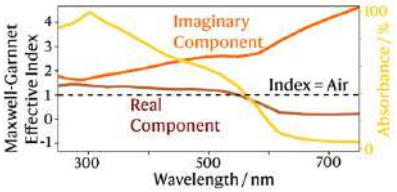


Figure 1. The cross-sectional microscopy image of the meta-surface (left). The optical absorption spectra of the fabricated meta-surface and uniform ZnO / Cu film (right). Effective medium theory shows the real and imaginary components of the refractive index of a Cu layer with a low volumetric filling ratio. Also shown is the simulated absorption spectrum of the Cu layer, which does not match the experimental absorption spectrum.

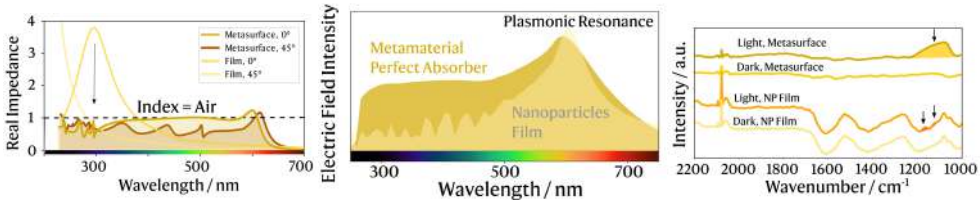

Figure 2. The Boundary Sheet theory shows the real impedances of the meta-surface and ZnO / Cu film. Average electric field intensities between the nano-cubes at the optimal periodicity, and nano-cubes with random periodicities, such that it is considered a nanoparticle film. The meta-surface impedance shows minor changes in profile whereas the film shows significant changes both across the spectrum and incident angle. Fourier transform infrared spectra of the meta-surface and quartz fiber surface coating under 250 °C temperature and CO_2 and H_2 flow, compared between under dark and light conditions.

In another example of meta-surface behavior for thermal emission, we show a multilayer metal-dielectric periodic array is able to generate either a broader peak matching the asymmetric O=C=O bond at ~2420 cm^{-1}. Adjoint optimization involving 2nd derivative softmax functions enables fast convergence of meta-surface design and thicknesses with near-zero error to the desired wavelength (**Figure 3a**). With adjoint method we were able to generate broadband and narrowband emitting designs matching the O=C=O bond (**Figure 3b**), an example is shown in Figure 3c. DFT simulations indicate with a slight asymmetric stretching of the CO2 bond by < 10% of the bond length, enables its chemisorption activation barrier to be reduced to 0 eV.

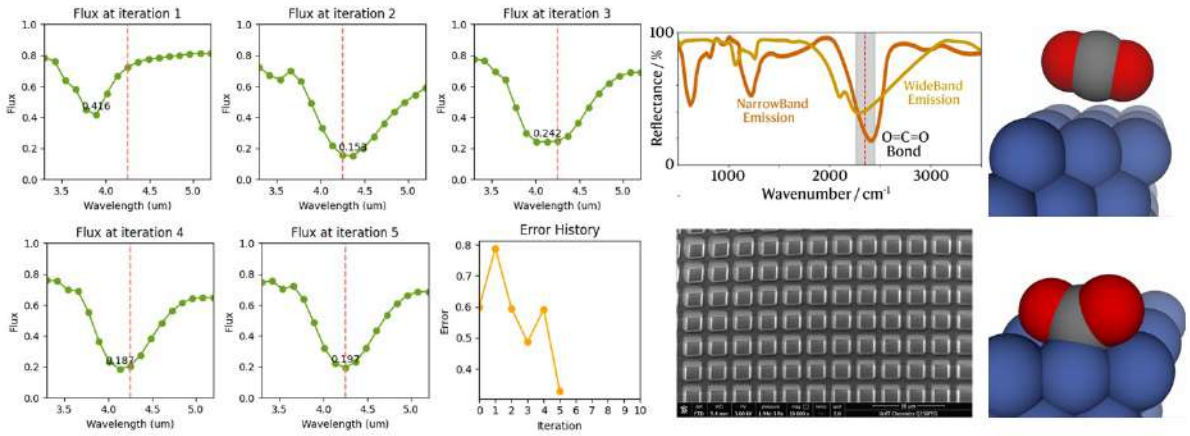

Figure 3. Adjoint method optimization of multilayer metal-dielectric The near-field thermal radiation of the meta-surface as determined by stochastic theory calculations. The wideband emitter shows higher radiation power than the narrowband emitter at 2 to 5 μm distance from the surface.

[*]corresponding author: ning.lyu@uni-jena.de

Abstract: A polarization-dependent metasurface of elliptical Au nanopillars selectively catalyzes reactions via localized surface plasmon resonance. Asymmetric nanopillars allow tuning the resonance wavelengths to maximize yield under x-polarization while suppressing activity under y-polarization, demonstrating a promising approach for controlling selectivity in multibranched reactions.

Photocatalysis holds significant potential for sustainable energy conversion, enabling chemical processes such as water splitting and CO_2 reduction [1]. These reactions typically involve multistep electron transfers, leading to the simultaneous formation of multiple products [2], [3]. However, efficiently harnessing solar energy while achieving selective product conversion remains a challenge. To address this, we focused on precisely controlling a single-step reaction: the N-demethylation of Methylene Blue (MB), activated by light within the 530–710 nm wavelength range [4]. We designed a polarization-dependent metasurface (Figure 1c) that exhibits localized surface plasmon resonance (LSPR) at a specific wavelength, allowing reaction control by tuning the polarization of incident light [5].

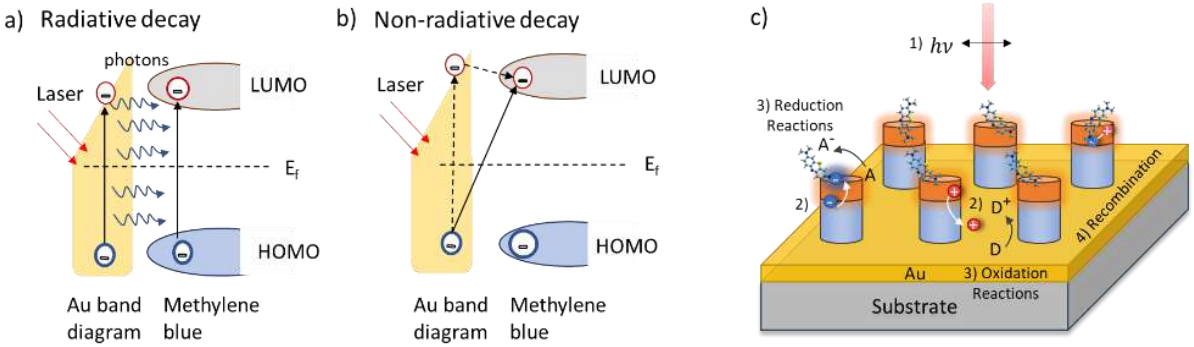

Figure 1. Metasurface nanostructure and photocatalysis mechanisms: a) LSPR radiative decay provides optical near-field enhancement for photocatalysis in MB. b) LSPR non-radiative decay provides direct and indirect hot electrons for reactions. c) Photocatalysis mechanisms on a Au-TiO_2 hybrid nanopillar array.

Metasurfaces feature nanoscale structures that enable precise tuning of optical properties by modifying their geometry. Elliptical TiO_2 and Au nanopillars with asymmetric diameters exhibit polarization-dependent optical behavior. A hybrid nanopillar array was modeled using the finite element method (FEM) and fabricated via a top-down approach with electron beam lithography (EBL). Under transverse magnetic (TM) mode illumination, the nanopillars exhibit peak absorption at 620 nm, aligning with the laser wavelength to activate the MB reaction. In contrast, absorption decreases in the transverse electric (TE) mode, suppressing the reaction, while the peak redshifts to 800 nm due to asymmetry along this direction.

To evaluate catalytic performance, surface-enhanced Raman spectroscopy (SERS) was used for real-time

monitoring of the N-demethylation reaction. The reaction yield was quantified by integrating the Raman peak of the product at 480 cm^{-1}, providing insight into reaction rate manipulation. By switching laser polarization from TE to TM, the yield increased from 4.7 to 9.8 over 10 seconds under consistent illumination conditions on the same sample.

This study demonstrates the potential of tunable metasurfaces for precise control of light-driven reactions, offering promising applications in selective photocatalysis. Utilizing advanced nanofabrication techniques, we engineered nanoscale morphologies to tailor optical properties, enabling targeted activation or suppression of specific reaction pathways. These metasurfaces provide a powerful strategy for selectively catalyzing optical resonance-driven reactions by modulating intermediate steps. Future research will explore the integration of tunable materials, such as phase-change materials, and extend this approach to complex multibranched reactions, including CO_2 reduction. This method presents a versatile solution for optimizing multistep reaction pathways, crucial for enhancing conversion efficiency in renewable fuel production.

Cofactor Regeneration in Enzyme Membrane Reactors by Photoenzymatic Methods: A Biomimetic Light-Harvesting Platform with Ionic Porphyrins for CO_2 Reduction

Zhibo Zhang, Manuel Pinelo*

[2]Department of Chemical and Biochemical Engineering, Technical University of Denmark, Søltofts Plads 228A, 2800 Lyngby, Denmark

*corresponding author: mp@kt.dtu.dk

Abstract: Photoenzymatic platforms enable efficient cofactor regeneration for enzymatic reactions requiring redox cycling. We present an ionic porphyrin-based light-harvesting system that enhances NADH regeneration and enzymatic CO_2 reduction. By optimizing photonic absorption and charge transfer, this biomimetic approach improves energy conversion, demonstrating potential for sustainable photocatalysis and solar-driven biomanufacturing.

Summary:

Cofactor regeneration is a fundamental challenge in enzymatic processes requiring redox reactions, particularly in biomanufacturing, carbon capture, and sustainable chemical synthesis. Many enzymatic reactions depend on nicotinamide adenine dinucleotide ($NADH/NAD^+$), but the high cost and instability of NADH hinder industrial scalability. Photoenzymatic regeneration of NADH, inspired by natural photosynthesis, provides a sustainable approach by utilizing solar energy to drive electron transfer, enabling efficient cofactor recycling and continuous enzymatic conversion of CO_2 (1).

In this study, a biomimetic ionic porphyrin-based platform was developed to enhance light-driven NADH regeneration and integrate it into a photoenzymatic CO_2 reduction system, demonstrating a scalable approach to solar-driven biocatalysis. The core innovation is the use of ZnTPyPBr, an ionic porphyrin photosensitizer that mimics chlorophyll's light-harvesting function while overcoming the limitations of conventional porphyrins. Ionic functionalization significantly improves hydrophilicity and charge separation, reducing charge recombination and aggregation, which are two major bottlenecks in nonionic porphyrin-based systems (2). The photonic efficiency of ZnTPyPBr results in a threefold higher NADH regeneration rate compared to its nonionic counterparts, offering a highly stable and efficient alternative to traditional semiconductor-based photocatalysts, which often suffer from poor stability and back-electron transfer losses (3).

The photoenzymatic membrane integrates a cascade enzymatic system immobilizing formate dehydrogenase (FDH), formaldehyde dehydrogenase (FaldDH), and alcohol dehydrogenase (ADH) to achieve CO_2 reduction to methanol. In this system, continuous NADH regeneration drives a sevenfold increase in methanol production compared to free enzyme systems, demonstrating the significance of sustained NADH availability in overcoming kinetic limitations (1). Additionally, the membrane modification with polydopamine (PDA) and polyethyleneimine (PEI) enhances enzyme stability and facilitates local CO_2 capture, further boosting reaction efficiency (4).

This study, which will be presented along with other potential photocatalytic platforms for cofactor regeneration, highlights the potential of bioinspired photonic materials for scalable solar-driven enzymatic processes, offering a sustainable alternative for biomanufacturing, artificial photosynthesis, and CO_2 utilization. By using ionic porphyrins for efficient cofactor regeneration, this approach aims at future developments in solar-driven biocatalysis, green chemistry, and renewable fuel production (3).

Plasmonically Enhanced Solar Water Splitting with TiO_2/Au/Pt Nanoparticles in three-dimensional porous PDMS Substrates

N. Albenge[1*], F. Laible[1], S. Glocker[1], and M. Fleischer[1]

[1]Institute for Applied Physics and Center LISA[+], Tübingen, Germany
[*]nicolas.albenge@uni-tuebingen.de

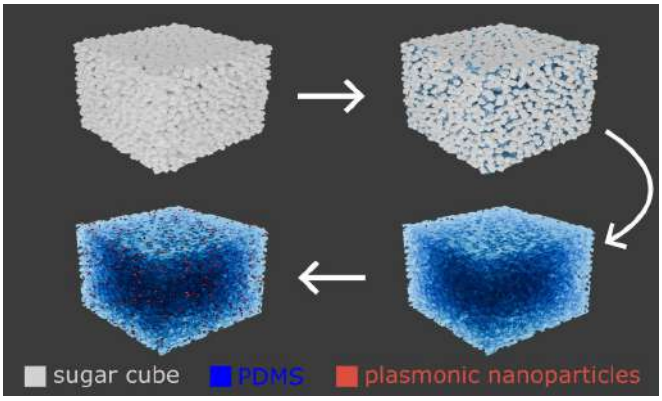
Abstract: Green hydrogen can be generated in a water-splitting process using solar energy and photocatalytic titanium dioxide. When this is brought into contact with gold and platinum nanoparticles and assembled on inner surfaces of transparent porous PDMS substrates for high absorption, the efficiency of the hydrogen generation reaction can be enhanced.

The current vastly growing global demand for ecologically green hydrogen (H_2) leads to many scientific studies on efficient H_2 generation based on renewable energy sources. Following the suggestions of the hydrogen ladder, the generated green H_2 should be used as the chemical itself, for example in the production of green ammonia for fertilizers, for hydrogenation processes or in steel production, and not as an energy source in cars or trucks [1]. In cases where there is no alternative to H_2, so far it is generated out of natural gas with a 99% share and thus drives climate change and globe pollution.

One method to generate green H_2 is electrolysis. Here, solar energy is indirectly transformed, using solar cells providing the necessary potential difference for water splitting reactions at two electrodes in a water bath. In this project, a more direct solar energy conversion method, namely photocatalysis, is investigated. Using the semiconducting photocatalyst titanium dioxide (TiO_2) with its large bandgap of 3.2 eV, light in the UV-regime leads to the creation of electron-hole pairs under photo-absorption with a potential difference high enough to drive water splitting reactions. Combining it with metallic nanoparticles (NPs), an increase in the water splitting efficiency can be observed [2]. This increase originates from the plasmonic behavior of gold (Au) NPs, which enable the absorption of wavelengths also in the visible spectrum. The excited localized surface plasmon of the Au particles can resonantly decay into hot electrons or holes that are injected into the conduction or valence band of TiO_2, providing more electron-hole pairs to enhance the redox reaction rates involved in water splitting. Efficiency can be further improved by reducing the amount of electron-hole recombination inside TiO_2. This can be achieved by adding catalytically active platinum (Pt) NPs [3].

Three-dimensional, highly porous PDMS structures that are fabricated by using commercial sugar cubes as a template (see Figure 1) [4] serve as substrates offering large inner surfaces for different material constellations realized out of TiO_2, Au and Pt (see Figure 2). In comparison to two-dimensional systems, these PDMS substrates can hold many more NPs, accessible to incoming light because of their transparency, enhancing absorption. A first constellation of a random NP distribution inside the three-dimensional substrate was achieved and its H_2 generation proven. The fabrication process, resulting structures and analysis by gas sensors will be presented.

Support by the Vector Stiftung (Grant number: P2021-0129) is gratefully acknowledged.



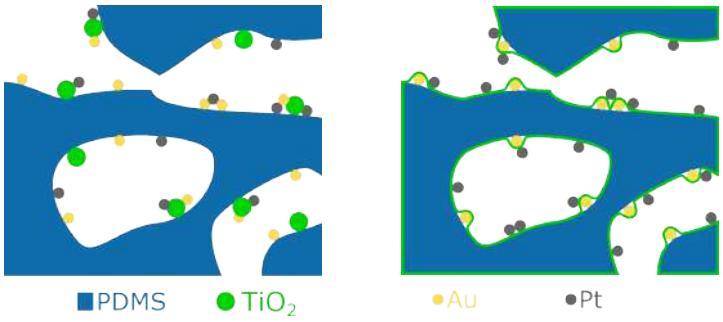


Fig. 1: PDMS substrate fabrication starting with a commercial sugar cube [4]. After filling the interstices between the sugar crystals with liquid PDMS and hardening the PDMS, the sugar cube can be dissolved in water. A three-dimensional transparent PDMS substrate with a large internal surface is realized. Residual PDMS-crosslinkers from its hardening process act as reducing sites for chemically grown metallic NPs.

Abstract: Perovskite thin films are promising materials for next-generation photovoltaic technologies, but their widespread adoption is limited by stability issues and lead toxicity. This study proposes plasmonic perovskite solar cells with Au@SiO_2 core-shell nanoparticles, which enhance efficiency, reduce the active layer thickness, and improve stability under real-world conditions.

Perovskite thin films have emerged as highly promising materials for next-generation photovoltaic technologies. Their solution-based fabrication process offers the potential to significantly reduce production costs, paving the way for widespread adoption of perovskite solar cells. However, two critical challenges hinder their large-scale implementation [1]: the instability of perovskites in real-world conditions and the reliance on toxic lead in their composition. This research aims to address these issues by developing plasmonic perovskite solar cells (PPSC) with enhanced power conversion efficiency, thinner active layers, and improved stability.

The proposed PPSC design has a multilayered structure. The base is a fluorine-doped tin oxide coated glass. A hole transport layer of PEDOT is followed by a cesium-lead-iodide perovskite layer, which may include a monolayer of gold core - silica shell (Au@SiO2) nanoparticles (NPs). The electron transport layer consists of either ZnO or TiO_2. Finally, a continuous electrical contact layer made of Au or Al thin film is deposited on top. This film serves both as a protective encapsulation surface, preventing perovskite degradation, and as a plasmonic cavity surface, where the electric field is enhanced in the gap between the Au@SiO_2 NPs monolayer and metal film, forming a hybrid plasmon polariton - gap modes [2].

Metal halide perovskite quantum dots (QDs) and clusters are critical for enhancing the efficiency of plasmonic solar cells [3]. Their band gap energy can be tuned by adjusting their size or composition. The photoluminescence of perovskite QDs is characterized by narrow emission bands and a high quantum yield, making them highly suitable for photovoltaic applications. The small size of the QDs, along with their tolerance to defects, ensures improved performance and durability. The use of perovskite QDs containing "inks" will enable scalable, cost-effective fabrication methods, such as spin-coating, to produce large-area solar cells.

The finite-difference time-domain computational method is used to estimate the enhancement of light absorption and the electric field, as well as for design optimization for enhanced efficiency and reduce material usage. By incorporating Au@SiO_2 NPs and optimizing the multilayer architecture, the proposed solar cells are expected to increase power conversion efficiency, reduce the use of toxic lead, and improve stability under atmospheric conditions.

The results of FDTD calculations of the absorption spectra of the solar cell (glass substrate – ITO (300 nm) – PEDOT (100 nm) – perovskite $CsPbI_3$ (100 nm) – ZnO (50 nm)) without plasmonic part and the plasmonic

solar cell (glass substrate – ITO (300 nm) – PEDOT (100 nm) – Au@SiO_2 NP monolayer (Au core diameter 40 nm, SiO_2 shell 3nm) – perovskite $CsPbI_3$ (100 nm) – ZnO (50 nm) – Al (100 nm)) containing the plasmonic cavity metasurface are peresenten in Fig. 1(a). Due to the thin-film structure of the solar cell, the spectra contain interference fringes. However, it can be seen that in the entire visible range and in the near IR up to 1200 nm, the presence of a plasmonic metasurface provides a noticeable enhancement of light absorption. Fig. 1(b) demonstrates the spectral dependence of the absorption enhancement factor for perovskite solar cell containing plasmonic metasurface in relation to the same solar cell without plasmonic metasurface. It is seen that the maximum enhancement is achieved at 960 nm that most probably is related to the excitation at this wavelength of the plasmon gap mode which is the eigenmode of the Au@SiO_2 NP monolayer – Al film plasmonic cavity. The assumption that the wavelength of 960 nm corresponds to the plasmonic cavity gap mode is confirmed by calculations of the absorption spectra for different distances between the surfaces of neighboring Au@SiO_2 NPs in the monolayer, Fig. 1(c). It can be seen that decreasing the distance between the NPs leads to a blue shift of the band with a maximum at 960 nm, while the spectral position of the other bands remains unchanged. Thus, the calculations have proven the effectiveness of incorporating a plasmon metasurface inside the photoactive layer of a solar cell to enhance light absorption.

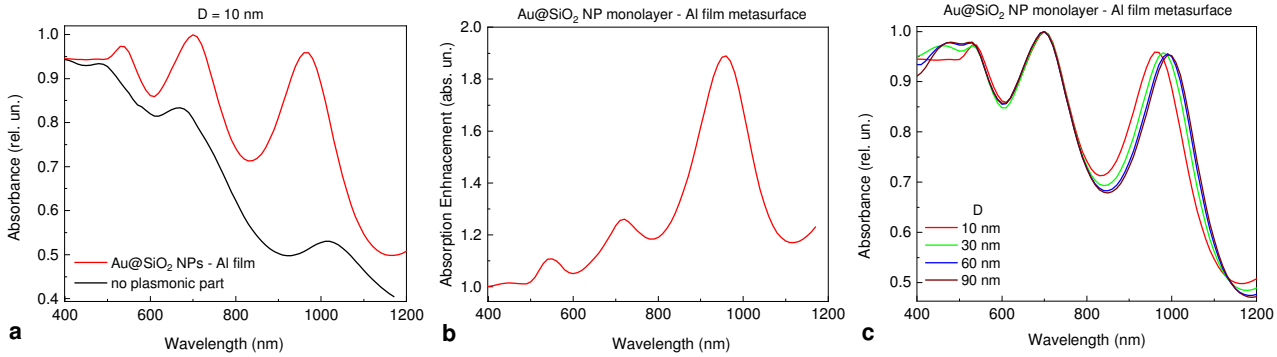

Figure 1. (a) – Calculated absorption spectra of perovskite solar cell with Au@SiO_2 NP monolayer – Al film plasmonic cavity metasurface (red line) and the same solar cell without plasmonic metasurface. (b) – Spectral dependence of the absorption enhancement factor for perovskite solar cell containing plasmonic metasurface in relation to the same solar cell without plasmonic metasurface. (c) – Calculated absorption spectra of perovskite solar cell with Au@SiO_2 NP monolayer – Al film plasmonic cavity metasurface with different distance D between the surfaces of neighboring Au@SiO_2 NPs in the layer. Abstract: A scalable plasmonic gold nano-dendrite catalyst enhances multiple electron transfer and carbon-carbon (C–C) coupling in CO_2 reduction reactions (CO_2RR). The dendritic morphology allows tuning of plasmonic resonance energies to optimize reaction efficiency, demonstrating a promising approach for enhancing product selectivity in CO_2 conversion.

Photocatalysis plays a pivotal role in sustainable energy conversion by driving chemical transformations such as CO_2 reduction into valuable products. However, selectively promoting multi-electron transfer pathways and C–C coupling remains a significant challenge[1]. To address this, we developed plasmonic gold nano-dendrites using a single-step electrodeposition process under controlled current and voltage conditions. By systematically varying the deposition parameters, we were able to tailor the dendrite morphology, optimizing localized surface plasmon resonance (LSPR) effects to maximize catalytic performance[2].

The structural and optoelectronic properties of the gold dendrites were characterized using scanning electron microscopy (SEM), X-ray diffraction (XRD), and high-resolution cathodoluminescence spectroscopy (CL). CL analysis provided critical insights into local photon density of states (LDOS) and hotspot formation, demonstrating the excitation of abundant plasmonic resonances at high-curvature regions within the dendritic architecture, which are essential for plasmon-driven charge transfer. CO_2RR efficiency was evaluated in a standardized photocatalytic reactor under continuous-wave (CW) solar illumination. Gas chromatography was employed to identify and quantify the reaction products, confirming an increased yield of multi-electron reduction products. Photoelectrochemical (PEC) measurements provided direct insights into hot electron generation and internal quantum efficiency. Additionally, spectral response analysis with a monochromator-assisted CW light source revealed wavelength-dependent catalytic activity, with peak efficiency observed in the visible range. High-resolution CL spectroscopy further demonstrated the excitation of abundant plasmonic resonances at high-curvature regions within the dendritic architecture.

Electrochemical CO_2RR experiments demonstrated that Au dendrites efficiently produced C_{2+} products. Upon light illumination, the Faradaic efficiency (FE) for C_2 species increased compared to electrochemical measurements in the dark. The catalysts exhibited improved charge transfer kinetics and enhanced multi-electron pathways, driven by plasmon-induced charge separation. Spectroscopic analysis confirmed prolonged hot carrier lifetimes, correlating with increased catalytic activity and selective C–C bond formation.

Catalyst degradation was assessed post-reaction using energy-dispersive X-ray spectroscopy (EDS) and XRD to analyze structural integrity and elemental composition changes after prolonged electrochemical and photoelectrochemical reduction. The results showed that the Au dendrites maintained their structural and catalytic stability over extended reaction cycles.

This study demonstrates the potential of tailored gold nano-dendrites for plasmon-enhanced CO_2 reduction, offering a tunable approach for selective multi-electron transfer and C–C bond formation. By leveraging plasmonic excitations, reaction pathways can be directed toward the formation of C_2 species through energy transfer mechanisms. Moreover, optimizing the optical response of photocathodes with plasmonic resonances introduces a new degree of control in designing highly efficient and selective photo-electrocatalysts. Future research will focus on dynamic plasmonic tuning through external stimuli to further enhance catalytic performance, with the goal of advancing sustainable fuel production and carbon valorization.

Abstract: Plasmon excitations in metals generate hot carriers, crucial for photoelectric conversion. While conventional theories attribute carrier generation to Landau damping, recent experiments reveal an unexplained IQE peak. Our theory shows that the radiative coupling produces resonant effects near the light energy, offering a compelling explanation for the observed IQE enhancement.

Fundamental excitations in a metallic system can be categorized into two distinct types: plasmon excitations and electron-hole pair (e-h pair) excitations. It is well established that optical excitation of plasmons at a metal surface can lead to the generation of high-energy e-h pairs, known as hot carriers, which exist beyond thermal equilibrium. The injection of these hot carriers into semiconductors or molecular systems facilitates photoelectric conversion within the visible to near-infrared spectral range. This phenomenon is particularly promising for applications in photovoltaic and photocatalytic devices [1]. However, to enhance conversion efficiency, further research is necessary. Achieving efficient photoelectric conversion requires the rapid transfer of plasmonic energy into hot carriers. Conventional theoretical approaches have typically described the hot carrier generation as a relaxation process caused by Landau damping [2]. It has been argued by Yamada [3] that this damping arises from the residual longitudinal interactions between plasmon and electron-hole pairs in the Bohm & Pines theory [4], and since this relaxation rate is described in a manner independent of the incident photon energy, the internal quantum efficiency (IQE) spectrum, which quantifies photoelectric conversion efficiency normalized by photon absorption, has been considered to be proportional to the density of states of electron-hole pair excitation. However, recent experimental observations indicate that the IQE spectrum exhibits a pronounced peak near the plasmon resonance energy [5]. This spectral feature cannot be solely attributed to a relaxation mechanism, highlighting the need for a more microscopic theoretical framework. To address this unresolved issue and explore new avenues for efficient photoelectric conversion, we have formulated a novel theory of metal optical responses. Bohm and Pines quantized plasmon and e-h pair excitations respectively, and constructed a theoretical model that can discuss the energy transfer between them only in bulk systems without coupling to light [4]. Therefore, we expanded their theory to finite systems with surfaces and constructed a theory that describes the further generalized optical response of idealized metals. In our theory, the Hamiltonian of the thin metallic film shown in Fig. 1(a) is expressed as follows:

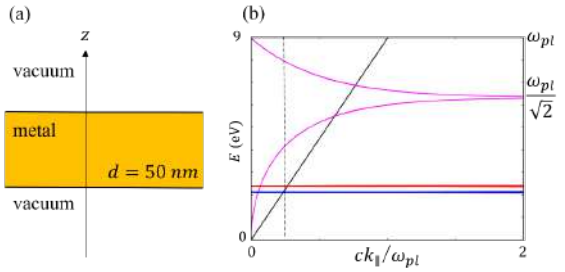

Fig.1: (a) Schematic view of metal film. (b)Dispersion relation of electrostatic plasmon (magenta) and specific e-h pairs (red,blue).

$$H = \sum_{\mu\mu'} \left(\hbar\omega_{\mu}^{(\mathrm{pl})}\delta_{\mu\mu'} + Z_{\mu\mu'}(\omega)\right)\hat{A}_{\mu}^{\dagger}\hat{A}_{\mu'} + \sum_{\nu} \hbar\omega_{\nu}^{(\mathrm{e-h})}\hat{B}_{\nu}^{\dagger}\hat{B}_{\nu} + \sum_{\mu\nu}\left(g_{\mu\nu}^{(L)} + g_{\mu\nu}^{(T)}(\omega)\right)A_{\mu}^{\dagger}\hat{B}_{\nu} + \mathrm{H.c.} \quad (1)$$

where $\hat{A}_{\mu}^{\dagger}(\hat{A}_{\mu})$is creation (annihilation) operator of plasmon and $\hat{B}_{\nu}^{\dagger}(\hat{B}_{\nu})$is creation (annihilation) operator of e-h pair. $\mu\,(=\boldsymbol{k}_{\parallel},m)$ is the index for in-plane and z-direction wavenumbers of the plasmon and $\nu\,(=\boldsymbol{k}_{\parallel},\boldsymbol{K}_{\parallel},n,n')$ is the index for the in-plane and z direction wavenumbers of the e-h pair excitations, respectively. $\hbar\omega_{\mu}^{(\mathrm{pl})}\left(\hbar\omega_{\nu}^{(\mathrm{e-h})}\right)$ are the energy quanta of plasmon (e-h pair) and expressed as follows:

$$\hbar\omega_{\mu}^{(\mathrm{pl})}=\frac{\hbar\omega_{pl}}{\sqrt{2}}\left[1-(-1)^{m}e^{-|\boldsymbol{k}_{\parallel}|d}\right] \quad (2)$$

$$\hbar\omega_{\nu}^{(\mathrm{e-h})}=\frac{\hbar^{2}}{2m^{*}}\left[\boldsymbol{k}_{\parallel}^{2}+2\boldsymbol{k}_{\parallel}\cdot\boldsymbol{K}_{\parallel}+\frac{\pi^{2}(n'^{2}-n^{2})}{d^{2}}\right] \quad (3)$$

where ω_{pl} represents the plasma angular frequency. $Z_{\mu\mu'}(\omega)$ is the radiative correction for plasmon, and the dispersion relation for coupled system of light and plasmon is given by the equation $\mathrm{Det}|S|=0$ with the matrix $S_{\mu\mu'}$:

$$S_{\mu\mu'}=\left(\hbar\omega_{\mu}^{(\mathrm{pl})}-\hbar\omega\right)\delta_{\mu\mu'}+Z_{\mu\mu'}(\omega) \quad (4)$$

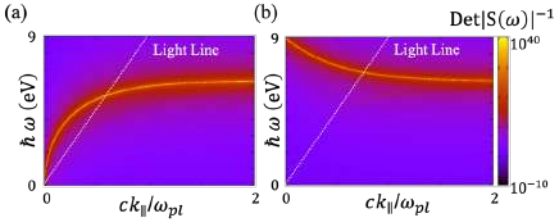

Fig.2: Dispersion relation for coupled system of light and plasmon in Ag film with thickness of 50nm. SR-SPP and LR-SPP appear as a surface mode of even plasmon (a) and odd plasmon (b).

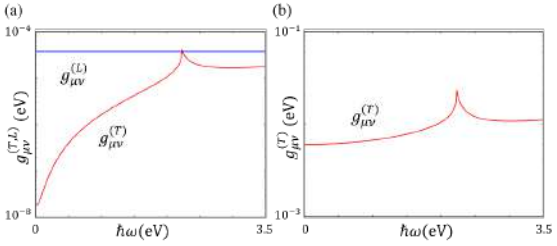

Fig.3: Comparison of incident photon energy dependency of $\boldsymbol{g^{(L)}}$ (blue) and $\boldsymbol{g^{(T)}(\omega)}$ (red). (a) m=0, n= 185, n'=220. (b) m=0, n= 180, n'=220.

Our analysis, applied to a 50nm-thick Ag film, reveals the well-known dispersion of Short- and Long-Range Surface Plasmon Polariton (S(L)R-SPP) (see Fig. 2(a), (b)). $g^{(L)}$ is the residual longitudinal interactions between plasmon and e-h pairs and gives landau damping as already mentioned. However, in the case of the surface system with light coupling, radiative transverse coupling $g^{(T)}(\omega)$ occurs. Comparing $g^{(L)}$ and $g^{(T)}(\omega)$, we get the interesting results regarding the parity of the polarization in z-direction. When the parity of plasmon (m) and e-h pairs (n'-n) are mismatched, $g^{(T)}(\omega)$ is less than $g^{(L)}$ regardless of incident photon energy (see Fig. 3(a)). However, when they are matched, we found that some combinations of plasmon and e-h pairs cannot interact via longitudinal field but can be coupled strongly via transverse field (see Fig. 3(b)). This fact is not addressed by conventional theories based on Landau damping, which considers only residual longitudinal interactions. Moreover, the radiative coupling $g^{(T)}(\omega)$ depends on frequency and increases resonantly near the light energy, which is a highly promising clue to explain the experimentally observed peak structure of IQE. In our future work, we plan to investigate the population dynamics of this system and analyze in detail the novel hot carrier generation process arising from this radiative coupling.

Enhancing Anti-reflective Coating Performance through Binary Optimization of Structural Parameters with Concurrent Material Selection and Thickness Optimization

S. Jung[1] and E. Lee[1*]

[1] Department of Electronic Engineering, Kyung Hee University, Republic of Korea
[*]corresponding author: eleest@khu.ac.kr

Abstract: Optimizing planar multilayer coatings is challenging due to vast parametric space and complex requirements. This study proposes an adaptive scheme using active learning for concurrent material selection and thickness optimization. Applied to antireflective coatings for infrared camera, it identified a five-layer design with 0.47% reflectance, reducing computational cost.

Optimizing planar multilayer optical coatings remains challenging due to the extensive parametric space and complex figure-of-merit constraints. This study presents an adaptive thickness approach incorporating active learning for simultaneous material selection and thickness optimization. Thickness is adaptively sampled within a continuous spectrum, while material status is represented as a discrete binary variable to enable flexible design exploration. Within this scheme, we evaluate three machine learning (ML) models—Gaussian process regression (GPR)[1], factorization machines (FM)[2], and field-aware factorization machines (FFM)[3]—as surrogate functions, alongside ML-specific optimization algorithms such as discrete particle swarm optimization (PSO)[4], artificial bee colony optimization (ABC)[5], and simulated annealing (SA)[6].

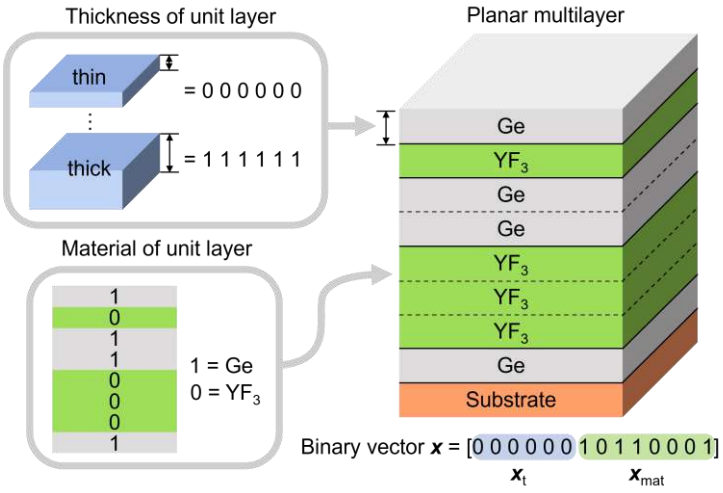

Figure 1. Schematic diagram of encoding optical coatings to binary vector

Optimization results showed that nearly all algorithms identified lower FoM values compared to conventional optimization with fixed thickness, with the optimized structures exhibiting greater thickness variation. In the benchmarking study of Ge-YF_3 antireflective coating for a Si substrate, the adaptive scheme discovered a high-performance five-layer structure using a more sparse dataset than the conventional

optimization with fixed thickness, achieving an average reflectance of 0.47%.

Abstract: We present a Tandem Neural Network (TNN) approach for the inverse design of Bullseye cavities, optimizing Purcell enhancement and emission efficiency. This method reduces computational demands, integrates fabrication constraints, and generalizes across materials, enabling efficient design of photonic structures with high performance and applicability to other complex cavity systems.

Developing and optimizing photonic devices and other nanostructure electromagnetic devices presents a computationally intensive task. Much optimization relies on finite-difference time-domain or finite element analysis simulations, which can become very computationally demanding for finely detailed structures and dramatically reduce the available optimization space. [1] Circular Bragg Grating cavities (aka “Bullseye”) are widely used in single photon sources due to their moderate Purcell enhancement and excellent emission directionality. Although fundamentally simple, the design of Bullseye cavities demands computationally intensive and time-consuming iterations for optimization, and is limited in performance due to designer intuition, particularly when the number of adjustable parameters is large. Therefore, the inverse design of a Bullseye cavity is ideal, where geometry is determined as a function of target cavity performance instead of calculating cavity performance based on geometry. Here, we demonstrate that a Tandem Neural Network (TNN) architecture for the inverse design of Bullseye cavities can optimize Purcell enhancement and collimation efficiency at target resonant wavelengths within a training dataset. We describe how to implement this approach for a dielectric-based Bullseye cavity with a resonant wavelength of 690nm, achieving a comparatively high Purcell enhancement of 32 and an extraction efficiency of 0.60. We also report the fabrication of Bullseye cavities and the measured optical quality factors (Q) for some TNN-designed Bullseye cavities, which match the design well. Furthermore, we demonstrate the technique's generalizability to other materials and Bullseye geometries. We also illustrate how to incorporate fabrication constraints to tailor the design to minimum feature sizes and/or layer thickness. This technique not only significantly reduces design and simulation time while uncovering new favorable geometries for Bullseye cavities but could also be extended to other multiparameter photonic cavity systems.[2]

Abstract: Metasurface color routers surpass color-filter arrays in image sensors by directing specific wavelengths of light to corresponding pixels. We inverse-designed a metasurface color router with high efficiency using a genetic algorithm accelerated by a U-net. The fabricated router shows efficiencies with 73 %, 69 %, and 45 % for RGB.

Conventional image sensors discriminate colors through the absorption by color filter arrays (CFAs). Since CFAs transmit only light of the desired color and absorb other colors, the theoretical maximum efficiency of CFA-based image sensors is restricted to approximately one-third. By contrast, metasurface color routers (MCRs), which are made of dielectric nanostructures that refract light depending on the wavelength, discriminate colors without absorption losses by directing light with specific color into the desired pixels in an image sensor. Therefore, an MCR can overcome the fundamental limitations of conventional image sensors with CFAs and show improved efficiency in color imaging as shown in Fig. 1 [1, 2]. In this work, we present an MCR with high routing efficiency that is enabled by inverse design using an accelerated genetic algorithm (GA) and demonstrated its enhanced performance experimentally.

GAs have been used to optimize MCR structures. However, GA-based optimization often faces challenges because simulating candidate structures is computationally expensive, limiting the exploration of potential designs. To address this, we replaced direct simulations with a U-Net neural network, trained to predict optical responses of given structures, thereby accelerating GA-based optimization. We trained the U-Net with electric-field (E-field) distribution datasets for approximately 140,000 structures, each consisting of a 16×16 array of randomly placed silicon nitride (Si_2Ni_3) nanopillars at three wavelengths (450 nm, 550 nm, and 650 nm for blue, green, and red, respectively). These datasets were produced using a finite-difference time-domain (FDTD) simulator (Lumerical FDTD). Once trained, the U-Net rapidly provides E-field dataset for any given structure, allowing the GA to explore millions of potential designs far more efficiently. After over 4,000 iterative generations, we identified an optimized MCR with peak routing efficiencies of 72.9% at 650 nm (red), 68.6% at 550 nm (green), and 45.1% at 450 nm (blue) as shown in Fig. 2.

The optimized MCR design was fabricated on a quartz substrate by depositing a 600 nm-thick Si_3N_4 layer, defining structures with an electron-beam lithography, and etching using inductively coupled plasma-reactive ion etching. To verify the routing performance, hyperspectral imaging with a xenon lamp and a high-numerical-aperture objective was performed on the fabricated MCR. Figure 2(b) shows both simulation and experimental results simultaneously and confirms that the two results are in excellent agreement. It means that our GA accelerated by U-Net neural network works well and is very efficient in optimizing MCR structure.

This study demonstrates a powerful framework for accelerating inverse-design processes, significantly

reducing computational overhead while enabling a broader exploration of design space. We expect that this approach not only paves the way for future high-efficiency MCRs but also can be applied for designing a wide range of nanophotonic device.

Abstract: We use synthetic photonic lattice constructed from two coupled fiber loops to design an optical convolution processing unit, achieving the arbitrary convolution operations. The convolution process is completed with two phase modulators and two intensity modulators, which the convolution kernels can be dynamically reconfigured through phase and intensity modulation.

Main results:

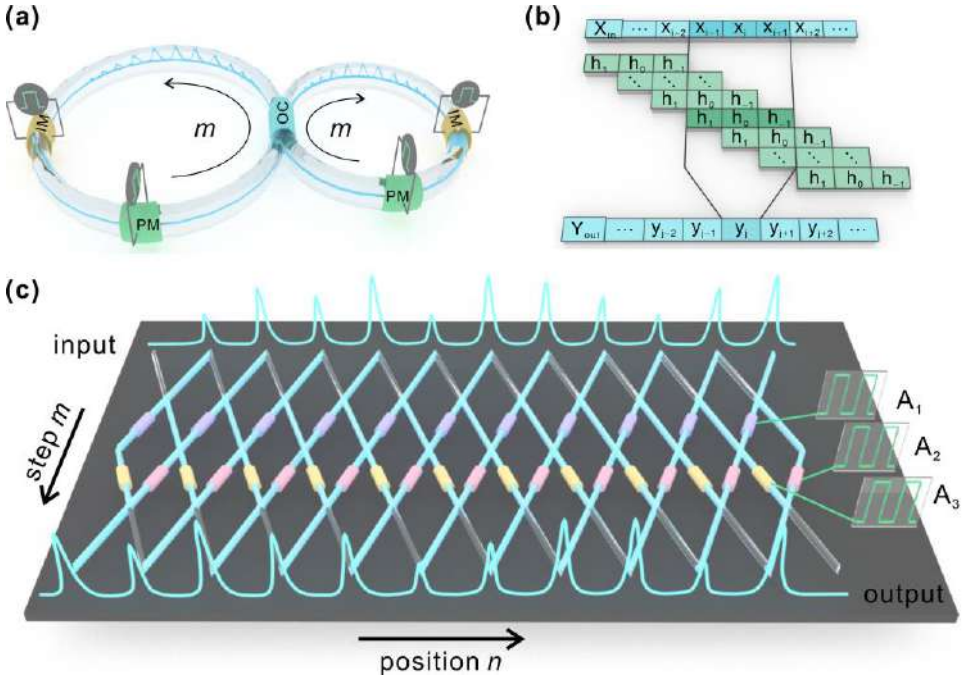

Fig. 1 Schematic diagram of the synthetic photonic lattice convolutional operation unit. **a.** Schematic of coupled fiber circuit to create the temporal lattice. **b.** Schematic of 2D convolution. **c.** Schematic of the synthetic lattice drawn based on the pulse evolution in the two coupled fiber loops in (a) and the convolution operation cell indicated by the blue grid.

Figure 1(a) and 1(c) show the evolution and construction of a synthetic temporal lattice through the mapping of pulses in two coupled fiber loops. The pulse sequences can be conceptually mapped to the "node-link" model by position n and step m of the synthetic temporal lattice. Additional phase shifts ϕ_n^m, ψ_n^m and intensity modulations G_n^m, F_n^m are introduced via a phase modulator (PM) and a Mach-Zehnder modulator (MZM)[1]. A convolution kernel of size $1\times M$ is designed by utilizing M steps of optical pulse propagation. Figure 1(b) constructs the most common and versatile 1×3 convolution kernel $[h_1\ h_0\ h_{-1}]$. The relevant pulse X_{in} is injected into the short loop at step $m = 0$, and the convolution result is obtained after two steps of modulation

$$\begin{cases} u_n^3 = C_1[A_v^1 A_v^2 u_{n-1}^0 + (A_v^1 A_u^2 + A_u^1 A_v^2)u_{n+1}^0 - (A_u^1 A_u^2 / t^2)u_{n+3}^0] \\ v_n^3 = iC_2\left[A_v^1 A_v^2 u_{n-3}^0 + (A_u^1 A_v^2 - A_v^1 A_u^2 t^2)u_{n-1}^0 + A_u^1 A_u^2 u_{n+1}^0\right] \end{cases}, \quad (1)$$

where, u_n^m and v_n^m represent the complex amplitudes of the pulses in the short and long loops, respectively, $\sin^2(\beta)/\cos^2(\beta)$is the splitting ratio of the central optical coupler ($\beta \in [0, \pi/2]$), and $A_u^m = G_n^m e^{i\phi_n^m}$, $A_v^m = F_n^m e^{i\psi_n^m}$ are the overall phase and intensity modulations applied to the loops. Here, $C_1 = -\sin^2(\beta)\cos(\beta)$, $C_2 = \sin(\beta)\cos^2(\beta)$, $t^2 = \sin^2(\beta)/\cos^2(\beta)$. By setting $X_{in} = [\ldots\ x_{i-1}\ x_i\ x_{i+1}\ldots]^T = [\ \ldots\ u_{n_1-2}^0\ \ u_{n_1}^0\ \ u_{n_1+2}^0\ \ \ldots\ ]^T$, $Y_{out} = [\ldots\ y_{j-1}\ y_j\ y_{j+1}\ldots]^T = [\ldots\ u_{n-1}^M\ \ u_{n+1}^M\ \ u_{n+3}^M\ldots]^T$, we obtain $y_j = h_1 x_{i-1} + h_0 x_i + h_{-1} x_{i+1}$, which corresponds to the classical form of convolution

$$y_j = H_{j,i} x_i = \sum_i h_{j-i} x_i = \sum_i h_i x_{j-i}\,. \quad (2)$$

Figure 2 demonstrates the process of convolution using the temporal photonic lattice convolution processing unit, where the convolution kernel [1 2 1] is employed. The figure illustrates the image convolution processing flow (the left figure), the corresponding electronic control signals and optical signal flow (the middle figure), the experimental setup (the right figure), and the evolution of the convolution pulse amplitude in the temporal photonic lattice (The bottom image in the middle).

Abstract:
Factorization Machine (FM) has been used for effectively designing optical systems, it is limited in expressing complex systems. To overcome this limitation, we propose higher-order factorization machine (HOFM). Compared to FM, HOFM predict more accurately than FM and find better optimal structures in optical systems.

Introduction

Optimizing structural parameters is important for improving performance in material science. The 2nd-order factorization machine (FM)[1] has been used for modeling optimal structures and predicting optical systems by factorizing pairwise interactions between two variables. However, FM has limitations in capturing intricate relationships among numerous system features and multiple variables. To overcome this limitation, we use a higher-order factorization machine (HOFM)[2], which has supplementary parameters up to the third interaction. In this study, we verify the predictive fidelity and efficiency of the surrogate model in optimizing optical design (e.g. Transparent Radiative Cooler (TRC)[3]) by 3rd-order FM compared to 2nd-order FM. To evaluate the designed structure, we define figure of merit (FOM), given by:

$$\mathrm{FOM} = \frac{10\int_{300}^{2500}\left(TI_{ideal}(\lambda) - TI_{designed}(\boldsymbol{\lambda})\right)^2 \mathrm{d}\lambda}{\int_{300}^{2500} S(\boldsymbol{\lambda})^2 \,\mathrm{d}\lambda}, \quad (1)$$

where , $S(\boldsymbol{\lambda})$, $TI(\lambda)$ respectively denotes the solar spectral irradiance, and transmitted irradiance.

Results and Discussion

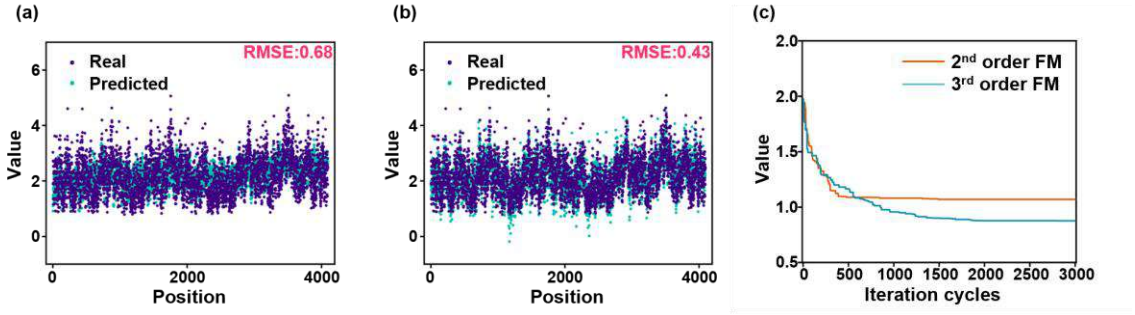

Figure1. The performance comparison between 2nd-order FM and 3rd-order FM with a TRC as a testbed. (a) and (b) is the accuracy of the surrogate model obtained from 2nd-order FM and 3rd-order FM, respectively. (c) Convergence of FOM values for iterative FMs integrated with active learning algorithms.

For the benchmarking analysis, the FOM of the TRC system is investigated by evaluating all possible material combinations and plotted as purple dots in Fig1. We made surrogate model obtained from FMs by training 500 randomly sampled binarized discrete data points in 2^{12} (= 4,096). The value of these 2nd-order and 3rd-order FM's surrogate models are shown as cyan dots in Fig.1 a and Fig.1 b respectively. 3rd-order FM shows better accuracy of TRC system than 2nd-order FM (Figs. 1a,b). The fact that the RMSE of 3rd-order FM (0.43) is lower than that of 2nd-order FM (0.68) supports it. This can be concluded as showing that the third order interactions are helpful for capturing the complex features in optical systems.

We perform active learning combined with both 2nd order or 3rd order FM (Fig. 1c) 10 times, each with a different initial training dataset for ensuring the reliable results. Solid lines denote the average minimum FOM values with 10 different datasets for each active learing iteration. It can be guaranteed that active learning combined with 3rd-order FM finds better optical structures on average.

The performance analysis demonstrates the enhanced surrogate modeling capabilities and optimization efficiency of 3rd-order FM compared to 2nd-order FM. Accordingly, our study indicates that 3rd-order FM-based active learning serves as a highly effective approach for material design, yielding optimally refined results. Moreover, we anticipate that quantum computing techniques can be incorporated into this 3rd-order FM active learning framework to optimize large-scale material optimization [4, 5].

Abstract: We demonstrate the design of nanoscale phonon polariton propagations by combining artificial intelligence and nanophotonics. Using neural networks and twisted α-MoO_3 multilayers, we achieve desired polariton propagations such as canalization and bi-canalization in unexplored frequency ranges, showcasing a powerful method for on-demand control of light at the nanoscale.

The field of nano-optics or nanophotonics has advanced rapidly, enabling unprecedented control of light at the nanoscale. One of the main driving forces behind this progress is the discovery of a variety of polaritons in van der Waals[1,2] (vdW) multilayers with never-before-observed properties, such as unidirectional[3] or ray-like propagations[4]. However, despite these exciting advances, nano-optics still presents a major limitation: obtaining propagations on demand, i.e. by design.

In this work, we overcome this limitation through the combined use of a **neural network** a**nd twisted polaritonic multilayers (Fig. 1)**. Our method enables **inverse design**, making it possible to **demonstrate desired (and thus novel) polariton propagations** by obtaining accurate predictions of subsequently fabricated multilayer configurations. Interestingly, this method efficiently handles possible system degeneracies, identifying multiple multilayer structures that give rise to the same desired propagations at the nanoscale.

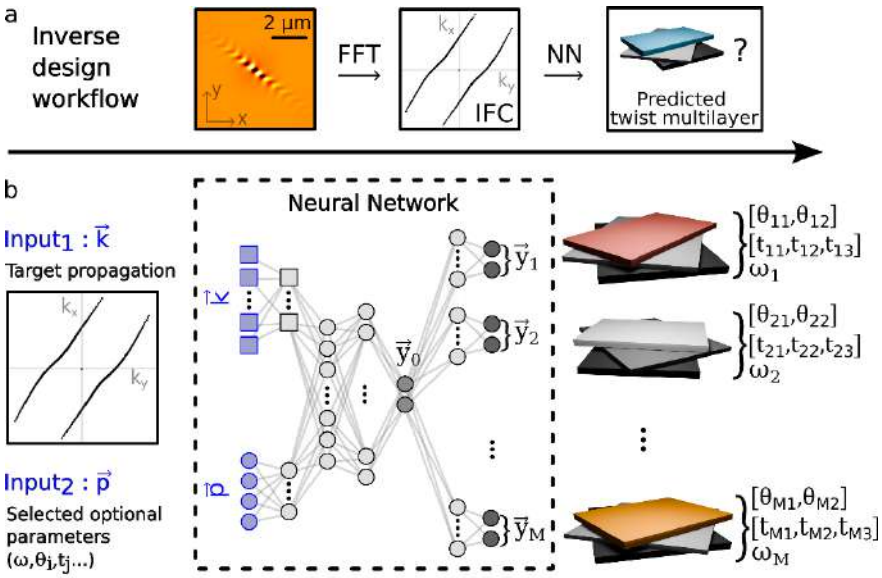

Figure 1: Designing nanoscale light propagation by combining deep learning and twistoptics. a) Schematic representation of the inverse design workflow using a NN in twistoptics. The desired polaritonic propagation in real space is transformed into an IFC that serves as input1 to the NN which predicts the optimal multilayer structure. b) The NN operates as a unified model with a set of M branches that allow finding multivalued solutions. The overall NN, trained with the customized loss function as described in ref. 5, accurately predicts the structure parameters ($\vec{\theta}$, $\vec{t}$, and ω) for one or multiple configurations.

Abstract: Different types of newly synthetized eco-friendly, low-cost carbon quantum dots (CDs) are evaluated to achieve carbon-based laser devices utilizing planar micro-cavities. The results constitute a step forward towards developing alternative eco-friendly carbon-based light-emitting devices aimed to replace current ones based on costly rare-earth and toxic metal elements.

In the last years, intense research efforts have been made in search of new strategic luminescent materials aimed to replace costly rare-earth and toxic metal elements as well as scarce semiconductors. On this account, a unique emerging class of metal-free luminescent materials known as carbon dots (CDs) has been successfully developed via low-cost methods, exhibiting intense photoluminescence and high stability together with excellent biocompatibility and environmental sustainability [1-3]. The outstanding properties of this promising new material has led to the development of proof-of-concept applications in sensing, photocatalysis, and bio-imaging among other fields. However, most of the reported CDs exhibit broad emissions that hinder their implementation in practical applications where commercial semiconductor quantum dots, rare earths and organic dyes are commonly used (LEDs, bio-labeling detection…). For this reason, CDs systems displaying narrowband emissions are essential to achieve the required technological breakthrough for the development of cutting-edge practical applications.

In this work, we made use of the excellent fluorescence properties of our synthetized metal-free, eco-friendly, and low-cost CDs to realize a CDs laser system with reduced linewidth [3]. Sputtered planar nano-photonic structures composed of low-loss materials were assembled to form a Fabry-Perot laser planar micro-resonator that allow exceptionally high reflectance spectral regions. This architecture realizes an excellent electromagnetic field confinement in the CDs gain media, thus providing appropriate optical gain to the system. Upon supplying an adequate amount of pump power, laser threshold is observed and single-mode narrow blue laser emission is finally achieved. The results constitute a step forward towards the development of novel eco-friendly carbon-based light-emitting devices.

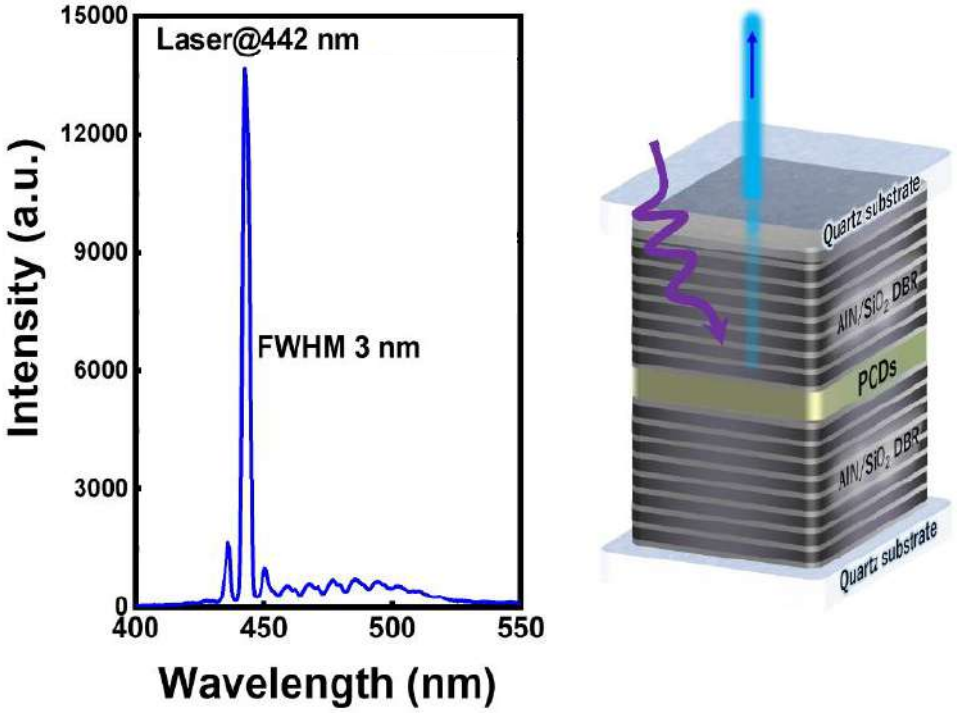

Figure 1: Narrowband laser emission from a CD-based laser system. Pump wavelength corresponds to UV radiation and lasing wavelength falls within the blue spectral region. A sputtered planar micro-cavity is utilized as micro-resonator.

AlGaInAs/InP microcavities for unidirectional and single mode lasing

You-Ling Chen
State Key Laboratory of Integrated Optoelectronics, Institute of Semiconductors, Chinese Academy of Sciences, Beijing 100083, China
*corresponding author: ylchen@semi.ac.cn

Abstract: A dual-port square microresonator for single-mode lasing has been fabricated, capable of providing two optical sources simultaneously for optical signal processing. Moreover, a deformed circular-side triangular microresonator is fabricated with unidirectional light emission, which has potential applications in portable and highly sensitive far-field detection of nanoparticles.

1. Introduction

Whispering-gallery mode (WGM) optical microcavities have found a wide range of applications such as highly sensitive bio/chemical sensing, and microlasers. However, light emission is isotropic in a traditional WGM microlaser. To realize efficient extraction and collection of light, the emission should be tailored. Here we report two schemes of realizing directional laser emission using semiconductor microcavities, benefiting the integration with other optoelectronic devices.

2. Dual-port square microresonator for directional single-mode lasing

For the cavity material of AlGaInAs quantum wells, we demonstrate experimentally a dual-port square microresonator for single-mode lasing with a side-mode-suppression ratio (SMSR) exceeding 40 dB. By connecting waveguides at two opposite vertices, the quality factor for the antisymmetric mode (ASM) is much higher than that of the symmetric mode (SM), enabling nondegenerate single-mode lasing.

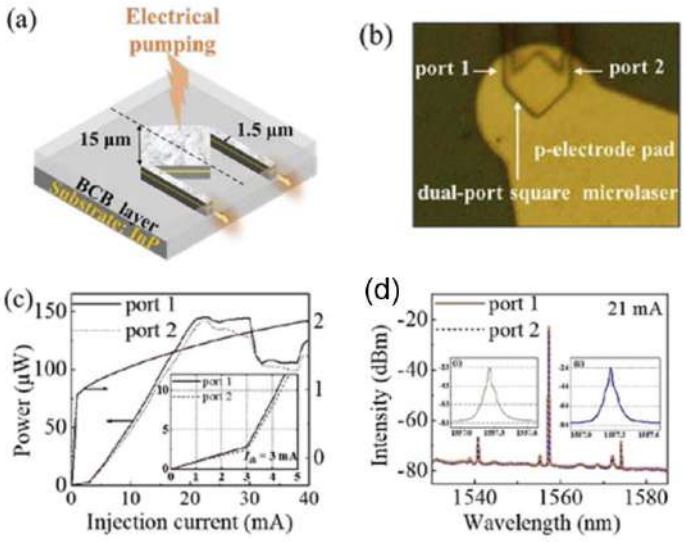

Fig. 1 (a) Schematic diagram of the dual-port square microcavity. (b) Microscopic image of the microlaser. (c) Output power coupled to MMF from two ports and V-I curve at 293 K versus continuous injection current; the inset is the enlarged view of the V-I curve for the injection current range of 0-5 mA. (d) Emission spectra for ports 1 and 2 independently at the injection current of 3 mA.

3. Deformed circular-side triangular microresonator for unidirectional lasing

A waveguide-connected deformed circular-side triangular microresonator (CTM) is designed and fabricated, as illustrated in Fig. 2.

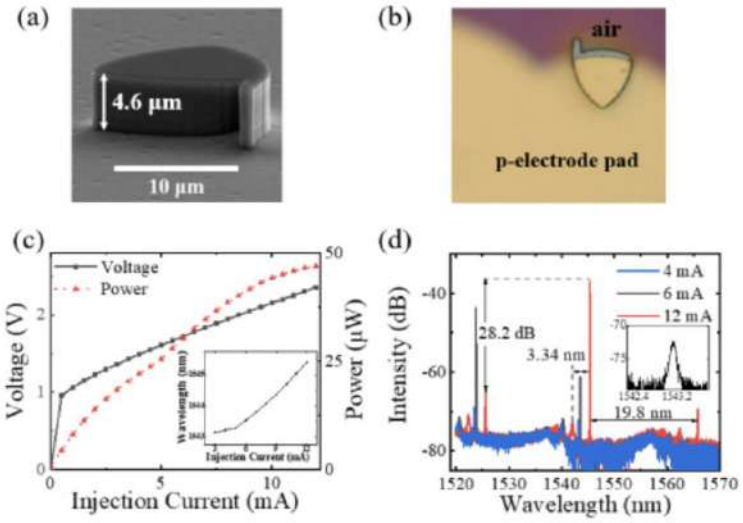

Fig 2. (a) SEM image of the circular side triangular microlaser after ICP etching. (b) Microscopic image of the CTM with p-electrode. (c) Integral ball output power and voltage versus continuous-wave injection current. The inset shows the wavelength of the main lasing mode versus the injection current. (d) Lasing spectra at injection currents of 4, 6, and 12 mA. The inset shows the detailed spectra at 4 mA near the wavelength of 1543.15 nm.

The far field light emission pattern is illustrated in Fig. 3. Fig. 3 (b) is the detailed experimental far field pattern for $I = 12$ mA. Unidirectional light emission from arc side 1 with a divergence angle of about 38° is obtained.

Abstract: The work demonstrates fabrication of the laser cavity with broken symmetry based on bound states in the continuum (BICs). A fabrication process for a 1D dielectric grating was developed to realize a newly designed cavity, achieving a mechanically stable laser, manufactured using standard semiconductor technology.

The research objective was to design a grating with broken symmetry relative to the plane of the periodic structure to achieve bound states in the continuum (BIC). This was pursued by developing a method for producing dielectric nanophotonic structures intended to replace one of the classically used Distributed Bragg reflector (DBR) in a vertical-cavity surface-emitting laser (VCSEL), epitaxially grown on a GaAs substrate (see Fig. 1a). The periodic structure enables the replacement of the upper distributed Bragg reflector (DBR) layer in VCSELs, resulting in a miniaturized device without compromising laser efficiency, while simplifying the manufacturing process, thus enhancing production efficiency and reducing costs on a larger scale. Existing lasers utilizing this idea have been created in a form of difficult to produce membranes with limited applications. Our solution provides a mechanically stable laser, manufactured using standard semiconductor technology.

The key aspect of the technology is the formation of subwavelength gratings with precisely defined geometry, in which the period *L*, the fill factor *F* and the etching depth *H* are designed to reflect a specific wavelength of light. Another important requirement is to make the grating in a material characterized by a refractive index lower than the index of the substrate material on which the grating is formed. The grating constructed in this way generates an antisymmetric mode and is an element of the cavity in which the DBR is designed to reflect specific, non-zero diffraction orders - usually the first one.

The goal was to establish a process for creating a 1D dielectric grating with straight and smooth walls to achieve an antisymmetric mode. High-precision electron beam lithography was employed to create the grating pattern, which was subsequently transferred to the substrate material via reactive ion etching (RIE). Numerical simul a) s were utilized to optimize the dimensions of the grating structure. For the epitaxial substrate with central wavelength at Λ_{DBR}= 995nm, optimal grating parameters were *L* = 910nm, *H* = 380nm, *F* = 0.5, *L-a* = 455nm. These dimensions can vary based on the e-beam dose, development time, and the parameters selected for the plasma etching process, therefore achieving the designed configuration is a challenge. To mitigate the impact of individual process steps on the final dimensions of the structure, a 10x10 matrix was established, accounting for period variations (*L*) from 902 to 920 nm and etched stripe width (*L-a)* from 420 to 520 nm, while maintaining constant dimensions: etched depth (*H*) at 0.38 μm and total oxide thickness at 0.8 μm. An etching procedure was developed, considering the influence of process gas pressure on wall shape and etch rate. Studies indicated that using lower pressure in the RIE etching process resulted in a higher etch rate and positively influenced the inclination of the etched walls, producing a more rectangular profile.

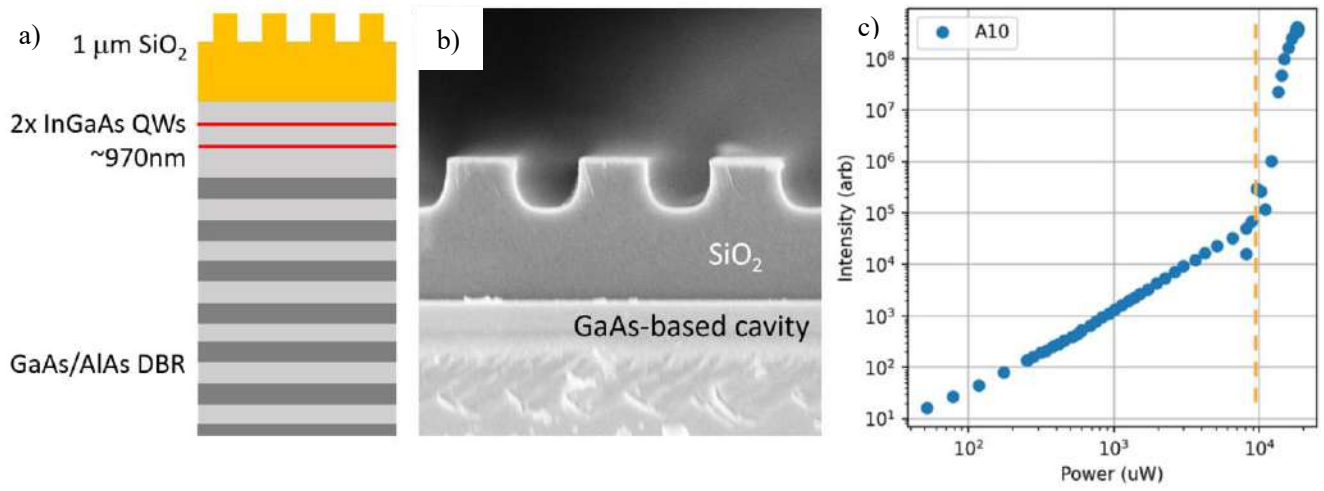

Figure 1 -Schematics of BIC-based cavity a), SEM image of cavity cross-section b), the dependence of the relative power emitted by the laser on the relative excitation power c)

The result of the research was the creation of a structure optimized in terms of dimensions, meeting the design requirement defined at the beginning of the work. The quality of the structure was checked by observations using a scanning electron microscope (see Fig. 1b), and its optical properties were characterized. Photoluminescence measurements were performed on the structure produced in this way, using a Mira Seed pulsed laser with a pulse length of 20 fs and an excitation wavelength of 755 nm. The tests performed at a temperature of 10 K showed lasing action of the structure for a minimum power of 10 mW of the excitation laser (Fig. 1c), as well as the presence of a polarization vortex, which confirms the occurrence of BIC in the structure.

Abstract: We present an end-to-end reconstruction framework that combines a three-layer multicolor scintillator with a physics-aware postprocessing algorithm to allow energy-resolved X-ray imaging. Using this framework, we demonstrate the simultaneous identification of iodine and gadolinium-based contrast agents from body tissues through simulations of a computational phantom.

Conventional X-ray imaging often relies on scintillators to convert impinging X-rays into visible light, which is then detected by image sensors. In a typical clinical setting, X-rays generated from an X-ray tube with a broadband energy spectrum passes through the specimen, and a grayscale image sensor is used to map the scintillation intensity from all incident X-ray energies into the same intensity channel. Such a single-channel setup is only able to record the energy-integrated absorption level of each region of the specimen (i.e., the source-spectrum-weighted average of the linear attenuation coefficient over the incident energy range).

This is a significant drawback for applications in which material identification is important such as medical contrast imaging and nondestructive inspection at security checkpoints. Energy-resolved imaging is particularly crucial for contrast imaging, where it is known that blood containing contrast agents are difficult to distinguish from calcium-rich media such as bones and calcified stones that also attenuate X-ray strongly [1,2]. Nevertheless, commonly used iodine or gadolinium-based contrast agent have characteristic absorption K-edges at 33 and 50 keV, respectively. Therefore, an appropriately designed energy-resolved imaging scheme would allow the contrast agents and calcium-rich media to be distinguished from one another based on each media's unique energy-dependence of X-ray absorption.

In our work, we present a general framework for energy reconstruction in X-ray imaging that combines a three-layer multicolor scintillator with a physics-aware postprocessing algorithm in an end-to-end approach (Fig. 1a). Through this, we demonstrate three-bin energy-resolved X-ray imaging tailored for identifying contrast agents for medical applications (Fig. 1b-d). In our framework, the multicolor scintillator acts as a physical "pre-processor" that preserves and encodes the energy information of incident X-rays onto an RGB detector. The scintillators used for the multilayer stack were carefully selected such that each energy bin is preferentially absorbed in different target scintillators, each with a different emission color. The postprocessing algorithm extracts the energy information from the size and color of the scintillation "spots" recorded on the RGB detector. All simulations were done using GEANT4, an *ab initio* Monte Carlo simulation tool for high-energy particle-matter interactions [3].

Abstract –We showcase a versatile metasurface-enabled design method for multichannel photon sources that enables arbitrary polarization control over multiple channels with distinct directions by exploiting the nonradiative interaction between quantum emitters and surrounding scattering meta-atoms. Furthermore, the integration of phase-change materials allows for the switching between multiple functionalities.

Solid-state quantum emitters (QEs) need to compensate several drawbacks to be purposefully used in quantum technologies. To overcome these issues bulky components are needed, which, however, are disadvantageous for implementation in devices. Some of the issues can be resolved by integrating QEs in photonic metasurfaces. [1,2] Embedding the QEs in nanocavities improves emission rates via the Purcell effect. However, simulatneous control of polarization states or directionality of the emission remains challenging. [3,4] Recently, on-chip plasmon-QE coupled metasurfaces have shown improvements in the control of the emission properties. [5] The QE excites surface plasmon polaritons (SPPs) that are outcoupled by the surrounding metasurface, resulting in defined polarization states.

We demonstrate a universal on-chip QE-coupled meta-optics platform that unlocks full DoFs in shaping the polarization states and direction in multiple channel emission by using metallic metaatoms with half-wave plate (HWP) functionality. These metaatoms are arranged around a QE, that is separated by a thin silica layer from a silver substrate. A quantum emitter with the dipole orientation out of plane decays mostly into radially outoing SPPs. By surrouding the QE emitter by a nanostructure the SPPs are outcoupled into the farfield. Therefore, it is possible through careful design of the metasurface that surrounds the QE to manipulate the outcoupled light with regard to propagation direction and polarization. HWP metaatoms have shown great capabilities in the manipulation of polarizations and the shaping of wavefronts. At each point surrounding the emitter the necesasary resonance and geometric phase can be calculated to outcouple the SPP into the desired photon state.

The versatility of this approach can be extended through the integration of phase-change materials (PCM) disc in the center of the structure surrounding the QE. This allows to selectively absorb the SPPs in certain directions before reaching the metasurface. Therefore, dividing the surrounding metasurface into segments with different functionalities allows for selective emission properties depending on the state of the phase-change, surpressing the emission of metasurface segments where the SPP is absorbed.

Polarization measurements at wavelength of 670nm show a S3-parameter value of -0.94 for single channel left-circularly polarized emission averaged over the entirety of the spot. Additionally, a metasurface, that directs 45°-linearly polarized (aLP) and 135°-linearly polarized (bLP) light into −y and y-direction showcase the multi-channel performance of this design principle. The measured avergaed S2-parameter values for this metasurface are +0.95 and −0.94.

Furthermore, the versatility of the design method is highlighted by fabricating a metasurface directing aLP and LCP light in different spatial directions (Fig. 1). This metasurface achieves avergaged S-parameters of +0.79

(S2) and −0.93 (S3) due to cross talk between the two non-orthogonal polarizations. In the second metasurface the intensities are reversed. In this case, the averaged S-parameter values are +0.79 (S2) and −0.92 (S3).

Simulations with an integrated PCM disc surrounding the QE made of Sb_2S_3 show a contrast in the signal between amorphous and crystalline close to unity allowing for an extension of this approach to a switchable multi-channel approach. However, the integration of the PCM discs slightly reduces the polarization purity.

Finally, it should be noted that this platform can be implemented for various wavelengths through thoroughly designing the metaatoms (i.e., dimensions and material).

We design a phonon-driven negative index metamaterial (NIM) using ZnO/(Zn,Mg)O heterostructures, demonstrating tunable hyperbolic behaviour via Mg content and layer thicknesses. Experimentally, we achieve type I hyperbolic dispersion in four samples. Spectroscopic characterization and calculations of modes dispersion and isofrecuency curves confirm the negative frequency dispersion.

Stacked semiconductor hyperbolic metamaterials (HMMs) exhibit opposite signs of the real part of the dielectric function along the directions parallel ($\varepsilon_{\parallel}$) and perpendicular ($\varepsilon_{\perp}$) to the surface plane. Type I HMMs ($\varepsilon_{\parallel} > 0$ and $\varepsilon_{\perp} < 0$) have been of special interest given their negative refraction capabilities [1,2]. Various approaches have been explored to achieve Type I HMMs, including arranging materials in periodic structures [3], designing plasmonic structures [2] and, only recently, the first phononic HMM was demonstrated using superlattices supporting surface phonon polaritons (SPhPs) [4]. Given the higher quality factor observed in SPhP materials compared to plasmonic materials [5], phonon modes hold promise for attaining low-loss, sub-diffraction-limited optical modes using SPhP excitations, hence our focus on this approach.

This study presents the demonstration of a Type I phononic HMM formed by ZnO/(Zn,Mg)O heterostructures. Our approach begins by designing the heterostructure using the transfer matrix method (TMM) to find the conditions that the structure needs to satisfy so that a Type I HMM spectral region exists. We control the epsilon-near-zero character of the alternating layers by shifting the LO phonon frequency of the ternary alloy via the Mg content. For this purpose, the HMM is studied as a function of two parameters: the thickness ratio of the layers (d_{ZnO}/d_{ZnMgO}) and the Mg concentration ([Mg]) in the ternary layers. **Figure 1** shows the peak value of the figure of merit (FOM), defined as $\mathrm{Re}[k_{\perp}]/\mathrm{Im}[k_{\perp}]$ and typically accepted for characterizing anisotropic NIMs [2], as a function of both parameters.

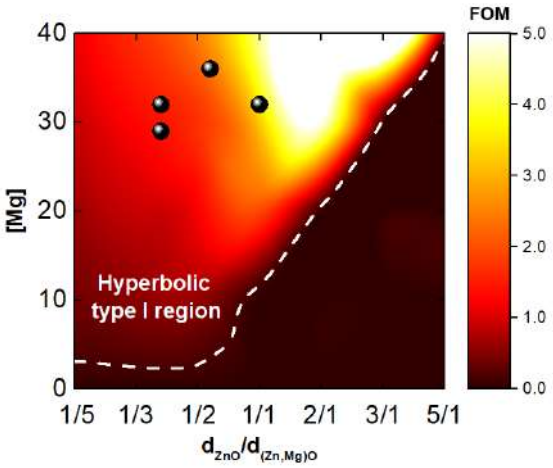

Figure 1: Calculated peak value of the FOM as a function of [Mg] and the layer thickness ratio. FOM is set to zero in the areas of the map where there is no type I hyperbolic region. The white dashed line defines the boundary between the region of parameter combinations for which a type I region is found and those for which it is not. The black dots indicate the experimental samples used in this work.

Once the combination of parameters needed to obtain a Type I HMM region is identified, we fabricate four samples (marked as black dots in **Figure 1**) which satisfy these conditions and characterize them experimentally by carrying out reflectance measurements in a FTIR spectrometer. For each sample, we then fit the measurements to the Gervais model, obtaining the dielectric functions of the two

constituent materials, ε_{ZnO} and ε_{ZnMgO}, from which we build ε∥ and ε⊥ by employing effective medium theory, and verify that this effective dielectric function exhibits Type I HMM behavior in a specific region.

The results of the study outlined above have been performed for all four samples, with **Figure 2** showing the results for one of the samples. First, we use attenuated total reflectance spectroscopy to report the presence of an SPhP mode in each sample, located within the type I hyperbolic region. Next, by employing the TMM, we demonstrate that this mode exhibits negative frequency dispersion, which is a hallmark of type I hyperbolic modes, and finally, isofrequency curve (IFC) calculations further confirm the hyperbolic behavior.

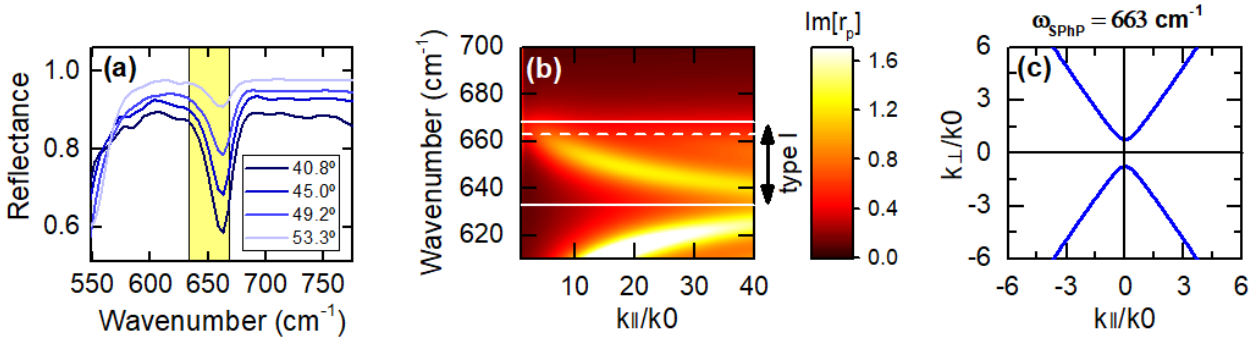

Figure 2: For one selected sample: (a) Measured ATR curves in p-polarization at different angles of incidence. The type I HMM behavior is highlighted in yellow. (b) Calculated polariton dispersion curves, computed with the TMM. Solid white reference lines show the region where the type I behavior has been found (635–668 cm^{-1}). (c) Calculated IFC of this sample for a frequency of 663 cm^{-1}, where the SPhP excitation is measured, and which lies within the type I hyperbolic region. This frequency is marked in (b) with a white dashed line. As expected, the IFC shows a hyperbolic shape characteristic of type I hyperbolic region. k∥ and k⊥ are the parallel and perpendicular components (with respect to the surface) of the wavevector, respectively. Both variables are normalized to k0, the wavevector in vacuum.

In summary, we have performed a detailed analysis of the design rules to obtain a phononic type I HMM using a realistic ZnO/(Zn,Mg)O heterostructure. Our study shows that increasing the Mg content in the ternary layers enhances the type I behavior, and that the optimal layer thickness depends on the Mg content. After examining the conditions for achieving a type I HMM, we experimentally validate this concept using four different samples.

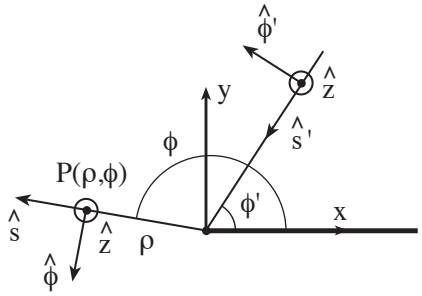
Abstract: A Uniform Asymptotic Physical Optics solution is provided to evaluate the plane wave diffraction by a uniaxial anisotropic chiral half-sheet with a perfect electrical conductor backing. The incidence direction is assumed to be perpendicular to the linear edge of the chiral sheet.

This summary deals with the evaluation of the diffracted field occurring when an incident plane wave travels in the free space and hits the upper surface of a uniaxial anisotropic chiral sheet with thickness *d* and a perfect electrical conductor (PEC) backing. At the best authors' knowledge, analytical solutions of this canonical problem don't exist in literature.

The structure thickness permits considering the plane wave diffraction by an equivalent impenetrable half-plane having the edge coincident with the *z*-axis of a useful coordinate system (see Fig. 1). The angle ϕ' defines the incidence direction and the polar co-ordinates ρ,ϕ describe the position of the observation point *P*.



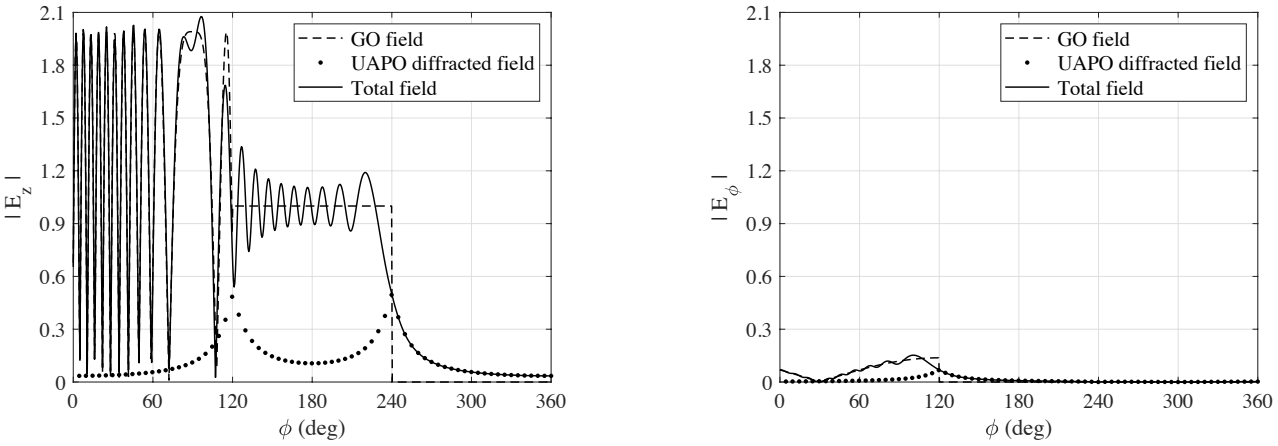


Figure 1. Geometry of the diffraction problem.

The Uniform Asymptotic Physical Optics (UAPO) approach is able to furnish an analytical solution to the tackled problem by adopting electric and magnetic PO equivalent surface currents as radiating sources. According to [1], if $\underline{E}^i = E_0^i \exp(j\beta_0 \rho \cos(\phi - \phi'))\hat{z}$ is the electric field associated to the incident plane wave, the resulting UAPO diffracted field can be so expressed:

$$\begin{pmatrix} E_z^d(\rho,\phi) \\ E_\phi^d(\rho,\phi) \end{pmatrix} = E_0^i \frac{\exp(-j\pi/4)}{2\sqrt{2\pi\beta_0}} \frac{\exp(-j\beta_0\rho)}{\sqrt{\rho}} \frac{F^d\left(2\beta_0\rho\cos^2\left(\frac{\phi \pm \phi'}{2}\right)\right)}{\cos\phi + \cos\phi'} \begin{pmatrix} (1-R_{22})\sin\phi' - (1+R_{22})\sin\phi \\ -R_{12}(\sin\phi' + \sin\phi) \end{pmatrix} \quad (1)$$

where β_0 is the free-space propagation constant and F^d is the transition function of the Uniform Geometrical Theory of Diffraction (UTD) [2]. The coefficients R_{12} and R_{22} are elements of the 2x2 reflection matrix related to the standard plane of incidence and are obtained by applying the boundary conditions at the upper and lower interfaces of the chiral material. In particular, the presence of a PEC support guarantees the total internal reflection of the eigenwaves at the lower interface.

Figure 2 refers to a uniaxial chiral sheet that is characterized by thickness $d = 0.05\lambda_0$, permeability parameters $\mu_t = \mu_n = \mu_0$, permittivity parameters $\varepsilon_t = 2.7\varepsilon_0$, $\varepsilon_n = 3.4\varepsilon_0$, and chirality parameter $\kappa = 1.9$. Parameters and wavelength λ of free space are denoted by the index "0". In particular, co- and cross-polar field components are shown in (a) and (b), respectively, when $E_0^i = 1$ and $\rho = 6\lambda_0$. The discontinuities of the Geometrical Optics (GO) field are compensated by the contribution of the UAPO diffracted field at the shadow boundaries $\phi = 120°$ and $\phi = 240°$, thus gaining a continuous total field as expected.

(a) (b)

Figure 2. Co- and cross-polar field components when $\rho = 6\lambda_0$ and $\phi' = 60°$.

Abstract

We report enhanced optical activity in the epsilon-near-zero regime in a chiral metamaterial composed of metallic nanospheres randomly dispersed in a chiral drug solution. Our results are relevant for developing innovative devices capable of detecting the chirality of low-volume samples with applications in nanomedicine and pharmaceutics.

In recent years, chiroptical sensing has emerged as the cornerstone of detecting specific enantiomeric forms of chiral biomolecules, including pharmaceutical chiral drugs, because the two enantiomers often exhibit different behavior and functionality. Current state-of-the-art chiral sensing techniques that measure enantiomeric excess of chiral mixtures, such as nuclear magnetic resonance and high-performance chromatography, are limited by macroscopic drug volumes and unsuitable for real-time analysis and on-chip integration schemes. Recent progress in nanophotonic metamaterials fabrication has enabled advanced chiroptical sensing techniques, including plasmon-enhanced circular dichroism (CD) and optical rotatory dispersion (ORD) spectroscopy [1, 2], to quantify enantiomeric imbalance in chiral drug solutions.

Here, we propose an ultrasensitive chiroptical sensing method based on epsilon-near-zero (ENZ) effective parameters of metallic nanospheres (NS) randomly dispersed in aqueous reparixin (a pharmaceutical molecule currently used in clinical studies, including COVID-19 and acute respiratory distress syndrome) with dilute molecular $\approx 10^{-2}\text{nm}^{-3}$ density. The proposed setup is illustrated in Fig. 1(a). In the limit of dilute drug solution, the effective bi-anisotropic optical parameters of reparixin dissolved in water are evaluated through a previously reported combined molecular dynamics simulation and quantum mechanical ensemble average approach [3]. Note that the chirality parameter of the chiral medium is determined solely by the mixing (magnetoelectric) polarisability, which flips sign for opposite enantiomers and enantiomeric imbalance. Due to the near-field and electromagnetic interactions, chiral molecules induce optical chirality in the plasmonic spectra of the metal NSs. Working in the quasi-static limit, we calculate the NS's induced electric, magnetic, and magnetoelectric polarizabilities [Figs. 1(b-d)]. The dielectric response of the metal is accounted for by the Lorentz-Drude model. Next, we apply Maxwell-Garnett's effective medium theory to account for the local field corrections and derive the effective constitutive relations of the chiral MM given by,

$$\begin{aligned} \mathbf{D}(\mathbf{r}) &= \epsilon_0\epsilon_{\text{eff}}\mathbf{E}_0(\mathbf{r}) \in \frac{i}{c}\kappa_{\text{eff}}\mathbf{H}_0(\mathbf{r}) \\ \mathbf{B}(\mathbf{r}) &= \frac{i}{c}\kappa'_{\text{eff}}\mathbf{E}_0(\mathbf{r}) + \mu_0\mu_{\text{eff}}\mathbf{H}_0(\mathbf{r}) \end{aligned} \tag{1}$$

where ϵ_{eff}, μ_{eff}, κ_{eff}, and κ'_{eff} are the effective optical constants for the bulk nanosphere-chiral medium, Each of them is a function of the NS filling fraction f and impinging wavelength λ. We observe enhanced ORD and CD in the ENZ regime $\text{Re}[\epsilon_{\text{eff}}(f,\lambda)] \approx 0$ of the bulk, as illustrated in Figs. 1(e)-(g). Our results hold potential applications in the development of ultrasensitive photonic probes to detect molecular chirality at the nanoscale level.

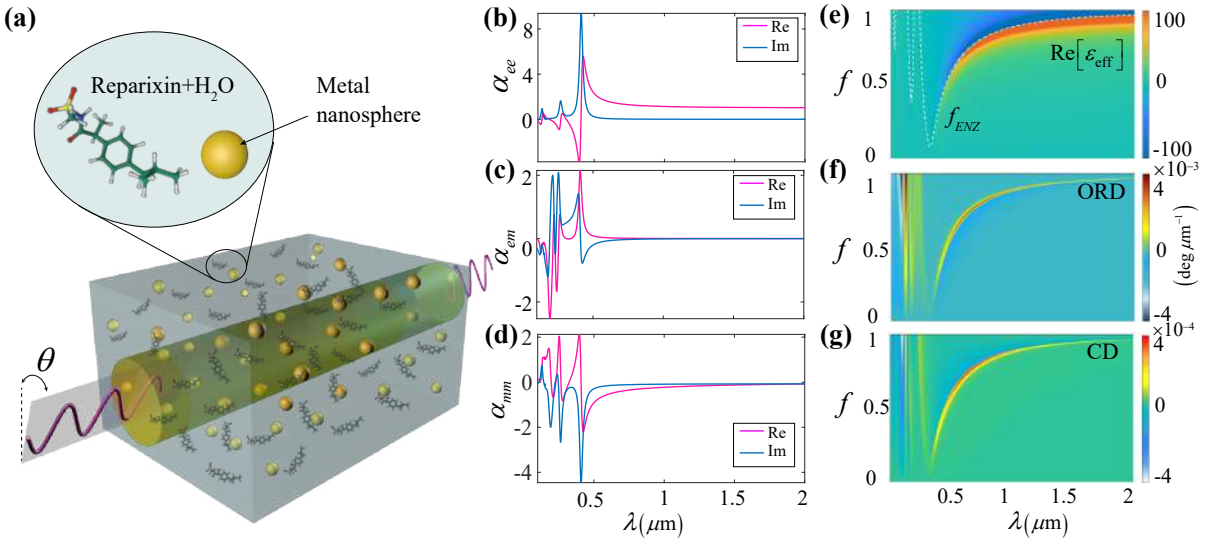

Figure 1: Fig. 1 **(a)** Schematic illustration of the proposed chiral metamaterial composed of silver nanospheres randomly dispersed in aqueous Reparixin solution. **(b)-(d)** Real and imaginary parts of the induced electric (α_{ee}), magnetoelectric (α_{em}), and magnetic (α_{mm}) polarizabilities of a nanosphere. **(e)** Effective permittivity of the bulk medium plotted against filling fraction f of the nanospheres and incident wavelength λ. Enhanced frequency conversion by plasmonic-dielectric metasurfaces with high-Q quasi-BICs in the visible spectral range

T. Stolt[1*], H. Bai[1], A. Shevchenko[1], and R. Kolkowski[1]
[1]Department of Applied Physics, Aalto University, FI-00076 Aalto, Finland

timo.stolt@aalto.fi (corresponding author)

Abstract

We numerically demonstrate plasmonic-dielectric metasurfaces with narrow-band resonances in the visible spectral range, showing exceptionally high quality factors ($Q \sim 6400$). These arise from hybridization between guided modes of different order. We predict up to 750-fold enhancement of second- and third-harmonic generation in these metasurfaces, revealing their potential for nonlinear nanophotonics.

Periodic metasurfaces with high-quality-factor (high-Q) resonances, such as quasi-bound states in the continuum (qBICs), show great potential for enhancement of nonlinear optical phenomena in highly compact structures [1, 2]. Typically, qBICs are realized in structures made of absorption-free all-dielectric materials, avoiding the use of lossy components, such as plasmonic nanoparticles. However, under certain conditions qBICs can be realized in plasmonic metasurfaces as well, leading to unique combinations of extremely high Q factors with strong local field enhancement inherent to resonant plasmonic systems [3, 4]. Here, by combining plasmonic nanoparticle arrays with dielectric slab waveguides (see Fig. 1a), we design hybrid metasurfaces that can exhibit qBICs with exceptionally high Q factors in the visible spectral range. By using a second-order nonlinear material for the waveguide, we show that the designed qBICs can boost the second- and cascaded third-harmonic generation (SHG, THG) by almost three orders of magnitude.

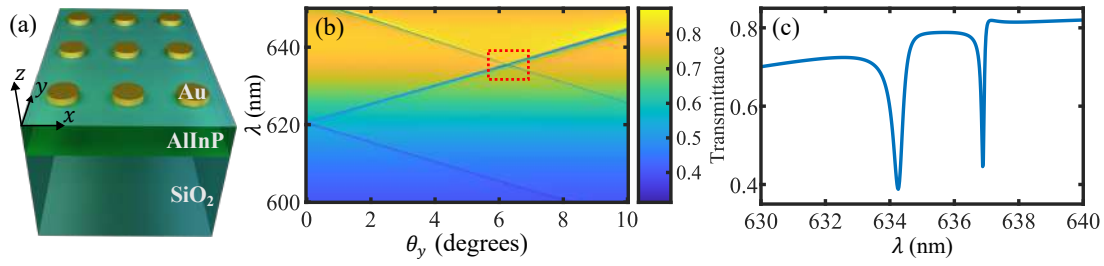

Figure 1: (a) Illustration of the designed metasurface. (b) Transmittance of TE-polarized light, calculated for the studied metasurface as a function of wavelength and incidence angle (θ_y). The dashed box indicates the location of the anticrossing between the two guided-mode resonances. (c) Transmittance spectrum at $\theta_y = 5.75°$, showing a bright and a dark hybrid resonance (qBIC).

The main component of our metasurface is a slab waveguide (thickness 400 nm) made of aluminum indium phosphide (AlInP). We choose AlInP due to its high refractive index (> 3), negligible absorption loss at $\lambda > 500$ nm, and relatively high intrinsic second-order susceptibility ($\chi^{(2)}$). The properties of this material are currently studied in our group. To obtain a qBIC, we place a rectangular array of gold nanodisks (radius 40 nm, height 40 nm) on the waveguide (see

Fig 1a). The periods along the x and y directions are set to 150 and 210 nm, respectively. The resulting dispersive guided-mode resonances (see Fig 1b) originate from TE-polarized guided modes of different orders. By changing the incidence angle θ_y (residing in the yz plane), we make the resonances intersect and anticross with each other. The anticrossing gives rise to a bright and dark hybrid mode, following a mechanism described in Ref. [4]. The dark mode is a qBIC with linewidth $\Delta\lambda \approx 0.1$ nm at $\lambda = 636.9$ nm, corresponding to $Q \approx 6400$ (Fig 1c).

To showcase the potential of the studied structures for nonlinear optical applications, we simulated the SHG and cascaded THG from the designed metasurface. We assumed a TM-polarized pump to be incident on the metasurface at $\theta_y = 5.75°$ (i.e., having significant E_y and E_z components) in the wavelength range between 1260 and 1280 nm. Due to the $\chi^{(2)}$-tensor symmetry of AlInP, this results in SHG fields in the range from 630 to 640 nm that are co-polarized with the qBIC (i.e., have a significant E_x component). Furthermore, we evaluated the cascaded THG at 420-427 nm, resulting from mixing of the SHG with the fundamental fields. We have found that both the bright mode and the qBIC give rise to strong resonant enhancement of the SHG and THG emission (up to 750- and 400-fold, respectively; see Fig 2).

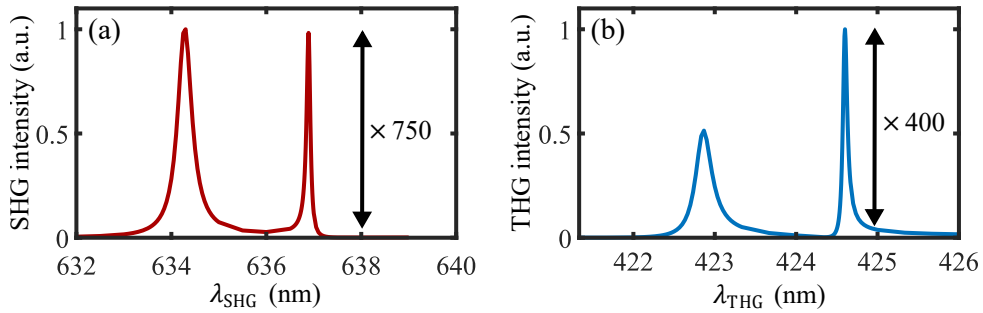

Figure 2: Calculated spectrally-resolved (a) SHG and (b) cascaded THG from the designed metasurface, with SHG wavelengths near the hybrid resonances.

To conclude, by combining a plasmonic nanoparticle array with a nonlinear dielectric slab waveguide, we have obtained a metasurface hosting hybrid plasmonic-photonic resonances that result from the coupling between guided modes of different orders. One of these resonances is a qBIC with $Q \sim 6400$, which is exceptionally high for a plasmonic system in the visible spectral range. We have shown that both hybrid resonances can boost SHG and cascaded THG by almost three orders of magnitude. Experimental demonstration of these predictions is a target of our ongoing research.

Abstract

We demonstrate scalable enhancement of second-harmonic generation (SHG) from metasurfaces using multipass cells, where the pump interacts multiple times with the metasurface. We achieve phase matching with superlinear dependence on the number of passes, promising applications in diverse nonlinear optics.

1 Introduction

Nonlinear metasurfaces and metamaterials have recently emerged as a promising solution to realize thin nonlinear devices. These artificial structures, composed of sub-wavelength building units, can exhibit properties not (easily) achieved in natural materials. Despite their advantages, nonlinear metamaterials have not yet found real-world applications, where they could outperform existing nonlinear material systems, such as nonlinear waveguides [1], fibers [2], or crystals [3]. This lack of applications is mainly related to the still-too-low conversion efficiencies of nonlinear metamaterials.

In this work, we introduce a straightforward approach to enhance nonlinear responses of metamaterials (and thus their conversion efficiencies), by incorporating them inside multipass cells and allowing the pump beam to pass through the metamaterial several times as demostrated in Fig. 1a. We experimentally demonstrate a tenfold enhancement in the SHG signal from a plasmonic metasurface after 9 passes [4]. Our results show a superlinear dependence of the SHG signal on the number of passes N, confirming a successful phase matching. Importantly, this demonstrated approach is generic, offering compatibility with various existing enhancement techniques and metamaterials.

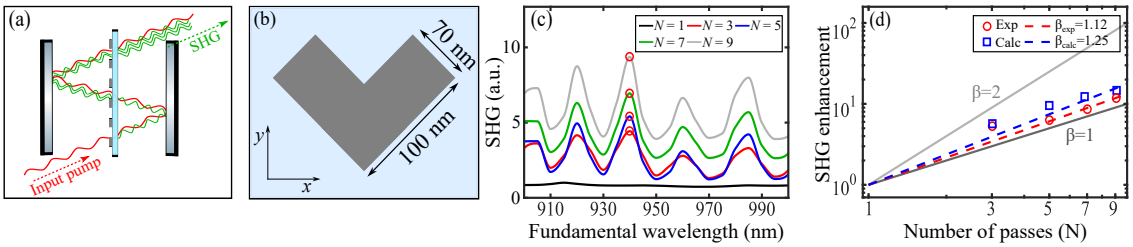

Figure 1: (a) A schematic showing the phase-matched SHG emission in case of 3 passes of the pump beam through the metasurface device. (b) A schematic representing a single V-shaped nanoparticle from the metasurface. (c) Measured SHG signal for different number of passes N. (d) The enhancement factor of the SHG signal as a function of the number of passes N.

2 Results and discussion

In our experiments, we used a sample consisting of V-shaped aluminum nanoparticles [Fig. 1b] deposited on a 0.5 mm-thick SiO_2 substrate. The nanoparticles were randomly positioned (being, however, similarly oriented). The sample was designed to have localized surface plasmon resonance (LSPR) around 420 nm for x-polarized incident light. We utilized the optical phase shifts induced by the LSPR to phase match SHG signal inside the multipass cell. The phase-matching condition was fulfilled for numerous pump wavelengths in our pump wavelength range from 900 to 1000 nm [see Fig. 1c]. The measured phase-matching wavelengths agree well on the ones calculated with a semi-analytical model [5].

Notably, the SHG response exhibited a superlinear dependence (SHG $\propto N^{\beta_{\text{exp}}} = N^{1.12}$) on the number of passes N [Fig. 1d], confirming successful phase matching. In the ideal scenario of a lossless and perfectly phase-matched sample, the SHG signal would exhibit a quadratic dependence on the number of passes N (SHG $\propto N^{\beta_{\text{ideal}}}$, where $\beta_{\text{ideal}} = 2$) [6]. However, various loss mechanisms, including transmission losses and beam intensity changes during propagation, result in a measured scaling factor less than 2. In future, we plan to fabricate metasurfaces directly on top of the mirrors or replace the mirrors with highly-reflecting metasurfaces. This would reduce the amount of normal dispersion, simultaneously increasing the achievable β. Such demonstrations could pave the way towards ultra-thin, tunable, and multifunctional nonlinear devices, eliminating the need for complex fabrication procedures.

Abstract: We numerically investigate nonlinear responses produced by Epsilon-near-zero (ENZ) material-based metasurface structure. Here we show that our proposed structure can produce a large nonlinear response with the change in refractive index, Δn, exceeding 2 near the ENZ wavelength range, even at very low pump fluence in the near-infrared spectral range.

Nonlinear effects offer vast opportunities across a wide range of applications like all-optical signal processing, optical computing, beam steering as well as sensing and detection. The size and energy efficiency of nonlinear optical devices are largely dependent on the strength of the nonlinear optical response of the materials from which they are made. Therefore, using conventional materials of weak nonlinear response, it is difficult to realize sub-wavelength all-optical devices. Therefore, materials exhibiting significantly stronger nonlinear optical responses are essential for developing highly dense on-chip optical devices.

Recent studies have shown that materials with vanishingly small permittivity, known as epsilon-near-zero (ENZ) materials, display remarkable linear and substantial nonlinear responses [1]. Transparent conducting oxides (TCOs like ITO, AZO, CdO etc.) are one of the most favorable materials as an ENZ material, in which optical properties can be easily tuned by manipulating the carrier concentrations [2]. In terms of nonlinear response, a thin film of TCOs can result in large nonlinearity around the ENZ wavelength of that material [3]. Here, we report a novel metasurface structure, as shown in Fig. 1(a), composed of an array of gold rings placed on a thin layer of cadmium oxide (CdO), which is situated on a silica (SiO_2) substrate. In this configuration, the CdO thin film functions as an epsilon-near-zero (ENZ) material. This proposed design demonstrates a significantly enhanced nonlinear response compared to traditional thin-film ENZ materials, and the required pump fluence is also comparably very small. The real part of the permittivity of the ENZ material used in this study vanishes at $\lambda \approx 1500$ nm as shown in Fig. 1(b). Here, two important resonance phenomena were observed in our structure; one is ENZ resonance

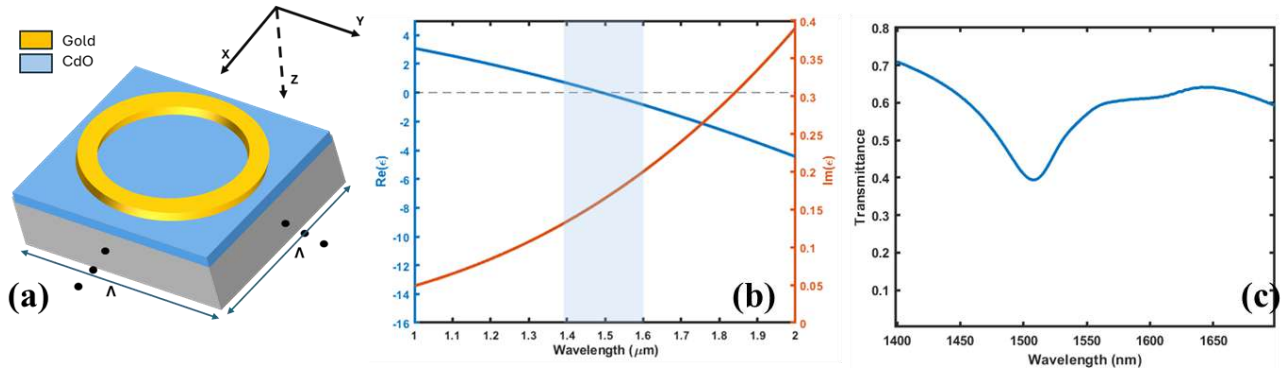

Figure 1: (a) Unit cell of our proposed metasurface structure, (b) Real and imaginary permittivity component of CdO layer, and (c) Linear optical transmittance of the proposed structure

supported by the thin layer of CdO due to electric field confinement within this layer near ENZ wavelength. And, the other one is the dipolar resonance of the metal ring array. We chose the metasurface parameters in such a way that both resonances significantly coincide with each other and the corresponding transmission spectrum is shown in Fig. 1(c). We then investigated the nonlinear responses using two-temperature model [4]. The optical nonlinearity observed in TCOs is governed by the heating of electrons via optical excitation of short-pulse laser source. As the laser pulse is applied, the electron temperature rises to the peak and then rapidly drops due to electron lattice interaction. After laser pulse absorption, the dynamics of both electron (T_e) and lattice (T_l) temperatures in CdO thin film can be described by the following sets of equations, with the relevant parameters defined in ref. [3]

$$C_e \frac{\partial T_e}{\partial t} = -g_{ep}(T_e - T_l) + \frac{N}{2\tau_{ee}} \quad (1)$$

$$C_l \frac{\partial T_l}{\partial t} = g_{ep}(T_e - T_l) + \frac{N}{2\tau_{ep}} \quad (2)$$

$$\frac{\partial N}{\partial t} = -\frac{N}{2\tau_{ee}} - \frac{N}{2\tau_{ep}} + P \quad (3)$$

For solving the equations, 100 fs pump pulses with wavelengths near the ENZ region and a very small pump fluence of 20 μJ/cm^2 are used. We find that a large change in electron temperature is due to the absorption of pump pulses, and it causes a significant manipulation in the optical properties of CdO film in terms of plasma frequency.

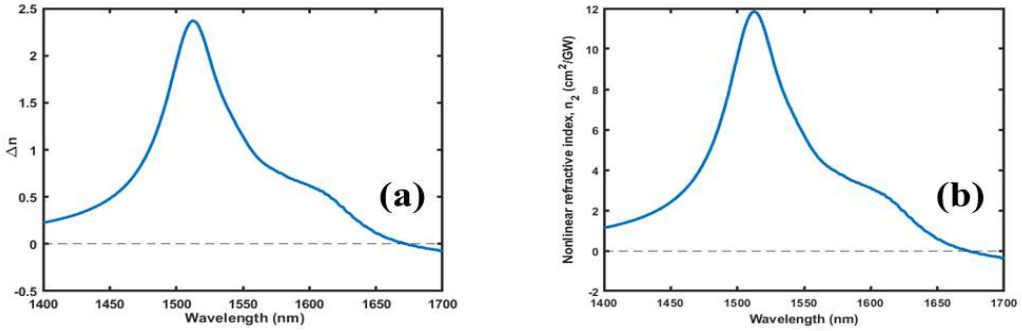

Figure 2: (a) Effective index change (Δn) and (b) Nonlinear refractive index of our proposed structure

Figure 2(a) shows the change in the effective refractive index (Δn) of the proposed structure which confirms that near the ENZ wavelength range Δn exceeds 2. The wavelength dependence of the nonlinear refractive index (n_2) is shown in Fig. 2(b). We observe that here the maximum value of n_2 is 11.83 cm^2/GW, which is almost 3 orders of magnitude greater than that of bare CdO film, as determined in ref. [5]. In conclusion, our findings can offer the possibility to develop low-power nonlinear nano-optical devices with drastically reduced footprints.

Polarization-Dependent Anapole States in Elliptical Nanodisks for Nonlinear and Filtering Applications

M.E.Kjellberg*, H. Kylhammar, and S. Anand

Department of Applied Physics, School of Engineering Sciences, KTH Royal Institute of Technology, Albanova University Center, Roslagstullsbacken 21, 106 91 Stockholm, Sweden

Abstract: We demonstrate anapole states in vertically stacked Si nanodisks by leveraging the high refractive index contrast between Si and SiO_2, simplifying fabrication. By extending this to elliptical disks, we achieve polarization-dependent dual-wavelength anapole excitation. This platform offers strong field enhancements, enabling advanced nonlinear optical applications and wavelength filtering.

The ability of sub-wavelength all-dielectric nanostructures to confine light in the visible and infrared spectral regions through Mie resonances offers significant potential for enhancing light-matter interactions, particularly in optoelectronic and nonlinear optics applications [1]. In this context, optical anapole states in Si nanodisks not only enable high optical field confinement but also offer novel ways for manipulating light scattering [2,3]. Furthermore, by vertically stacking nanodisks, the degree of field confinement can be significantly enhanced, opening new avenues for advanced photonic device design [4].

Anapole states, characterized by suppressed far-field radiation and enhanced optical field confinement, are highly sought after for nanophotonic applications. By utilizing the high refractive index contrast between Si ($n \approx 3.5$) and SiO_2 ($n \approx 1.45$), we design vertically stacked Si nanodisks that support anapole states without requiring complex fabrication steps. This approach simplifies production and enables strong light-matter interactions. Additionally, we show wavelength selective transmission/reflection by tailoring the dimensions and arrangement of nanodisks, enabling functions such as filters and structural coloration.

Elliptical nanodisk stacks introduce geometric anisotropy, enabling polarization-dependent anapole excitation at two distinct wavelengths [5]. When light is polarized along the major axis, the anapole mode occurs at a shorter wavelength, while polarization along the minor axis shifts it to a higher wavelength. This dual-wavelength behavior, controlled by the aspect ratio of the elliptical disks, provides a versatile platform for nonlinear processes, paving the way for advanced devices like tunable frequency converters and ultrafast optical switches.

Deep and vertical etching technique using hydrogen fluoride gas for glass-based metasurfaces

Y. Ono[1*], K. Sano[1], A. Ueno and Y. Hayashi[1]

[1]Innovative Technology Laboratories, AGC Inc., Japan
[*]corresponding author: yoshitaka.ono@agc.com

Abstract: This report introduces a glass-etching technique using hydrogen fluoride gas, where the photoresist, which typically acts as a mask, serves as a catalyst. This technique, enabling selective, faster, deeper, and more vertical etching than conventional reactive-ion etching, is promising for glass-based metasurface applications.

The demand for lightweight and compact metasurfaces in practical applications is growing, with recent research extending beyond monochromatic light to visible and ultraviolet (UV) regions. In the visible region, thin films of TiO_2 and SiN are widely used, although glass, commonly used for optical lenses, is also a promising candidate.[1] In the UV region, silica glass (pure SiO_2) offers advantages as a substrate,[2] and direct processing of glass substrates may lead to cost reduction. However, conventional reactive-ion etching (RIE) techniques suffer from mask erosion, resulting in tapered shapes and limited etching depth, which adversely influence the performance and application of glass-based metasurfaces.[1] Additionally, RIE exhibits low selectivity when etching glass, leading to low rates and throughput owing to single-wafer processing. Therefore, a batch processing method enabling deep and vertical glass etching is required.

For nearly 10 years, we have been investigating glass etching using hydrogen fluoride (HF) gas. HF gas etches glass by fluorinating its oxide groups.[3] Leveraging this, we discovered that photoresist, typically used as an etching mask, acts as a catalyst when exposed to high-temperature HF gas, enabling a novel selective-etching method[4] named advanced gas-phase chemical reaction for anisotropic catalyst etching (AGC-ACE). Figure 1 presents a schematic of AGC-ACE. After patterning the resist on silica glass using i-line photolithography, etching is performed with HF gas. The catalyst is then removed using oxygen plasma. The core of this method is the catalytic effect of the resist, which accelerates etching in the coated areas, while uncoated areas exhibit minimal reaction. Consequently, only the area under the resist is selectively etched. Density functional theory calculations suggest that this catalytic mechanism involves interactions between -OH groups in the resist polymer and H from the HF gas, which activate F and promote nucleophilic reactions with Si.

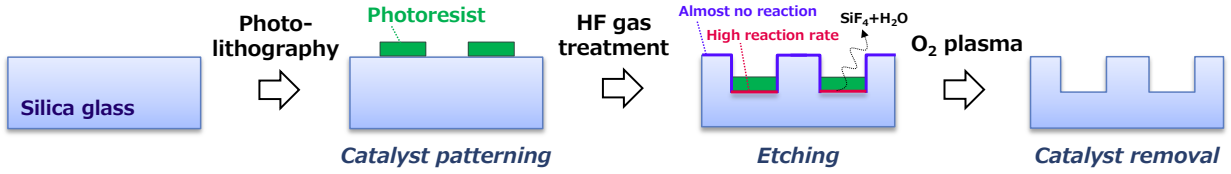

Figure 1. Schematic of AGC-ACE

Figures 2(a)–(d) show scanning electron microscopy (SEM) images captured before and after HF gas treatment. The resist-coated areas are selectively etched, confirming the conceptual illustration in Figure 1. Structures processed by RIE (Figure 2(c)) exhibit an 85° tapered shape, whereas AGC-ACE (Figure 2(d)) achieves nearly vertical etching with an angle of less than 1°. Moreover, the etching rate is 2.6 times higher (1.3 μm/min) than that of RIE (0.5 μm/min). As AGC-ACE is a plasma-free process, it enables batch processing. This allows the simultaneous treatment of multiple wafers, thereby significantly increasing throughput.

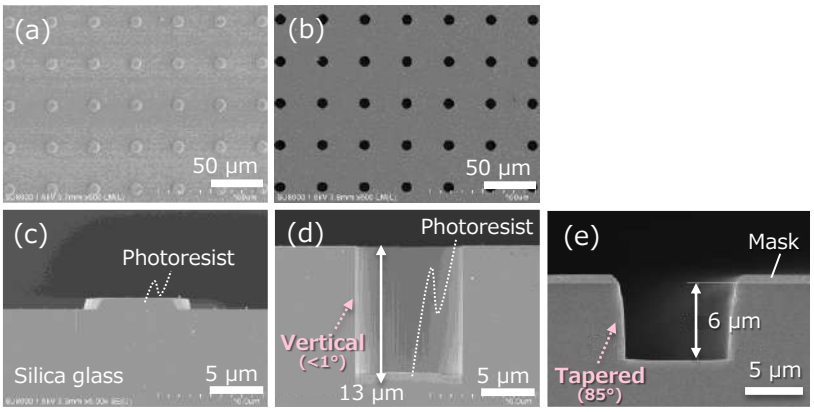

Figure 2. SEM images of silica glass before HF gas etching (a, c), after HF gas etching (b, d), and after RIE (e)

Figure 3 shows SEM images of microfabricated silica glass structures produced using AGC-ACE. High verticality is achieved in both trench and dense pillar structures. Unlike RIE, where the resist is consumed, the resist acts as a catalyst in AGC-ACE, enabling unlimited etching depth. In fact, successful etching up to 100 μm depth has been demonstrated. Furthermore, pillars with a diameter of 500 nm and depth of 25 μm (aspect ratio: 50) have been fabricated, which was impossible with conventional techniques. As the resolution is determined by photolithography, sub-100 nm fabrication has been achieved by changing the patterning method.

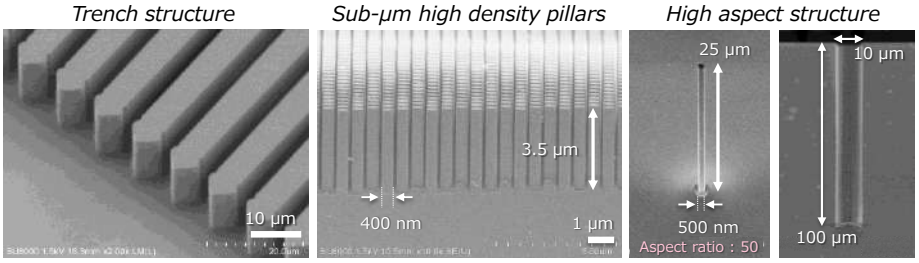

Figure 3. SEM images of silica glass substrate fabricated using AGC-ACE

AGC-ACE enables high-throughput etching of glass with excellent verticality and depth in a batch process. Therefore, it is expected to enable the low-cost fabrication of high-efficiency glass-based metasurfaces, overcoming limitations of conventional methods. We will present the most recent work towards applying this method to fabricate visible metasurfaces.

Gold nanostructure gratings produced using direct laser writing with pulse energy-dependent morphology for SERS substrates

K. Vilkevičius[1*], I. Ignatjev[2], G. Niaura[2], and E. Stankevičius[1]

[1]Department of Laser Technologies, Center for Physical Sciences and Technology, Savanoriu Ave. 231, Vilnius, Lithuania

Abstract: Direct laser writing is a versatile tool for producing free-form periodic arrays of gold nanostructures by modification. Pulse energy, grating period, and film thickness lead to variations in produced structure morphology, which in turn provide tunable resonant properties. The formation and application of such structures for SERS are presented.

Periodic gratings of plasmonic nanostructures provide the ability to efficiently couple plasmonic modes leading to an enhancement and improvement of their properties. Grating-coupling of the plasmonic modes achieved by a periodic array provides the flexibility and compactness of the platform where an additional element as a prism is not required for the excitation. Therefore, rapid, scalable, and reproducible fabrication of such structures is of high importance for practical applications and mass production. In this work, we employ a direct laser writing (DLW) technique using a sharply focused femtosecond laser beam onto the metal surface to achieve a single-step formation of free-form arrays with high precision. Variation in fs-pulse energy leads to the formation of distinct morphologies of the structures [1,2] produced with single pulses – bumps, cones, and jets (Figure 1a,b). Additionally, adjustments in the grating period and gold film thickness provide additional control of the structure shape [3]. This, in turn, allows for a more accurate manipulation of plasmonic properties.

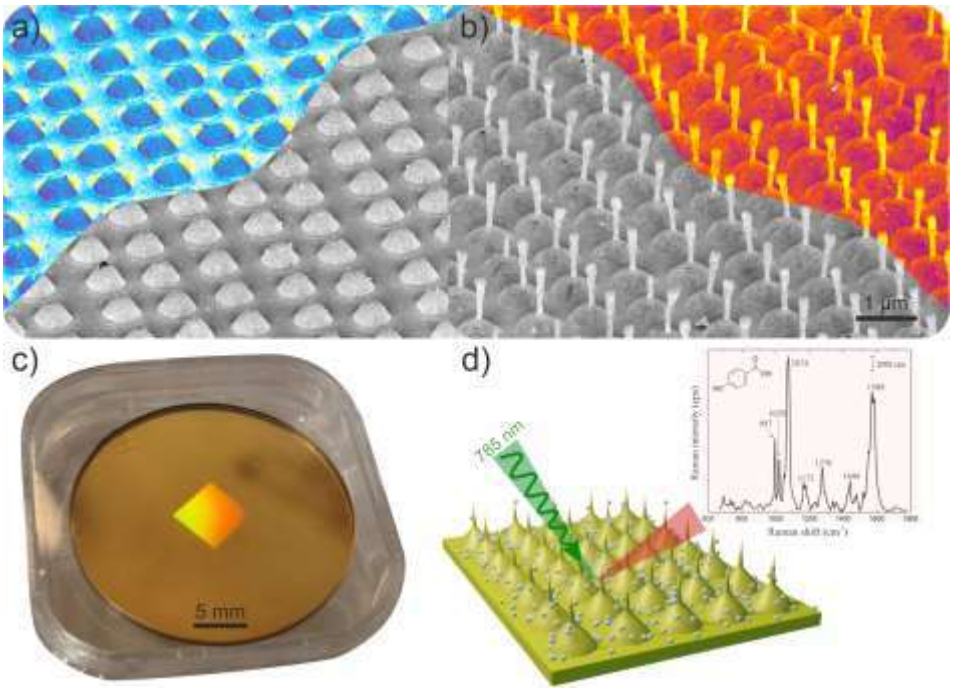

Figure 1. a) Periodic array of gold bumps. b) Periodic array of gold jets. c) Large-scale gold grating used as a SERS platform. d) Raman measurements using 4-MBA and obtained SERS spectrum.

This study investigates the influence of DLW-produced structure shape on the plasmon resonance and evaluates their applicability for surface-enhanced Raman spectroscopy (SERS). Large-scale arrays of 5×5 mm^2 were produced on thin gold films of varying thickness from 50 nm to 200 nm (Figure 1c) using femtosecond laser pulses. The formation with different pulse energies at various thicknesses leads to a great control of structure shape, with small bumps being similar in all thin films, and jets changing their shape depending on the gold layer thickness. Morphological changes significantly affect the enhancement of the local electromagnetic field, leading to variations in the signal enhancements [4]. Using 4-mercaptobenzoic acid as a Raman reporter, we examined the impact of structure shape and film thickness influence on the measured Raman signals (Figure 1d). The main 2 characteristic bands of 4-MBA at 1074 cm^{-1} and 1589 cm^{-1} were examined to determine the enhancement factor. While bumps achieved only a 10^5-order enhancement factor, its order can be increased at jet-like structures up to 10^7. Moreover, since structures are produced in a grating, the results also correspond to a repetitive manner at each structure.

The authors acknowledge the Research Council of Lithuania (LMT, Lithuania) for the received funding under project No. S-MIP-23-32.

Comparative Study of Nanocrystalline Dy_2O_3 Thin Films deposited on Sapphire and Silicon Wafers by Means of Electron Beam

Faisal Alresheedi
Department of Physics, College of Science, Qassim University, Buraidah 51452, Saudi Arabia.
F.alresheedi@qu.edu.sa

Abstract:

In this work, we reported a comparative study of dysprosium oxide (Dy_2O_3) thin films deposited on sapphire and silicon substrates by electron beam evaporation technique. X-ray diffraction (XRD) was used to investigate the crystal structural of Dy_2O_3 thin films, which showed that all films possess a polycrystalline nature and possess a cubic-type structure. The average crystallite size was calculated and it shows that the film deposited on the silicon substrate is slightly larger than the film deposited on the sapphire substrate. Scanning electron microscopy (SEM) was employed to investigate the morphological characteristics of the thin films. The film grown on the sapphire substrate has a granular surface while the film grown on the silicon substrate has a more compact surface and is free of pores. Spectroscopic ellipsometry (SE) was used to obtain the optical constants of both thin films. The reflectance of both samples was examined using UV-Vis spectrophotometry, with the findings demonstrating that the deposited layer on the sapphire substrate serves as a preferable choice for creating an improved anti-reflective layer in compared to a silicon layer.

Abstract: This study employs quadriwave lateral shearing interferometry (QLSI) to characterize singular metasurfaces generating optical vortex beams. By analyzing effective refractive index (ERI) and Pancharatnam-Berry (PB) phase metasurfaces, we demonstrate QLSI's accuracy in detecting phase errors, non-integer topological charges, and complex multi-vortex configurations, offering robust phase metrology for advanced photonic applications.

Photonic orbital angular momentum (OAM) is a fundamental property of light that results from its wavefront structure. OAM beams, also known as vortex beams, exhibit a helical phase distribution, leading to a central phase singularity where intensity is zero. This property is quantified by the topological charge (TC), which determines the number of phase twists in one wavelength. OAM has applications in optical communication, [1] imaging, microscopy, [2] and quantum information processing due to its capacity for encoding multiple information states. Traditional methods of OAM generation, such as spiral phase plates and spatial light modulators, suffer from size constraints and limited design flexibility. To address these issues, metasurfaces (MSs) have emerged as a powerful alternative, allowing precise phase manipulation at a subwavelength scale [3]. However, discrepancies between theoretical design and experimental fabrication necessitate robust phase characterization techniques. Interferometric methods, previously used for this purpose, are highly sensitive to noise. This study employs quadriwave lateral shearing interferometry (QLSI) as an alternative, [4] offering a more accurate characterization of singular MSs. We demonstrate that QLSI can be effectively applied to achieve high precision phase metrology of arbitrary singular MSs, imprinting either high-order integer or non-integer OAMs. Specifically, we showcase the technique's ability to detect fabrication imperfections and their influence on the generated vortex beams. This is achieved by studying various MS designs based on effective refractive index (ERI) and Panchratnam-Berry (PB) phase. We also studied vortex-like MSs with non-integer topological charges and complex multi-vortex configurations.

A comparative analysis of ERI and PB MS-based vortex beams was conducted by fabricating and characterizing MSs with TCs ranging from 1 to 10. QLSI measurements confirmed that PB MSs had lower phase errors than ERI MSs due to better fabrication tolerance and phase discretization. Far-field intensity profiles showed that both MS types generated the expected vortex beams; however, PB MSs exhibited more accurate donut-shaped intensity profiles. The superior performance of PB MSs was attributed to their higher phase discretization capability and lower sensitivity to fabrication errors.

We further characterized MSs generating vortices with non-integer TCs ranging from 0.1 to 1. QLSI successfully retrieved the phase profiles for non-integer vortices with high accuracy. This capability is particularly interesting for MS-based vortex metrology, where non-integer TCs may arise from design or fabrication errors. By leveraging a straightforward optical characterization approach, we identified singular

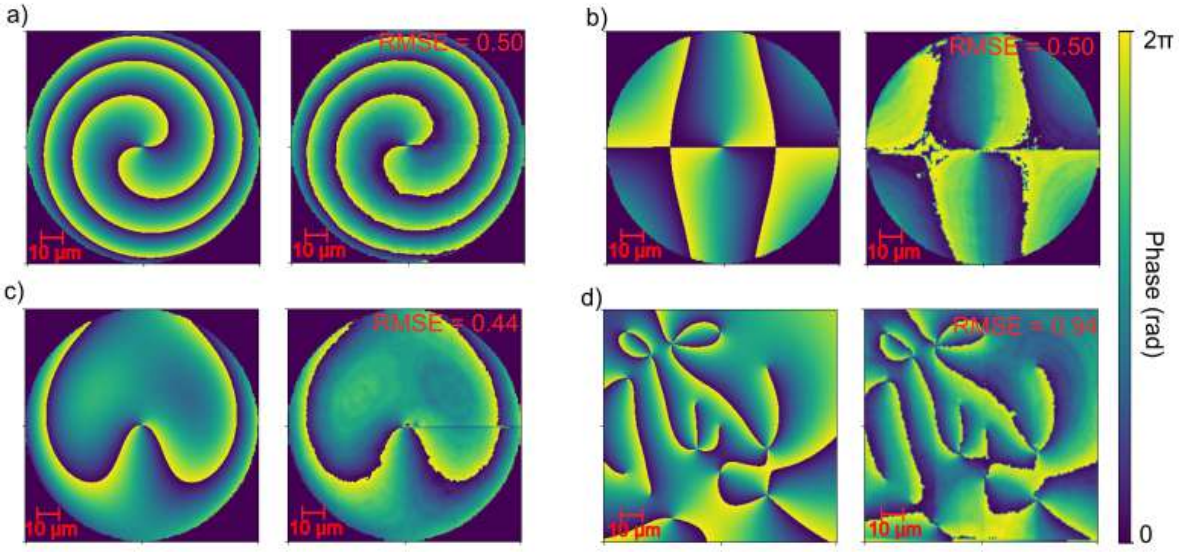

Figure 1: Characterization of PB MS with multi-vortices and other optical functionalities. Design (left) and measured (right) phase profile for vortex of CT=2 associated with a lens profile (a), astigmatism aberration profile (b) and coma aberration profile (c). d) Design (left) and measured (right) phase profile MS caring 15 vortices with TCs ranging from -4 to 4.

wavefront discrepancies without relying on expensive and intricate morphological analyses.

The versatility of QLSI in characterizing complex phase profiles is further demonstrated by analyzing metasurfaces (MSs) designed to generate multiple optical vortices and those incorporating additional optical functionalities, such as lens aberrations described by Zernike polynomials. The characterization results are benchmarked against their designed profiles, as shown in Fig. 1. Several examples illustrate the combination of a vortex with a TC of 2 and different phase profiles: a lens profile (Fig. 1a), astigmatism (Zernike moment Z_2^2) (Fig. 1b), and coma (Zernike moment Z_3^1) (Fig. 1c). In each case, the designed phase maps (left) are compared with the measured phase profiles (right). A strong qualitative agreement between the designed and retrieved profiles is evident, further supported by the root mean square error (RMSE) values of approximately 0.5 rad. The minor discrepancies observed primarily arise from measurement noise, design limitations, and fabrication imperfections, with numerical artifacts from the phase unwrapping process being particularly noticeable in Fig. 1b. Figure 1d presents the designed (left) and measured (right) phase profiles for an MS generating 15 vortices with TC values ranging from -4 to 4. The retrieved phase profile closely matches the designed structure; however, as the complexity of the phase distribution increases, the RMSE value slightly rises to 0.94 rad. This increase is likely due to the greater intricacy of the phase structure, making it more susceptible to minor deviations.

Thermal-Mechanical Coupling Performance of the Printable Al-Si Alloy Antisymmetric Lattice Metastructure

J. Q. Yan[1], Y. D. Gao[1], and H. Y. Huang[1*]

[1]School of Aeronautics, Northwestern Polytechnical University, China
[*]corresponding author: huangheyuan@nwpu.edu.cn

Abstract: This study investigated the mechanical behavior of four lattice structures using AlSi12Fe2.5Ni3Mn4, a newly developed alloy. A novel antisymmetric anti-buckling lattice cell (ASLC-B) based on a rotation reflection multistage design was developed. Quasi-static compression tests showed that ASLC-B outperformed the other three types in energy absorption, and heat transfer efficiency.

1. Structural Design

As shown in **Figure 1(a)**, by using a one-rod core of the PLC as the basis and performing a 180° rotation reflection within the plane of the structure's spatial center, a newly designed antisymmetric lattice cell (ASLC) was obtained. Then, a secondary cross-core has been incorporated into the rod core for anti-buckling constraint, resulting in a pyramid anti-buckling lattice cell (PLC-B) and antisymmetric anti-buckling lattice cell (ASLC-B).

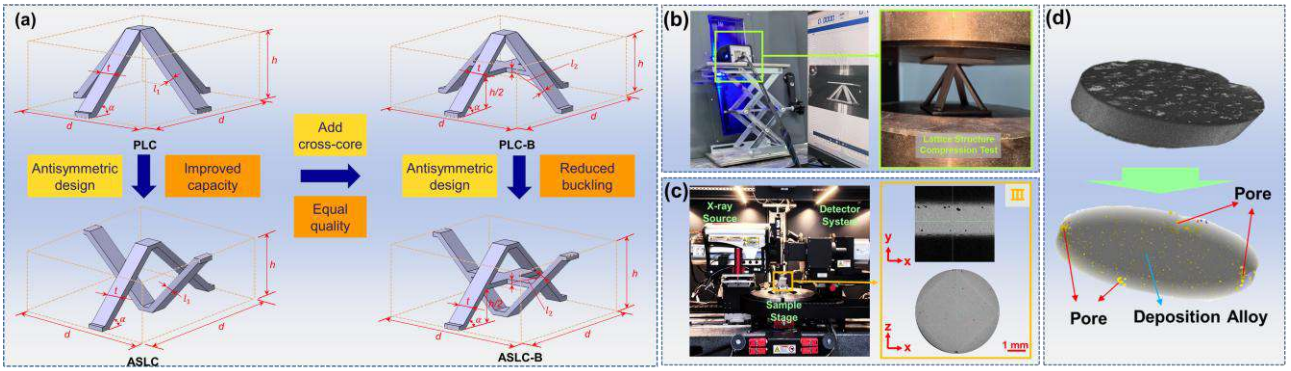

Figure 1. (a) Designing concept of lattice cells; (b) Schematic of lattice cells quasi-static compression test device; (c) Micro-CT device and the schematic of scanning results; (d) Distribution and 3D morphology of pores.

2. Test and Characterization

The lattice structure test pieces fabricated using SLM technology included PLC, PLC-B, ASLC, ASLC-B designs. The laser power for printing was 360W, with a scanning speed of 1250mm/s and a scanning spacing of 0.14mm. The tests were conducted using an MTS-E42 Universal Testing Machine equipped with a 500°C Environmental Box at a loading rate of 1mm/min. The compression test setup and the actual loading conditions were illustrated in **Figure 1(b)**.

The porosity of the printed lattice structures was analyzed using CT technology. For this purpose, an X-ray Micro-CT system (model: ZEISS Xradia 620 Versa) equipped with a 120kV voltage and 25W output power was employed to inspect the AlSi12Fe2.5Ni3Mn4 lattice structure. **Figure 1(c)** displayed the setup of the scanning device and the images of the scanning results obtained from different directions. By applying the global gray threshold to the Micro-CT reconstructed volume model, the pore distribution and morphology were determined in detail, as shown in **Figure 1(d)**. The porosity values ranged from as low as 0.307% to as high as 0.583%. After fitting and calculating the curve, the average porosity of the test piece was determined to be 0.454%.

3. Results and discussion

The comparison leveraged quantified indicators of structural performance, including the load-to-weight ratio (F_b), specific energy absorption (SEA), mean crushing force (MCF), crushing force efficiency (CFE), and structural stiffness (K)[1-3]. **Figure 2(a)** offered a comprehensive comparison of the load-bearing efficiency of the four lattice cells at 25°C and 200°C. **Figure 2(b)** offered a comprehensive comparison of the load-bearing efficiency of ASLC-B(AlSi10Mg) and ASLC-B at 25°C and 200°C. **Figure 2(c)** showed the N_{uL}-R_{eH} curves of four configurations, and the comparison showed that ASLC-B had the highest heat transfer efficiency.

At temperatures of 25°C and 200°C, the ultimate load of ASLC-B increased by 36.04% and 38.85% respectively, compared to PLC. Additionally, the heat transfer efficiency increased by 27.34%. Moreover, when comparing different materials, ASLC-B exhibited a 39.39% (25°C) and 44.14% (200°C) higher load-bearing capacity than ASLC-B(AlSi10Mg).

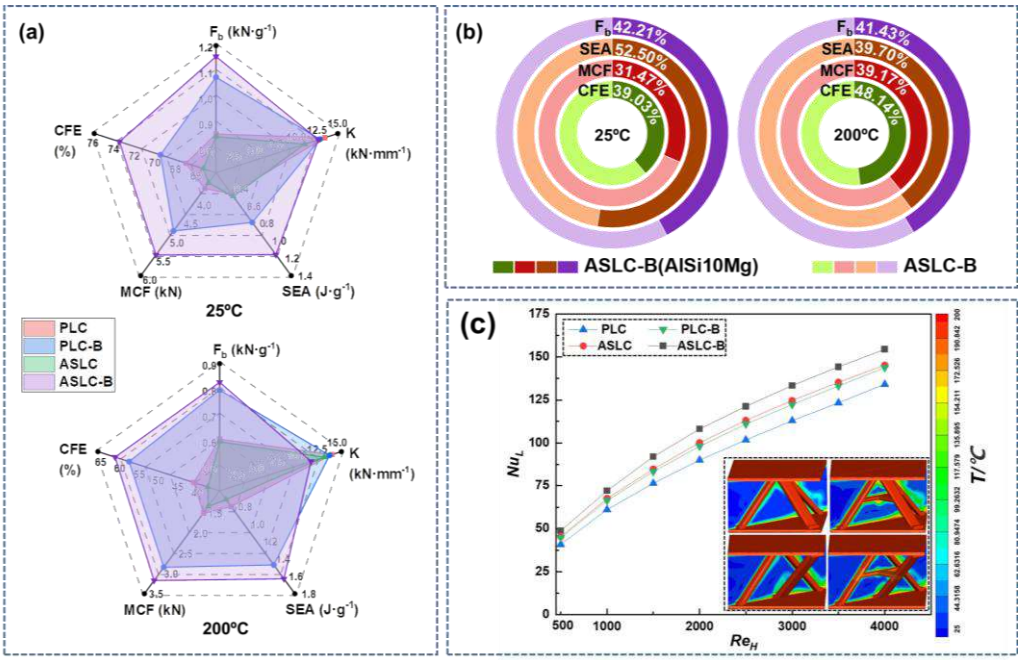

Figure 2. (a) Comparison of PLC, PLC-B, ASLC, and ASLC-B; (b) Comparison of ASLC-B(AlSi10Mg) and ASLC-B; (c) N_{uL}-R_{eH} curves.

Abstract

Given their unprecedented control over the degrees of freedom of light, metalenses showed great potential for structuring light. In this work centimeters-wide metalenses for the generation of self-accelerating vector beams are designed, fabricated and characterized.

Metasurfaces gained a lot of attention for their capacity to tune materials' properties. The field of structured light hugely benefits from metasurfaces, since the ability to spatially tune the light beams' degrees of freedom has always been a technological challenge. Moreover, metasurfaces can display anisotropic behaviour, enabling the polarization to be controlled with spin-decoupled meta-atoms [1]. In common types of light beams, only phase and intensity are spatially tuned, but thanks to recent advances in optical devices, light beams with a spatially-varying polarization state, the so-called vector beams, are gaining new interest. Applications of vector beams are reported in microscopy, communication and encryption. Regarding the application of metasurfaces for generating vector beams, multiple references can be found but they are limited to small sizes [3,4]. While size is not a limiting factor for research, larger devices may be needed for certain applications. For example, Gaussian-Bessel beams exhibit longer non-diffracting length if generated by larger optics. For applications involving structured light in free-space telecommunication, large optics are required to propagate signals for long distances [5]. Large metalenses are challenging for every step of their development: bigger memories are needed for simulating their response, huge amount of pattern data is to be generated and conveyed to the lithography tool, lithography takes longer and is subject to stricter stitching requirements.

In this work, we designed, fabricated and characterized spin-decoupled metalenses up to 2cm-wide for the generation of vector beams, working at 1310 nm of wavelength.

A spin-decoupled metalens is able to control the phase of a spin state independently of the other. This can be accomplished by designing a set of meta-atoms that act as half-wave plates (HWP): they exhibit spin-dependent and spin-independent phase contributions which can be respectively tuned by rotating and reshaping the pillar. A library of HWP meta-atoms was generated through FEM simulations and encoded in an ASCII file.

The metalens was designed to generate a self-accelerating propagating-variant Bessel beam. Such beam displays a non-linear focal curve in the non-diffracting range of the Bessel-like beam [6], which can be interpreted as the constructive interference of bundles of rays coming from circles of the input plane with different radii and center position. Moreover, a radius-dependent angular orbital momentum term was added, so that their Bessel order increased with propagation. The local meta-atom shapes and rotations were calculated to match the phase needed for such optical transformations.

In order to represent the pattern efficiently, shapes and rotations were encoded as losslessly-compressed bitmap images. Compared to a standard structure-reference-based GDS file, this encoding was 140 times more efficient. After some lithography-related preprocessing, the library file and images were fed to an algorithmic patterning script of the electron beam lithography

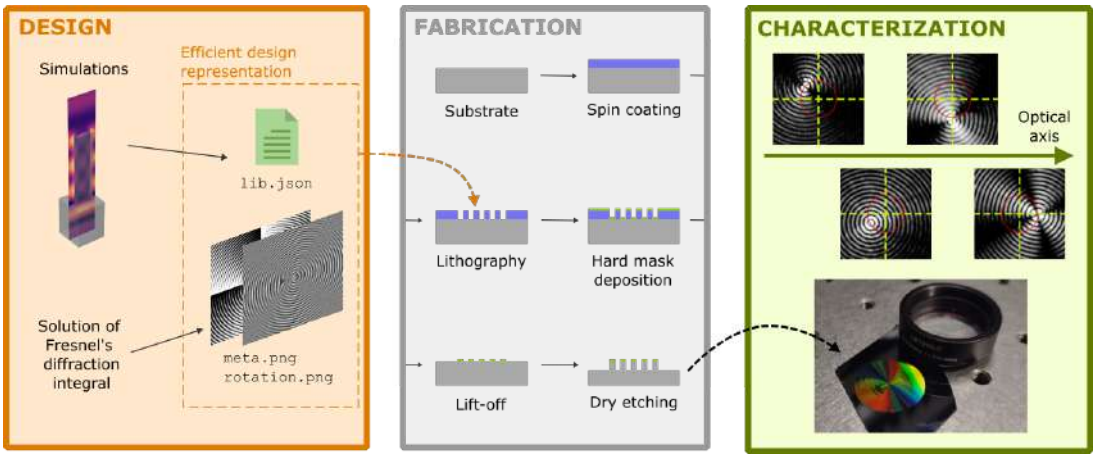

Figure 1: Scheme of the design, fabrication and characterization phases. Regarding characterization, the images were taken by shifting the image-collecting objective. On the low-right, the metalens is compared with a inch-sized lens.

(EBL) tool. Fabrication involved a two-phase protocol. First, a resist was patterned on a silicon substrate through EBL. In the second phase, the pattern was transferred to the underlying silicon by means of hard mask deposition, lift off and dry etching.

Devices were characterized on an optical bench. By shifting the image-collecting objective along the optical axis, the beam clearly shifted its center and the Bessel order increased, showing the desired self-accelerating behaviour.

Abstract: This paper delves deep into the application of Micro-CT technology in the performance characterization of composite materials. It elaborately expounds how this technology precisely reveals the internal structures and defects, and analyzes its vital significance for accurately evaluating composite properties.

Introduction

Traditional methods for characterizing the performance of composite materials mainly present numerical results (such as load, stress, etc.). The amount of information that can be reflected in this form is very limited, and it lacks intuitiveness. In contrast, micro-CT technology, with its advantages such as non-destructive testing, high-resolution imaging, three-dimensional visualization, and high detection efficiency, provides a feasible way to efficiently obtain internal information, preserve the original state of the sample, and accurately present the fine structures[1-3].

Experiment

In this paper, the Micro-CT technology is applied to detect the area around the holes of the bolted joint structure of carbon fiber composite materials under 150℃, and the internal damage forms and distribution laws are discussed. The schematic diagram of the sampling part and experimental devices are shown in **Figure 1**.

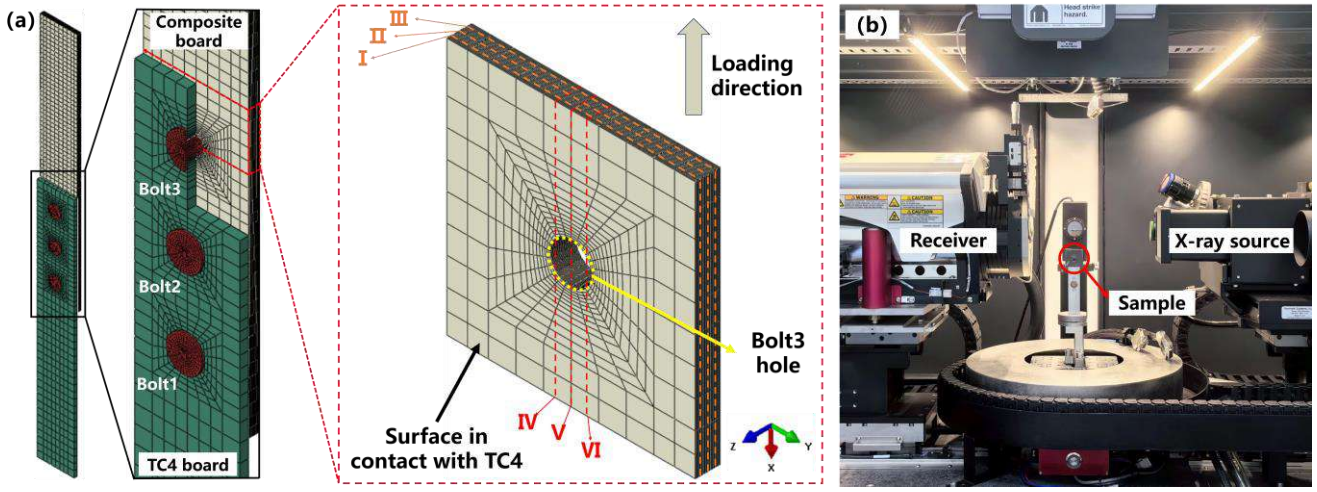

Figure 1 (a) Schematic diagram of the sampling part; (b) experimental devices.

The test piece is a hybrid bolted connection structure of T1000/BMI composite material and TC4 metal. The sample is taken from the area around the hole near the clamping end of the composite material plate. The three-dimensional reconstructed image obtained after Micro-CT scanning is shown in **Figure 2(a-b)**.

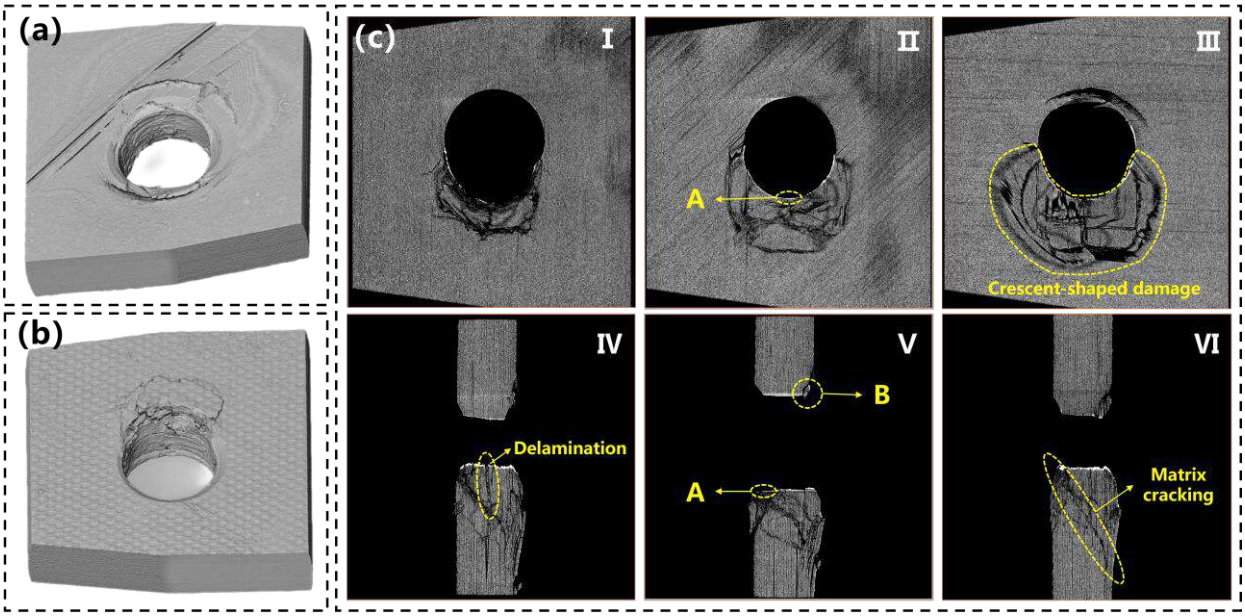

Figure 2 Results of the three-dimensional scanning: (a) the surface in contact with the TC4; (b) the reverse side; (c)the cut section diagrams in xy and xz directions (sections I to VI are intercepted according to Figure 1)

Results and Discussion

As can be seen from **Figure 2**, the extrusion damage (internal shadow) of the composite laminate shows a trend of gradually increasing from the inner side to the outer side, and a mixed damage of laminate delamination and matrix cracking has occurred. The extrusion damage is symmetrically distributed along the central position of the bolt hole, that is, the distribution laws of Section IV and Section VI obtained by micro-CT are basically the same. The damage on the outer side of the laminate at Section V in the middle of the bolt hole is weaker than that at Section IV and Section VI, but the damage on the inner side is stronger, reflecting that the vertical extrusion effect of Position A on the laminate is more obvious. At Position B, the outer plane of the composite laminate within a certain range has also been damaged.

In summary, Micro-CT technology can intuitively and efficiently assist in detecting the internal damage of the test piece without causing any damage, thereby facilitating the analysis of the mechanism.

Abstract: Direct laser interference patterning of metal layer followed by thermal oxidation for the fabrication of fully inorganic transparent submicron periodic structures, avoiding complexities of direct patterning of dielectric materials.

Periodic structures, featuring periodic modulation of optical constants, exhibit polarization control, spectral and angular selectivity of light and thus were found extremely useful for laser radiation manipulation. However, fabrication technologies of periodic structures have to face strict requirements for laser optics, especially for high-power systems. Despite a sub-micrometer scale of periodicity required for visible and infrared spectral region applications, the following significant criteria are optical transparency and durability, which require a completely inorganic composition of all constituent materials. Polymers are quite easily processed and can be transparent in the target spectral regions, but they exhibit lower optical resistance than fully inorganic materials such as metal oxides [1]. However, direct patterning of the dielectric materials is non-trivial, especially if sub-micrometric periodicity is required with sufficiently low surface roughness. To get around a direct patterning of metal oxides, a thin metallic layer deposited on a glass substrate can be structured. Subsequent annealing promotes a metal oxidation reaction, producing a fully inorganic, transparent periodic surface structure on a glass substrate.

The fabrication method proposed in our work [2] involves the structuring and subsequent thermal oxidation of a thin metallic layer on a glass substrate, as schematically shown in Fig. 1. For this, thin tantalum metal films were formed on fused silica substrates using ion beam sputtering technology. The pristine thin film samples were thermally annealed in an ambient atmosphere under various conditions (varying annealing temperature and heating rate) to evaluate optimal oxidation conditions for the structured thin film. Investigating the structural, optical, and chemical characteristics of various annealing procedures applied to tantalum thin films offered insights into the optimal parameters for thin film thermal oxidation. Thus, to avoid high optical losses and reach the purest Ta_2O_5 composition, 600 °C annealing temperature and 2 °C/min heating rate were used.

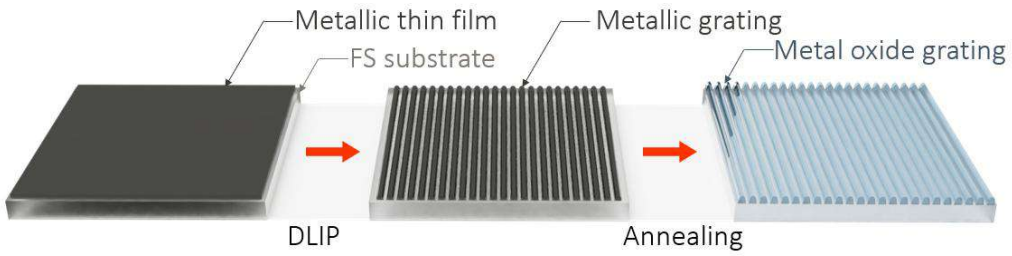

Figure 1. Fabrication steps of submicron periodic surface structure in metal oxide thin film, including Direct Laser Interference patterning (DLIP) of metallic layer and thermal oxidation (annealing).

Linear periodic structures – gratings – in thin metallic films were formed via the Direct Laser Interference Writing (DLIP) technique. The two-beam interference pattern was produced from the second harmonic (515 nm wavelength) laser beam of 7 ps short pulses. The resulting period of the linear interference pattern on the sample was 750 nm, with the laser spot size diameter at a $1/e^2$ level of 1.36 mm. After forming the grating structure by DLIP, the last step was annealing to complete metal oxidation, thus forming non-absorbing gratings. The structured films were annealed using the optimal parameters obtained from the investigation of as-grown films. The characterization results of the formed grating structure in thin films before and after annealing are summarized in Fig. 2. The atomic force microscope captured surface morphology images show increased modulation depths and fill factor, as shown in Fig. 2a. As it is inevitable during the oxidation process, the attachment of oxygen atoms to metal causes material volumetric expansion. Generally, the average modulation depth has increased from 280 to 420 nm, and the fill factor has increased by approximately 10 % for metal oxide structures.

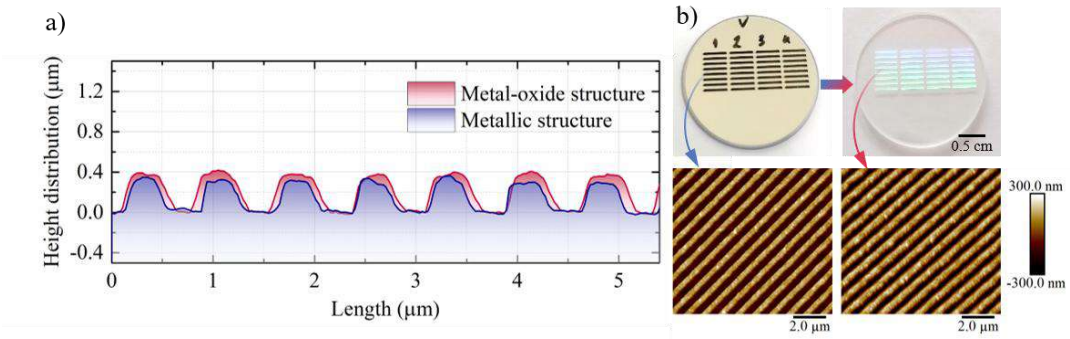

Figure 2. a) The atomic force microscope captured cross-sections and b) images of the patterned niobium thin film sample before (metallic structure) and after (transparent metal-oxide structure) annealing at niobium oxidation temperature.

The presented method of direct laser interference patterning of metal layers followed by thermal oxidation by annealing has been proven effective for obtaining sub-micrometer non-absorbing gratings. No absorption has been detected by spectrophotometric measurements, which allows the use of the developed nanostructures for high-intensity laser optics applications. This investigation shows that this method can overcome the problems associated with traditional glass microstructuring and is a promising route for developing advanced optical elements.

Abstract: We present an optical biosensor for detecting the protein S of COVID-19. Based on a low-refractive-index contrast subwavelength grating, we employ Fano resonance for high-sensitivity detection. The platform, fabricated using E-beam lithography and plasma etching, can be adapted for various biomarkers, including cancer-related proteins and pathogens.

Introduction

Various biosensors are currently being developed to detect analytes such as biomolecules and biological cells. These sensors hold significant potential for applications in diagnostic systems and screening tests.

Biosensors can be classified based on the type of signal transducer used, including electrochemical, mechanical, and optical sensors. Examples include electrochemical sensors, chemiluminescence and colorimetric sensors, surface plasmon resonance (SPR) sensors, localized surface plasmon resonance (LSPR) sensors, fluorescence-based sensors, fiber-optic sensors, terahertz-based biosensors, and surface-enhanced Raman spectroscopy (SERS) sensors [1,2], among others.

The design of biosensors varies significantly, particularly in terms of recognition elements, which depend on the specific of analytes [2] they are designed to detect. Electrochemical sensors operate by detecting electrochemical changes, such as variations in conductance, current, and potential, which may result from redox reactions [3]. Optical biosensors, on the other hand, detect changes in the properties of transmitted or reflected light, such as wavelength, intensity, and polarization [3]. They are highly sensitive to alterations in the optical properties of their environment, including changes in the refractive index.

Biosensors have enormous potential, particularly in medical applications, where they are used in diagnostic systems and screening tests. They can detect bacteria [4] and viruses [5,6], as well as various molecular and cellular analytes that serve as predictive, prognostic, or diagnostic biomarkers, such as glucose [7]. These biosensors employ diverse biorecognition elements, including proteins (antibodies, enzymes), nucleic acid probes

(deoxyribonucleic acid (DNA), ribonucleic acid (RNA)), and other specific biomolecules immobilized on the transducer surface [8,9].

Results

In this work, we present the design of an optical sensor for detecting the S protein of COVID-19. The sensor can be easily adapted to detect other viruses or cancer-related proteins without altering its fundamental design. The structure is based on a low-refractive-index contrast subwavelength grating (LC-SG) (Fig.1), which has been shown to support Friedrich–Wintgen Bound States in the Continuum (FW-BICs) that are non-radiative states in trully periodic configuration, and create high quality factor resonances in real-world realisations. This type of BIC is highly sensitive to environmental changes since resonating optical field interacts significantly with surroundings. Consequently, a structure based on FW-BIC exhibits an immediate response to variations in the surrounding environment or thickness, manifested as a spectral shift or a decrease in the quality factor. This characteristic makes it an ideal optical sensor.

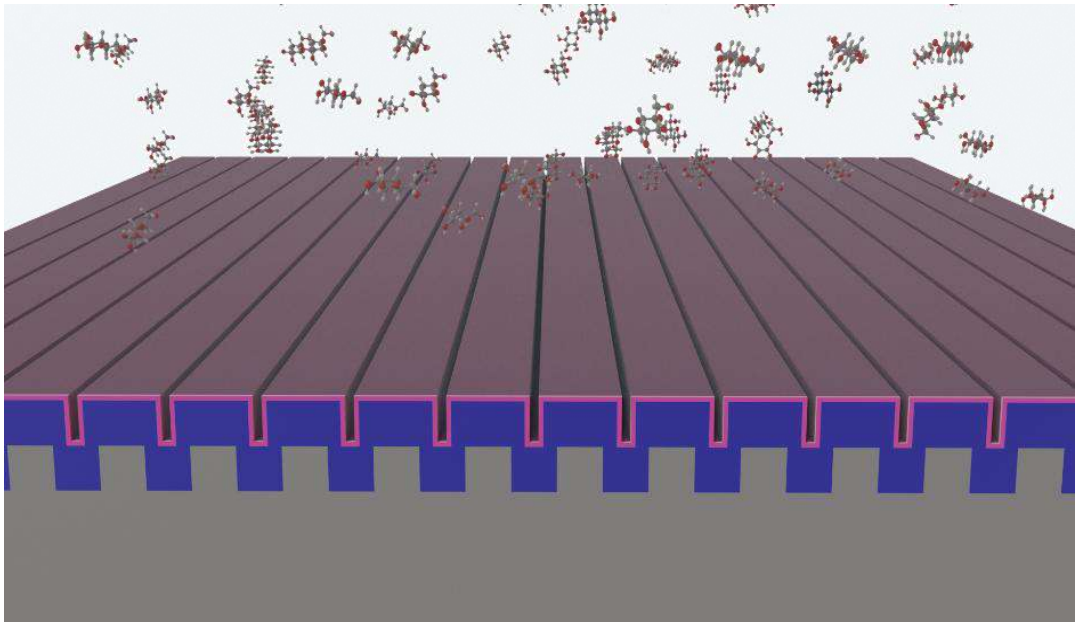

Fig. 1. Biosensor concept.

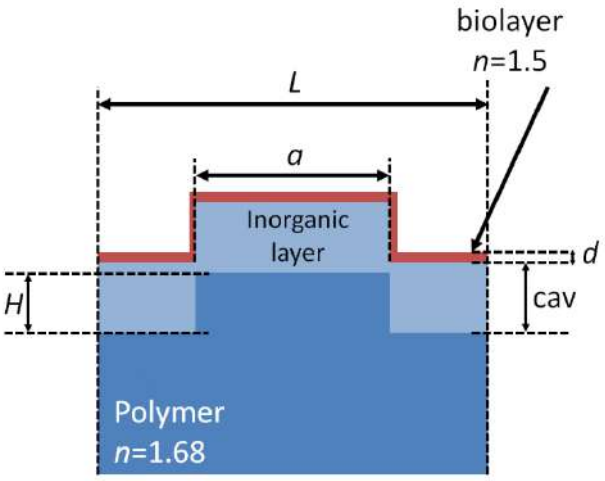
This sensor operates by exploiting changes in reflection or transmission resulting from the modification of Fano resonance conditions. Our approach involves creating subwavelength quasi-periodic structures, both one- and two-dimensional, made of polymer and coated with an inorganic layer (for example, HfO_2 or ZrO_2) with properly designed thickness to reveal a resonance peak (Fig. 2). The development of the sensor's platform involves a multi-step process. Firstly, the structures are designed based on numerical modeling, taking into account the desired sensing properties. Subsequently, E-beam lithography and plasma etching are used for master stamp fabrication. Next, the achieved stamp is replicated into the polymer. An inorganic coating with designed and precisely controlled thickness and optical properties is deposited onto the fabricated structures to enhance the sensor's performance. In the next step, the sensor surface is biofunctionalized, enabling

immobilization of specific bioreceptors that show particular affinity to the designed analytes, which are selected medical biomarkers in this case. These steps are crucial due to the challenges associated with preparing organic layers on polymers and achieving an effective layer for detection.



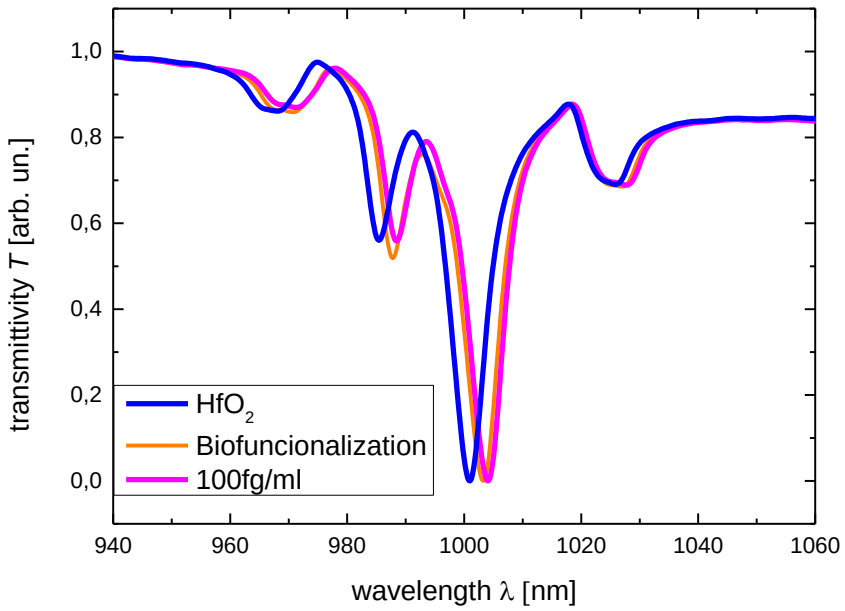


Fig. 2 Subwavelength quasi-periodic structures (a - 214 nm, L - 560 nm; H= 120 nm, cav(HfO_2)=319 nm).

The detection mechanism primarily relies on the optical response of the biosensor. The presence of analytes induces a spectral shift of the Fano resonance (Fig. 3), which is caused by modifying the biolayer thickness. First, the response is shifted after the biofunctionalization process (Fig. 3, orange line) and then again after the detection of 100 fg/mL of protein S (Fig. 3, pink line)

.

Fig. 3. The spectral shift of the Fano resonance, which is caused by the modification of the layer thickness.

This optical sensor platform holds significant potential for the detecting a variety of medical biomarkers, including analytes related to pathogens, cancer biomarkers, and others. By leveraging the unique properties of Fano resonance and utilizing engineered subwavelength quasi-periodic structures with specially designed optical coatings, the sensor can be tailored for detecting selected biomarkers.

Broadband Anti-Reflectance by Disordered Si Nanodisks for Thin-Film Solar Cells

H. Kylhammar*, S. Zayouna, A. Dumitrescu, M.E. Kjellberg, and S. Anand

Department of Applied Physics, School of Engineering Sciences, KTH Royal Institute of Technology, Albanova University Center, Roslagstullsbacken 21, 106 91 Stockholm, Sweden

Abstract: We design and fabricate spatially disordered Si nanodisks by colloidal lithography for broadband antireflection and light trapping. Absorption is optimized for thin-film solar cells through control of the geometrical features, dimensions, and density of the nanodisks. For comparison, periodic arrangements with unit cells containing more than one disk are investigated.

The development of semiconductor based metasurfaces enables light management for a wide range of optoelectronic device applications[1]. Dielectric nanostructure arrays provide significant improvement in antireflection and light trapping for thin-film solar cells[1-3].

The Mie resonant nanodisks are designed to induce forward scattering, implying a strong dependence on the nanodisk dimension and shape for the desired antireflection and wavelength dependent light scattering. Effective refractive index-matching improves the anti-reflection further and is controlled through nanodisk packing density as well as through disk height profile. Arranging nanodisks in a disordered array minimizes the effects from spatial correlation,[4,5] and provides weaker angular dependence compared to periodic arrays, which is beneficial for solar cell applications.

In this study, we utilize colloidal lithography to fabricate disordered Si nanodisk arrays on Si substrates (and thin films). Negatively charged polystyrene nanoparticles are adsorbed on a positively charged layer (polydiallyldimethylammonium, PDDA) on a silicon substrate forming a disordered, self-assembled mask. The interparticle spacing is controlled by the ionic strength of the particle suspension medium. The nanodisk height profiles can be controlled by changing the conditions of the dry etch process. We investigate the antireflective properties of disks of varying height profiles, ranging from nearly cylindrical to tapered and conical.

The measured reflectance of the fabricated arrays is compared with finite-difference time-domain (FDTD) simulations. Separately, for comparison FDTD simulations of the reflectance are performed for periodic structures, specifically considering a square lattice with a basis composed of 1 and 2 nanodisks. The scattering profiles from single nanodisks and from arrays are simulated and optimized to generate forward scattering into the Si substrate for targeted wavelengths to increase the path length for absorption. Our results show both the geometrical size and shape of the nanodisks and their spatial arrangement are important for enhancing solar light absorption in thin film Si solar cells.

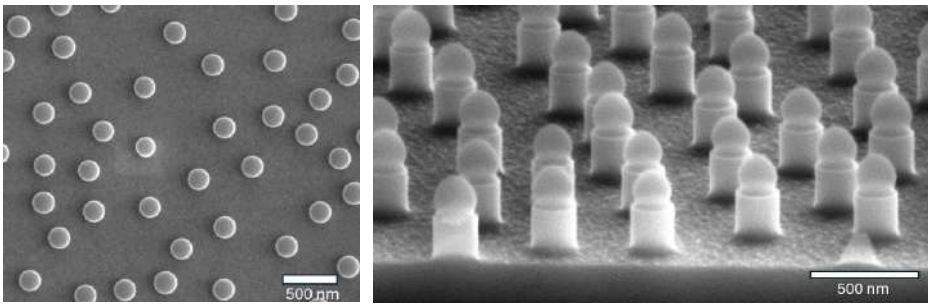

Figure 1. Left: Spatially disordered polystyrene nanoparticles (etch-masks) dispersed on Si substrate. Right: Si nanodisks fabricated by a pseudo-Bosch process; the remnant mask particles are also visible.

Abstract: We report a novel bistable current-voltage behavior observed in a Si pn-junction formed by direct wafer bonding at cryogenic temperatures below 30K. The phenomenon, driven by a 6nm SiO_2 barrier layer at the interface, reveals negative differential resistance and suggests potential applications in high-performance and quantum devices.

As the semiconductor industry prepares for the "post-Moore" era, the pursuit of further performance improvements through traditional miniaturization techniques has become increasingly challenging. To overcome these limitations, leading semiconductor companies such as Intel, Samsung, and TSMC are focusing on the development of advanced 2.5D packaging technology with direct wafer bonding. This innovative approach connects chips directly without the use of bumps, offering significant benefits, including reduced transmission delays, minimized parasitics, and enhanced power management and heat dissipation. These advantages make direct wafer bonding a critical technology for the development of high-performance semiconductor devices. Simultaneously, the growing demand for higher performance, as well as advancements in quantum computing, has pushed the exploration of silicon electronics into the cryogenic temperature regime.

In this study, we present a novel phenomenon observed in the cryogenic operation of a silicon p-n junction, formed by direct wafer bonding. The p-type and n-type silicon wafers, heavily doped to achieve desired electrical properties, were bonded together using this direct wafer bonding technique. The electrical properties of the junction were measured using metal ohmic contacts on both the top and bottom surfaces. At room temperature, the device exhibited typical diode current-voltage (I-V) characteristics. However, when the device was tested at cryogenic temperatures below 30K, an unexpected S-shaped I-V characteristic emerged, which became more pronounced as the temperature was reduced. This change in I-V behavior resulted in a bistable current switching response when sourcing voltage, attributed to the presence of negative differential resistance between the two stable states.

A key factor contributing to this intriguing behavior is the formation of a 6 nm thick silicon dioxide (SiO_2) barrier layer at the metallurgical interface between the p-type and n-type wafers during the wafer bonding process. This layer plays a crucial role in the switching mechanism and in the observed negative differential resistance. Our study, supported by computational modeling simulations, provides valuable insights into the underlying mechanisms driving this bistable behavior. Furthermore, it suggests potential applications for this novel functionality in the development of high-performance and quantum computing devices, where such switching properties could be leveraged for innovative use cases in next-generation electronics.

Cost-effective and mass production of meta-hologram using photolithography and Nanoimprint lithography

Chanwoong Park[1], Seungyeon Lee[1], Hansang Sung[1], Jaein Park[1], Heon Lee[1,*]

[1] Department of Materials Science and Engineering, Korea University, Seoul, 02841 Republic of Korea

Abstract: This study introduces a cost-effective, scalable manufacturing technique for metasurfaces using ArF scanner and nanoimprint lithography. The process allows high-throughput production with an 8-inch master stamp. A demonstration meta-hologram using TiO_2 nanoparticle-embedded resin achieved optical efficiencies of 44.8%, 32.3%, and 22.9% at different visible wavelengths.

A metasurface is a two-dimensional plane designed to have optical properties that do not exist in nature by arranging meta-atoms smaller than the wavelength of light. The shape and arrangement of the meta-atoms are designed differently depending on the purpose of the metasurface. When incident light passes through the metasurface, meta-atoms change the phase and amplitude of the light, resulting in unique optical properties that cannot be found in natural materials. These engineered electromagnetic responses enable precise control over light propagation, scattering, and focusing at the subwavelength scale. Using these remarkable properties, metasurfaces are applied to various fields such as metalenses, metaholograms, waveguides, cloaking, and color filters.

Small and lightweight optical devices are increasingly required in markets such as home appliances, automobiles, optical fiber and medical imaging. The miniaturization of optical systems like lenses becomes more important as devices become smaller and more compact. Traditional optical components rely on phase accumulation through propagation, necessitating specific thicknesses and curvatures that limit miniaturization. High-resolution hologram technology, lightening and miniaturization of devices are essential for immersive virtual reality (VR) and augmented reality (AR) experiences, where user comfort and portability are crucial factors. However, with current hologram technology, it is difficult to implement realistic images and reduce the form factor of the device simultaneously. Metasurfaces offer a promising solution to these problems by enabling optical functionality within ultracompact form factors, but issues such as manufacturing cost, yield, and productivity must be addressed before widespread commercialization can be achieved.

Electron-beam lithography (EBL) is generally used to fabricate metasurfaces for high-resolution patterning. Since the size of the meta-atoms constituting the metasurface is subwavelength (typically 100-500 nm for visible light applications), EBL is preferred for the accuracy of the designed patterns, allowing precise control of meta-atom geometry at nanometer resolution. However, EBL has significant limitations for commercialization because it is expensive, has low productivity, and is difficult to use for forming patterns over large areas. EBL irradiates electron beams one by one to produce patterns in a serial writing process, resulting in slow writing speed and narrow writing area. This point-by-point patterning approach makes EBL impractical for mass production scenarios where throughput and cost-effectiveness are essential considerations.

To overcome these limitations, photolithography using argon fluoride (ArF) laser has been employed to manufacture master stamps. This technique, widely used for high-resolution patterning in the semiconductor industry, operates at 193 nm wavelength and allows the production of metasurfaces much faster and over larger areas than EBL, though cost remains an issue when producing metasurfaces with photolithography alone due to the expensive equipment

required. ArF immersion lithography, which increases resolution by introducing a liquid medium between the final lens element and the wafer surface, enables feature sizes below 40 nm, suitable for many metasurface applications.

Nanoimprint lithography (NIL) presents an efficient method to reduce the cost of fabricating metasurfaces. Unlike conventional processes that require thin film deposition and etching in multiple steps under vacuum conditions, NIL can be performed much more easily and quickly than EBL through a simple mechanical embossing process. Once a master stamp is created, replica molds can be produced continuously as long as the stamp remains intact, dramatically improving throughput and reducing per-unit costs. By combining photolithography and NIL, it's possible to enhance productivity in metasurface fabrication while compensating for the cost disadvantage of using photolithography exclusively, creating a scalable approach suitable for industrial applications.

In this study, we demonstrated a platform for one-step printing of millimeter-scale metahologram patterns on a wafer scale using this combined approach. By preparing a resin with dispersed TiO_2 nanoparticles (NPs), researchers have created a high refractive index material with low extinction coefficient in the visible region, essential for efficient light manipulation. The NIL process using this TiO_2 nanoparticle-embedded-resin (nano-PER) forms meta-atoms on the substrate without requiring a vacuum process, further simplifying manufacturing. The direct patterning of nanoparticle-embedded resins eliminates several processing steps typically needed in conventional metasurface fabrication.

The fabricated metahologram demonstrated excellent performance across the visible spectrum, operating effectively with all three primary colors (RGB). It achieved maximum efficiencies of 60.7% at 450 nm (blue), 45.1% at 532 nm (green), and 38.5% at 635 nm (red), respectively. This broadband efficiency across RGB wavelengths is particularly significant for full-color holographic applications, enabling more vibrant and realistic holographic displays. These results suggest that EBL, which has been hindering the commercialization of metaholograms, can be successfully replaced by highly productive photolithography and NIL processes, potentially enabling widespread adoption of metasurface technology in consumer applications.

Mass Production of Metasurfaces Using $BaTiO_3$ Nanoparticle-Embedded Resin (nano-PER)

Seungyeon Lee[1], Chanwoong Park[1], Hansang Sung[2], Heon Lee[1*],

[1, 2]Department of Materials Science and Engineering, Korea University, Republic of Korea
[*]corresponding author: heonlee@korea.ac.kr

Abstract: In this study, we fabricated a high-performance meta-hologram using $BaTiO_3$ nanoparticle-embedded resin (nano-PER) via nanoimprint lithography. $BaTiO_3$ offers a high refractive index, low extinction coefficient, and ferroelectric properties. By uniformly dispersing these nanoparticles in nano-PER, we developed an optimized resin and mass-produced meta-holograms.

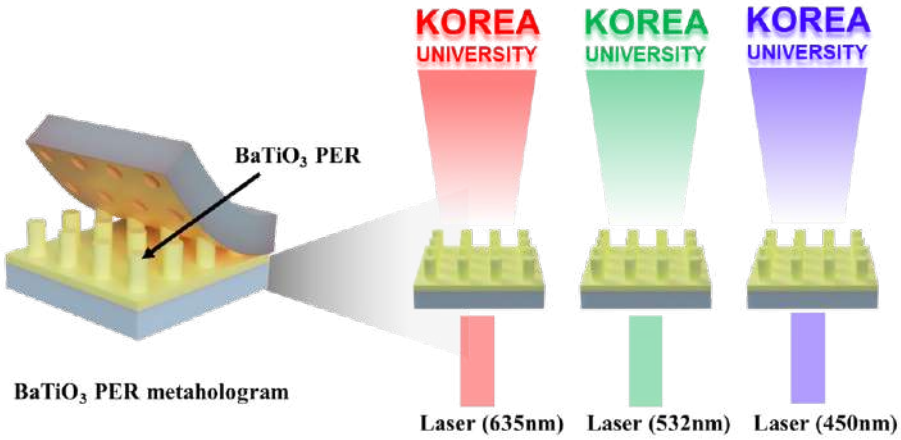

Figure 1. Schematic of meta-holograms fabricated using nanoimprint lithography

Recently, metasurfaces have received significant attention for various applications including metalenses, metaholograms, cloaking, waveguides, and color filters. They are also increasingly being integrated into various fields such as augmented reality (AR), virtual reality (VR), 3D displays, and medical imaging technologies.[1] Metasurfaces consist of meta-atoms arranged in specific structures on a 2D plane, with each meta-atom having a subwavelength size smaller than the incident light's wavelength. When light passes through the metasurface, the meta-atoms induce a phase shift, changing the phase and amplitude of the light and shaping the wavefront, giving the metasurface unique optical properties. By adjusting the arrangement, shape, and size of the meta-atoms, it is possible to control the phase and amplitude of the light.[2] Specifically, metaholograms encode desired images into the metasurface, which are displayed when light passes through it. Metaholograms can overcome the limitations of traditional holography technologies by providing a thin and lightweight alternative to bulky optical devices, while also enabling high-resolution images through the precisely designed meta-atoms.[3]

Despite their promise, fabricating metaholograms presents several challenges. Metaholograms require precisely arranged structures at the nanometer scale, making high-resolution lithography techniques essential for their fabrication. Nanoimprint lithography (NIL) is an efficient and cost-effective method that offers low manufacturing costs, high throughput, and the ability to produce high-resolution patterns. NIL makes the formation of precise nanostructures simple, ensuring the high resolution and accuracy that are critical for

determining the performance and quality of metaholograms. Moreover, NIL can be used for patterning with various materials, including polymers, dielectric materials, and ceramics, making it adaptable for a wide range of applications. [4]It is also suitable for large-area patterning and compatible with flexible substrates, making it ideal for mass production and use across different substrate types. [5]NIL is a cost-effective alternative to costly techniques such as electron-beam lithography or those requiring vacuum environments. The reusability of the master stamp further enhances its cost-efficiency, providing significant economic benefits for metasurface production.[6]

In this study, we propose a method to fabricate wafer-scale metahologram patterns using NIL and a newly developed $BaTiO_3$ -based resin in a single process. $BaTiO_3$ is a ferroelectric material with a high refractive index and low extinction coefficient in the visible spectrum. [7] By dispersing $BaTiO_3$ nanoparticles (NPs) into a thermal curable resin, we developed a $BaTiO_3$ nanocomposite resin (nano-PER) with ferroelectric properties and nano-formability. The $BaTiO_3$ nano-PER enables precise fabrication of nanostructures on a 2D plane and allows for the recording of electrical signals due to its ferroelectricity. [8]Additionally, its high refractive index facilitates phase modulation of light in the visible spectrum. Using this resin, we performed an NIL process to form meta-atoms composed of $BaTiO_3$ nanoparticles directly on a substrate without requiring additional vacuum process. The fabricated metaholograms achieved an efficiency of 34.2% at a blue light wavelength (λ = 450 nm), demonstrating the combined excellence of the optical properties of the BaTiO-based resin and the precision of the NIL process. This work opens up new possibilities for high-efficiency and commercially viable metaholograms and suggests promising applications in optical and electronic devices.

Fabrication and study of Nd-doped BCT-based dielectric ceramics for functional metamaterial applications

J. Makowska[1*], K. Feliksik[1], M. Adamczyk-Habrajska[1] and B. Wodecka-Dus[1]

[1] University of Silesia, Faculty of Science and Technology, Institute of Materials Engineering, 75 Pułku Piechoty 1A, 41-500 Chorzow, Poland;

[*]corresponding author: jolanta.makowska@us.edu.pl

Abstract: Nd-doped $Ba_{0.75}Ca_{0.25}TiO_3$ ceramics were synthesized using the solid-state method to improve dielectric properties. Due to their low losses and thermal stability, these materials show strong potential for applications in functional metamaterials.

Barium titanate ($BaTiO_3$, BT) is one of the most important electroceramic materials due to its excellent dielectric and ferroelectric properties [1–3]. Its performance can be significantly improved through chemical modification, particularly by doping with ions at A and/or B sites of the perovskite structure. Among these, doping with rare-earth elements like neodymium (Nd^{3+}) offers a promising route to enhancing dielectric behavior, reducing losses, and stabilizing phase transitions [4–9]. Additionally, processing parameters such as sintering temperature are known to play a crucial role in tuning the microstructure and electrical performance of BT-based ceramics [10-15].

Recent developments in ceramic-based dielectric metamaterials have highlighted the potential of such materials as low-loss, tunable alternatives to metal-based metamaterials, with applications in electromagnetic and energy systems, non-Hermitian physics, and components with near-zero or negative refractive index [16].

In this work, Nd-doped $Ba_{0.75}Ca_{0.25}TiO_3$ (BCT:Nd) ceramics were synthesized via the conventional solid-state reaction method, using high-purity oxides and carbonates as starting materials. The study aimed to modify the structural and dielectric properties of BCT ceramics through rare-earth element doping, in view of their potential use in functional metamaterial devices. The phase composition of the synthesized ceramics was confirmed by X-ray diffraction (XRD), indicating the formation of a single-phase perovskite structure. Basic microstructural observations using scanning electron microscopy (SEM) showed that sintering temperature and Nd incorporation affected grain growth and morphology. Dielectric measurements were performed as a function of temperature (from room temperature up to 200 °C) and frequency (1 kHz to 1 MHz). The incorporation of Nd significantly influenced the dielectric response, improving thermal stability and reducing dielectric losses — both essential for the performance of high-frequency metamaterial systems. The results demonstrate that Nd doping effectively enhances the functional properties of BCT-based ceramics, supporting their application in tunable and low-loss dielectric components for metamaterials, such as phase shifters, resonators, and adaptive electromagnetic devices.

Synthesis and Characterization of Dielectric Metamaterials Based on BLTF Ceramics

B. Wodecka-Dus[1*], M. Adamczyk-Habrajska[1], and J. Makowska[1]

University of Silesia, Faculty of Science and Technology, Institute of Materials Engineering, 75 Pułku Piechoty 1A, 41-500 Chorzow, Poland;
[*]corresponding author: beata.wodecka-dus@us.edu.pl

Abstract: Dielectric BLTF metamaterials with a perovskite structure were obtained using solid-state synthesis. Analysis of the microstructure, crystal structure, and electrical properties confirmed their high dielectric permittivity and low dielectric losses. Increasing Fe^{3+} doping significantly enhances the piezoelectric properties, indicating their potential for modern technological applications..

Dielectric metamaterials based on ceramics have attracted significant interest in recent years due to their high dielectric permittivity, relatively low dielectric losses, and other outstanding functional properties (e.g., ferroelectric, piezoelectric, dielectric, and magnetic) relevant to various resonance effects, their simple crystal structure, excellent multipolar tunability, and good environmental adaptability [1–5]. Compared to structures composed of discrete components (capacitance or inductance) in metal-based metamaterials at high frequencies, a single ceramic dielectric block can perform a basic resonance function, indicating that the structure of ceramic-based dielectric metamaterials is simpler and their preparation more convenient [6–9].

The aim of this study was to produce ceramics with the general formula $Ba_{1-x}La_xTi_{1-y}Fe_yO_3$ (BLTF) for concentrations x=0.004 and y=0.001, 0.002, 0.003, 0.004, characterized by a perovskite-type ABO_3 structure. These materials were obtained by conventional ceramic powder synthesis based on the solid-state reaction method (MOM method) using simple oxide powders, followed by free sintering and uniaxial hot pressing to densify the obtained powder materials.

All ceramic powders underwent thermal analysis (TG/DTA) and differential thermogravimetric analysis (DTG). The chemical composition of BLTF powders was determined by energy-dispersive X-ray spectroscopy (EDS). The microstructure of the resulting powders and BLTF ceramics was examined using scanning electron microscopy (SEM). EDS analysis confirmed the assumed chemical compositions for all ceramic powders. The crystal structure of BLTF ceramics was studied using X-ray diffraction. At room temperature ($T_r<T_C$), the obtained ceramic exhibits a single-phase, tetragonal structure with space group P4mm. An increase in iron content slightly reduces the unit cell volume.

BLTF ceramics exhibit a classical phase transition, high dielectric permittivity (ε), and low dielectric loss tangent values (tgδ), both at room temperature and in the phase transition region. Analysis of temperature-dependent DC conductivity revealed the presence of a positive temperature coefficient of resistivity (PTCR) in the phase transition region [10]. The dependence of piezoelectric coefficients on iron content in BLTF ceramics was determined using quasi-static and resonance methods. The results show that the addition of 0.3mol% Fe^{3+} ions to the ceramic structure increased the piezoelectric coefficient d_{33} to a maximum value of 159pC/N [11]. The electrical properties of BLTF ceramics were tested using impedance spectroscopy in the frequency range of 20Hz–2MHz and temperature range of 20–580°C. To ensure the consistency of the measured data, the obtained impedance spectra were analyzed using the Kramers–Kronig method. The use of an equivalent circuit proposed by the authors allowed for the extraction of grain and grain boundary resistivity. Based on the plot of the natural

logarithm of resistivity versus the inverse absolute temperature, the activation energies for conduction processes were determined. The values indicated that the iron dopant in the BLTF ceramic played a key role in grain and grain boundary conductivity [12].

This review summarizes recent advances in ceramic-based BLTF dielectric metamaterial technologies for electromagnetic applications. Following the developmental trends of modern physics, multifunctional devices realized solely with ceramic-based dielectric metamaterials are expected to evolve rapidly. They may be integrated into many other devices, offering broad application prospects in the future.

Fabrication of optical phase elements in bulk sapphire by ultrashort pulses

E. Aleksandravičius[1*], G. Kontenis[1], I. Meškėlaitė[1] and D. Gailevičius[1]

[1]Vilnius university, Laser Research Center, Saulėtekio ave. 10, Vilnius, Lithuania
[*]corresponding author: edvinas.aleksandravicius@ff.vu.lt

Abstract: Sapphire possesses many desirable properties for use in photonics, however there are many challenges when it comes to fabricating optical phase elements in it. We show that the use of ultrashort pulses <100 fs can alleviate many of these issues, particularly the formation of cracks in larger structures.

The aim of this study is to fill the gap in available research on the fabrication of geometric phase elements in sapphire. The use of sapphire is desirable due to its excellent thermal stability and conductivity, broad transmission spectrum, high optical damage threshold, chemical inertness, and nonlinear properties, which could lead to interesting interplay with various phase elements. Because of these properties, sapphire is commonly used as a substrate for the deposition and subsequent direct laser writing of other materials. Still, there are very few examples of fabricating phase elements in sapphire itself, with much of the present literature focusing instead on the use of the induced nanogratings[1] or chemical etching of the modified material[2]. The core of this research is a parametric study of direct laser writing in sapphire aiming to circumvent the issues of the sapphire crystal cracking, induction of mechanical stress, and formation of nanogratings, all of which reduce the quality of any fabricated phase element. We note that the availability of high pulse energies for pulse durations down to >200 fs allowed us to explore these phenomena in some regard. However, improvements given by <100 fs have not been realized in the context of high repetition rates and high pulse energies.

We fabricated single-layer phase diffraction gratings to help evaluate the modified refractive index contrast and multi-layered spatial filtering photonic crystals to assess the formation of cracks in the sapphire. We used crossed-polarizer microscopy to evaluate the formation of nanogratings and the induction of mechanical stress. The determination of the crystal's cracking and strain-induced failure is performed by standard bright-field microscopy.

The results show that using ultrashort pulses down to 60 fs can significantly improve the quality of the fabricated elements. Shorter pulse durations significantly shift the fabrication window, the optimal pulse energy being nearly double that of 240 fs pulses. The formation of cracks can be seen in Figure 1. Fig. 1 (a) and (c) show single- and multi-layered structures fabricated with 240 fs, while (b) and (d) – structures fabricated with 60 fs, respectively. The structure (a) (240 fs) already shows some signs of small cracks, particularly at the corners and edges; on the other hand, (b) (60 fs) appears to be nearly ideal. However, a much more significant difference can be seen in the multi-layered structures, with (c) (240 fs) exhibiting large-scale cracks, rendering the structure entirely unusable, whereas (d) (60 fs) shows only minor defects. Therefore, we can conclude that the use of shorter pulses leads to reduced mechanical stress and, thus, reduced likelihood of cracking. However, the effect on the formation of nanogratings appears negligible. Additionally, the refractive index contrast induced by the material modification at optimal pulse energies does not show a significant dependence on pulse duration. Regardless, by employing 60 fs laser pulses, we could fabricate high-quality optical phase elements, such as photonic crystal spatial filters and phase diffraction gratings.

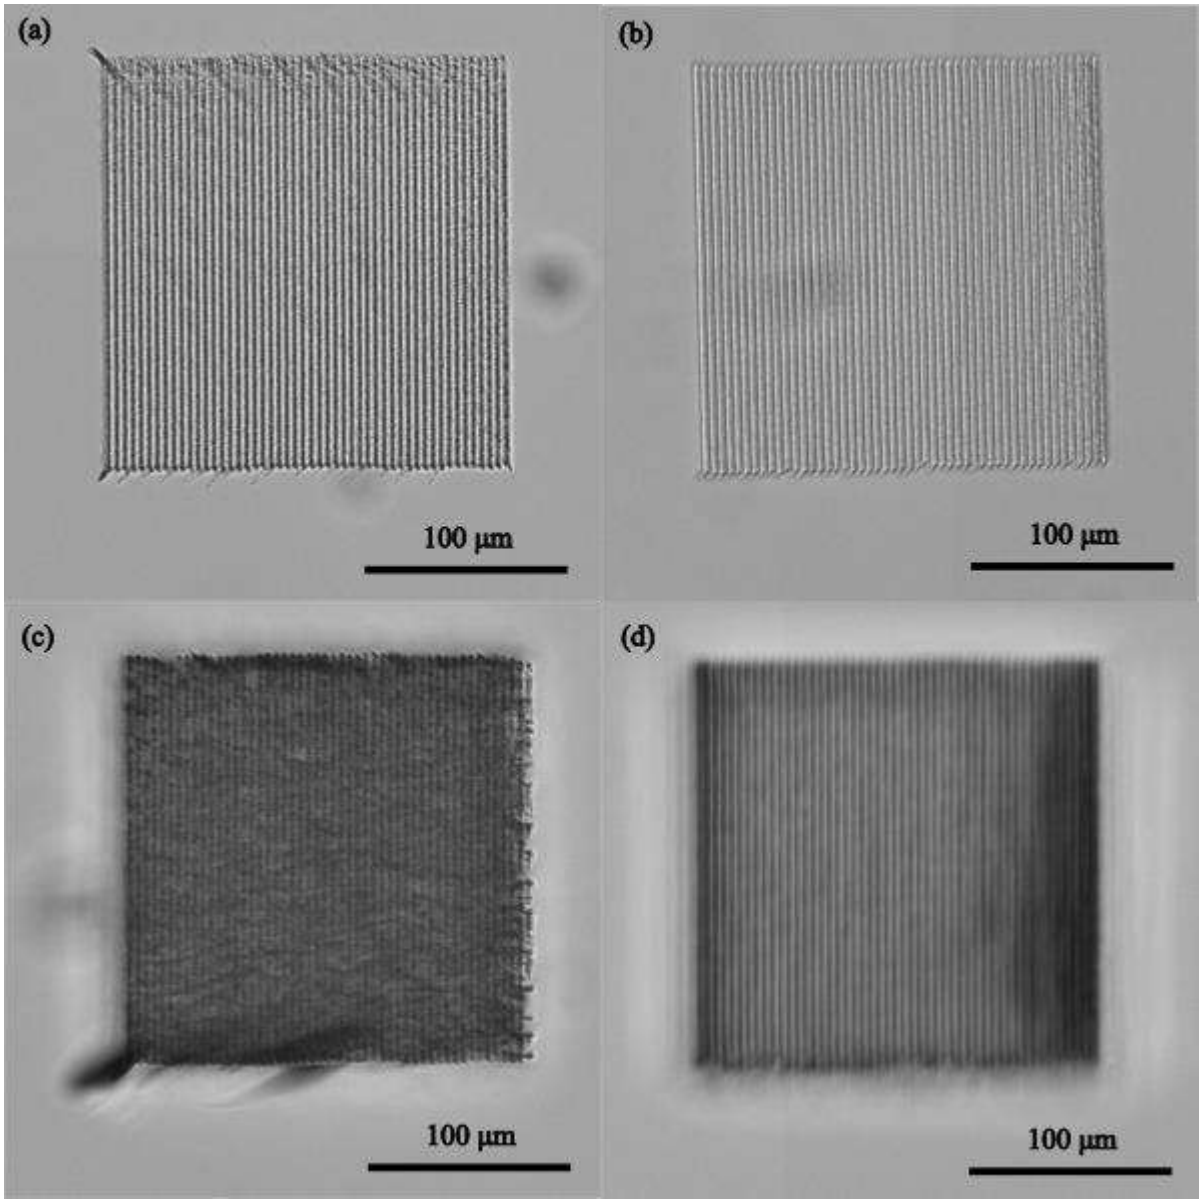

Figure 1. Microscope images of single-layer structure (a) and multi-layer structure (c) fabricated with 240 fs pulses and single-layer structure (b) and multi-layer structure (d) fabricated with 60 fs pulses.

This research has been funded by the Research Council of Lithuania, project S-MIP-23-49, "Supercontinuum generation in super-diffracting bulk photonic crystals".

Acoustic, Seismic, and Thermal Metamaterials

Dual-Directional Acoustic Metamaterial Absorber for Noise Reduction

Tzu-Hsuan Chan[1], **and Tsung-Yu Huang**[1,*]

[1]Department of Materials Engineering, Ming Chi University of Technology, New Taipei City, Taiwan, 243303
[*] Email: huang.tsungyu@mail.mcut.edu.tw

Abstract: This study explores an acoustic metamaterial with dual-directional absorption, allowing sound waves to enter from two perpendicular directions for multi-directional noise absorption. This study utilizes a 3D printer to create Lego bricks, which can be assembled. Users can customize the structure as needed. This design enhancing flexibility for various environments.

This study improves the limitations of traditional acoustic metamaterial absorbers, which are primarily designed with a single opening and thus cannot effectively absorb sound waves from orthogonal directions. To address this issue, we propose a sound-absorbing structure with dual openings, utilizing a quasi-Helmholtz resonance mechanism. This mechanism is like that of a conventional Helmholtz resonator, where sound wave resonated within the cavity. When sound waves impinged on the metamaterial, the air inside the cavity vibrated, generating thermo-viscous losses that gradually converted acoustic energy into thermal energy, thereby achieving effective absorption. As shown in **Figure 1(a)**, our designed acoustic metamaterial revealed a 4 folded symmetry, consisting of four sealed side resonance cavities and a central resonance cavity, with two openings at both the x- and y-axes. The proposed acoustic metamaterial absorber achieves a high absorption rate of 97% at 990 Hz, demonstrating excellent acoustic absorption performance. Additionally, the overall thickness is only 1/30 of the working wavelength, achieving a subwavelength miniaturized design. Furthermore, for the sound waves incident along the x- or y-axis, the absorption peak remains the same, confirming the ability of dual directional incidences. Besides, it was observed that the cavity thickness would affect the absorption performance of the acoustic metamaterials. As shown in **Figure 1(b)**, when the thickness increases to 4 mm from 2 mm, the absorption peak significantly decreases. ◦

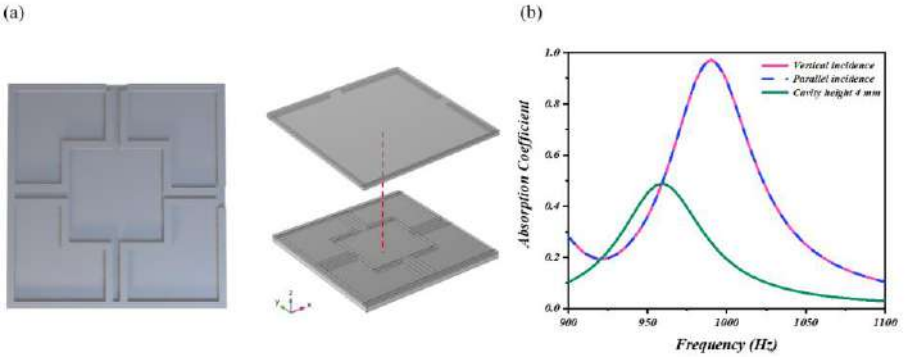

Figure 1. (a) Schematic diagram of the proposed acoustic metamaterial absorber, (b) absorption spectra for sound waves incident from the vertical and parallel directions, as well as the absorption spectrum for a cavity height of 4 mm.

Taking a step further, as shown in **Figure 2(a)**, we utilized a 3D printer to print LEGO-like components, which were then assembled into the designed acoustic metamaterial absorber. We found that by adjusting the structural parameters, the absorption frequency range could be further tuned to match different application needs. As shown in **Figure 2(b)**, simply modifying the structural parameters of the model allows for changes the

absorption frequency of the acoustic metamaterial. Additionally, the LEGO-style assembly method using 3D printing not only enhances design flexibility but also enables users to fine-tune the structure according to their needs, further optimizing the absorption frequency range and providing an efficient and adjustable noise control solution.

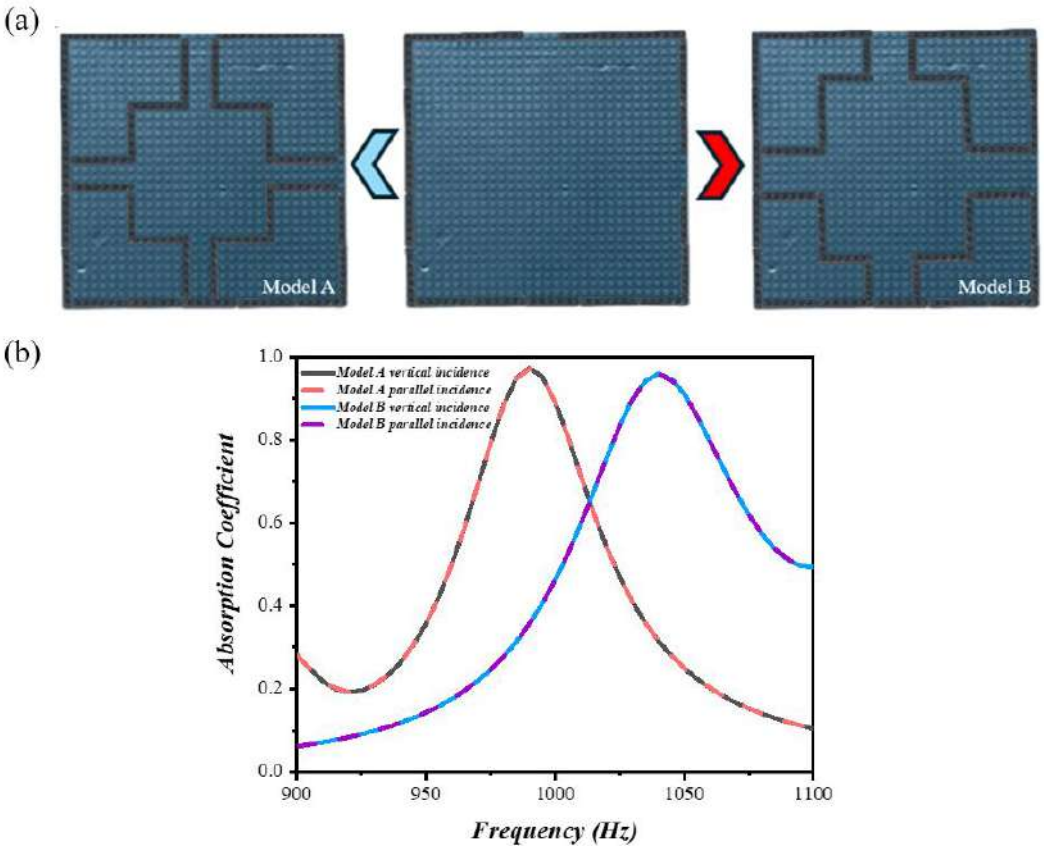

Figure 2. (a) 3D-printed LEGO-like blocks that can be arranged into different acoustic metamaterials. (b) Absorption spectra of Model A and Model B.

In summary, this study features a symmetric bidirectional absorption structure with a subwavelength thickness. The proposed acoustic metamaterial achieves a high sound absorption efficiency of 97% at 990 Hz, demonstrating excellent potential in noise control applications and offering significant practical usage.

Bound states in the continuum of underwater phononic crystals

Yuzhen Yang[1*], Han Jia[1]

[1]Key Laboratory of Noise and Vibration Research, Institute of Acoustics, Chinese Academy of Sciences, China
[*]corresponding author: yangyuzhen@mail.ioa.ac.cn

Abstract: This study focuses on the bound states in the continuum of underwater phononic crystals, specifically examining symmetry-protected bound states and Fabry-Perot bound states. These bound states in the continuum enhances the potential for developing high-Q acoustic devices, which are of paramount importance for applications in underwater communication, imaging, and detection.

Acoustic resonators are the fundamental components of many modern acoustic devices and can be used as unit structures for acoustic metasurfaces to achieve arbitrary wavefront manipulation[1,2]. So far, most of the reported acoustic resonators exhibit relatively small quality factors, which hinders their application in the design of acoustic filters, sensors and other devices. Bound states in the continuum (BICs), also known as capture modes with infinite quality factors, have attracted widespread interests from researchers in the fields of optics and acoustics[3,4]. It is a non-radiative mode embedded in the continuous spectrum. Due to its excellent field confinement, it can enhance the interaction between waves and matters. On the basis of underwater phononic crystals, this work focuses on the formation mechanisms of different kinds of BICs in one-dimensional phononic crystals, such as symmetry-protected BICs and Fabry-Perot BICs. In addition, we explored the evolution characteristics of BICs in parameter space, such as merging and splitting. This work will provide potential applications in constructing ultra-high Q value underwater acoustic devices.

In single-layer square phononic crystals, symmetry-protected BICs were achieved in the case of incompatibility between mode symmetry and radiation channels. The sound pressure distributions of modes M2 and M4 in water are both odd symmetric at Γ point, which can not be excited by vertically incident plane waves. In the simulation, rotating square structures were used to break the symmetry of the phononic crystal, which is shown as in FIG.1(a). It was demonstrated that structural symmetry is a necessary condition for the formation of symmetry-protected BICs. By calculating the transmission spectra of various rotating structures, the disappearance of transmission valley linewidth was observed and the appearance of symmetry-protected BICs was verified, as shown in FIG.1(b).

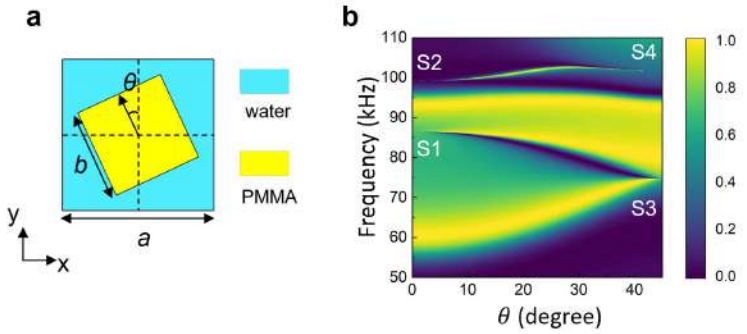

FIG.1 (a) Symmetry-broken unit cell. (b) Reflection spectrum with different rotation angles.

Then, we used bilayer structures that shown as in FIG.2(a) to form Fabry-Perot resonance between two

resonant systems. The distance between layers is adjusted to cause destructive interference in the external radiation channels. The simulated transmission spectrum is shown in FIG.2(b). At some specific distance, Fabry-Perot BICs are achieved when sound energy is localized between two layers and radiation is prevented. For different resonance modes of single-layer structure, the conditions for the formation of Fabry-Perot BICs can be achieved by changing the interlayer distance, and a periodic distribution is formed in the axial of parameter δ. Two broadband transmission valleys were observed in transmission spectra, and narrowband transmission peaks appeared in the broadband transmission valleys. The simulation result showed the disappearance of line width at the BICs formed within these transmission peaks.

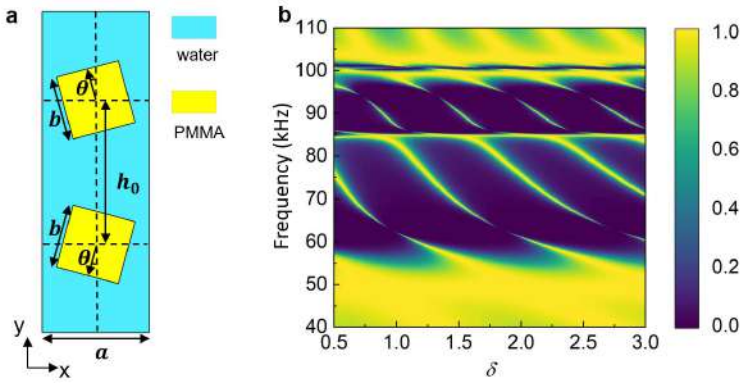

FIG.2 (a) Unit-cell composition of bilayer structure. (b) Transmission spectrum of bilayer phononic crystal with variable parameter δ.

By combining the Fabry-Perot resonance of bilayer structures with the coupled resonant modes in a single system, the Fabry-Perot BICs formed by two different resonant modes can be merged together, and the Q value divergence rate will change into $(\delta - \delta_0)^{-4}$, forming a high-order BIC. The merging BIC achieved a stable high-Q bound state in a larger parameter region. To accomplish this objective, we proposed bilayer rectangular structure. By changing two parameters about spacing distance δ and side length d, two Fabry-Perot BICs with the same symmetry merge together to form a single high-order BIC.

Abstract: A tunable curved piezoelectric metasurface is proposed here, which is attached on the surface of host cylindrical shell to achieve anomalous refraction of flexural waves. This study extends the research on elastic metasurfaces from planar structures to non-planar structures, and provides a new method for wave manipulation in cylindrical shells.

Non-planar structures such as cylindrical shells and conical shells are widely used in engineering fields, and the control of elastic wave and vibration in service is always a key issue [1]. Metasurface has received extensive attention due to its compact configuration and strong ability to manipulate the wave propagation [2]. Whereas, the current researches on elastic wave metasurface are mainly focused on wave manipulation in plates by planar metasurface. In this study, we design a curved piezoelectric metasurface, which consists of piezoelectric transducers with shunting negative capacitance circuits, and attached it on the surface of host cylindrical shell (shown in Figure 1) to realize the manipulation of flexural waves. Considering the anisotropy properties of piezoelectric transducers introduced by the curvature, the generalized Snell's law and diffraction law [3] for waves passing through the curved piezoelectric metasurface are obtained, and the wave motion characteristics in the cylindrical shell are analyzed. Then, the tunable ability of metasurface is investigated by adjusting the shunting circuits for the incident waves at different frequencies, and the symmetric and asymmetric transmissions of flexural waves in cylindrical shell are realized by designing the phase gradient distribution of metasurface.

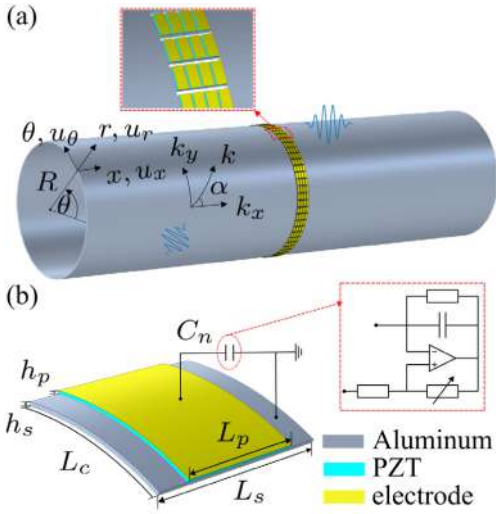

Figure 1. Schematic diagrams of (a) the host elastic cylindrical shell with a piezoelectric metasurface and (b) the basic unit cell of metasurface.

To verify the effectivencess and tunable ability of metasurface to manipulate flexural waves, numerical simulations are carried out. By altering the shunting circuits to design different distributions of phase gradient, the metasurface can achieve asymmetric and symmetric transmissions of flexural waves in cylindrical shell as shown in Figures 2(a) and (b), respectively. The transmission angle obtained by simulation is consistent with the theoretical value, which verifies the correctness of our metasurface model. In addition, results show that the proposed piezoelectric metasurface has the tunable ability in a wide frequency range by only adjusting the circuits and without changing its physical structure.

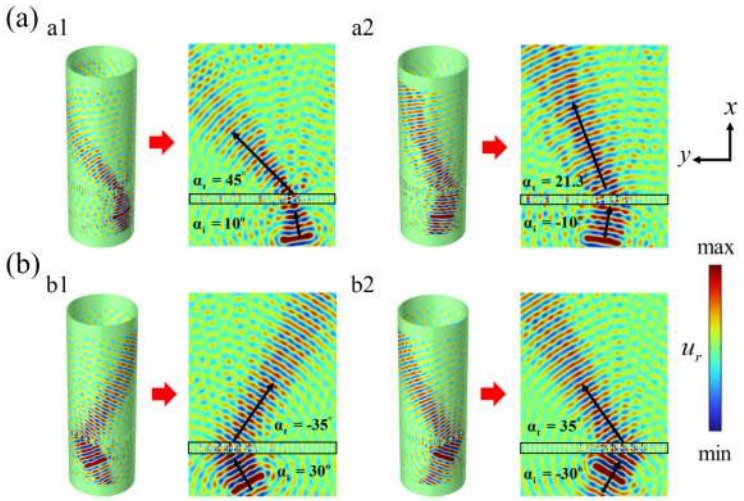

Figure 2. Asymmetric and symmetric transmissions at f=30 kHz: (a) radial displacement fields with incident angles $\alpha_i = \pm 10^\circ$, (b) radial displacement fields with incident angles $\alpha_i = \pm 30^\circ$.

In this paper, the concept of elastic metasurface is extended to apply in curved structures, and a tunable curved piezoelectric metasurface is proposed to realize the anomalous refraction of flexural waves in cylindrical shells. Our research could broaden the application of tunable piezoelectric metasurface and provide an efficient method for the wave manipulation in curved structures.

Abstract: In this research, a tunable Friedrich-Wintgen bound state in the continuum (FW BIC) is designed to achieve an elastic waveguide with a high-quality factor. Numerical simulations and experimental tests are conducted to verify the formation of FW BIC. Furthermore, a perfect absorption of flexural waves can also be realized.

As engineering structures have become increasingly complex to meet the requirements of industries, the study of propagating guided waves within them presents a significant difficulty due to the characteristics of dispersion and multimodality. In addition, it poses a considerable obstacle for guided wave-based nondestructive testing techniques (NDT) [1]. Although diverse metamaterial-based sensors have been proposed to extract desired information from complex signals, most of them have many unit cells and are generally difficult to reach a high-quality factor (*Q*-factor). Consequently, the design of guided wave sensors with compact configuration and high *Q*-factor is of paramount importance.

In this study, we design a non-Hermitian electromechanical system, which integrates Friedrich-Wintgen bound states in the continuum (FW BICs) [2] into an elastic plate using two PZT (lead zirconic titanate) patches with shunting circuits, as shown in Figure 1. Each PZT patch can be a tunable resonator by altering the inductor in the circuit. It doesn't like metamaterials, FW BICs can be formed by two PZT patches and can exhibit a very high *Q*-factor. The complex eigenfrequency is calculated by using the finite element software COMSOL Multiphysics. Results not only exhibit the existence of a high *Q*-factor but also show the coupled mode of FW BICs. Experimental tests are also conducted to verify the numerical results.

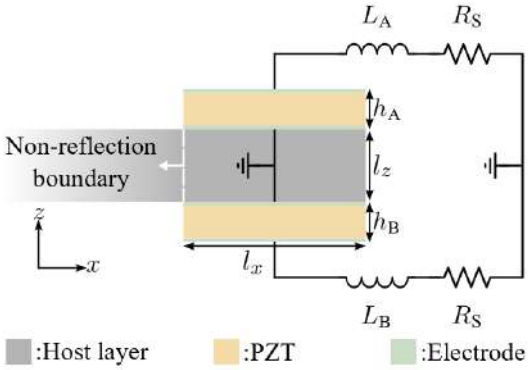

Figure 1. The non-Hermitian electromechanical system: A plate attached by two PZT (lead zirconic titanate) patches with shunted circuits.

For indicating the robustness and effectivity of FW BICs, the influences of manufacturing errors and material properties of host plate are discussed. By tuning the resonance frequency of resonators, the reduction in *Q*-factor can be repaired. And the designed FW BICs are observed within diverse host waveguides with different parameters. Furthermore, FW BICs can realize perfect absorption of flexural waves at the resonant frequency as shown in Figure 2, in which the critical coupling conditions $\Gamma = \Gamma_S$ and $\Gamma = \Gamma_A$ are separately for symmetric mode and antisymmetric mode, and the reflection ratio *R* is calculated by finite element method and temporal coupled-mode theory [3].

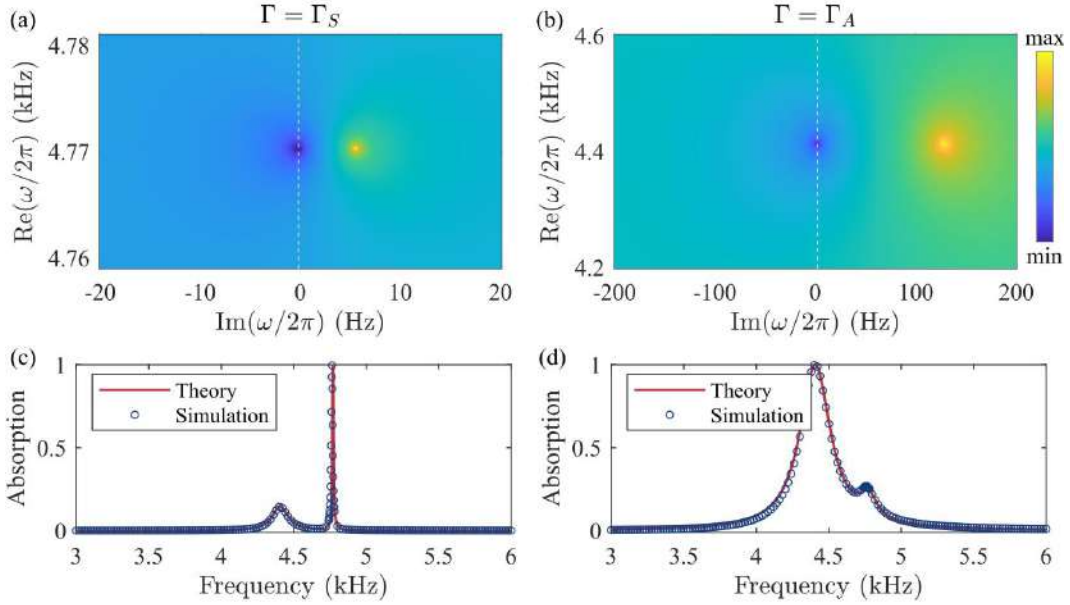

Figure 2. The $\log_{10}|R|$ in the complex frequency plane for (a) $\Gamma = \Gamma_S$ and (b) $\Gamma = \Gamma_A$, and the perfect absorption for (c) $\Gamma = \Gamma_S$ and (d) $\Gamma = \Gamma_A$.

In this research, we propose a tunable FW BIC in an elastic plate. Based on the FW BIC, the tunable resonance with a high *Q*-factor can be realized, and the perfect absorption of flexural wave can also be successfully achieved. Therefore, our research paves a new way for designing miniaturized high-*Q* sensors.

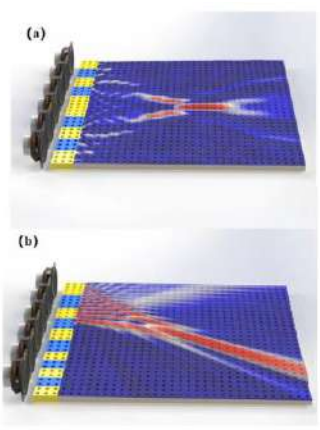
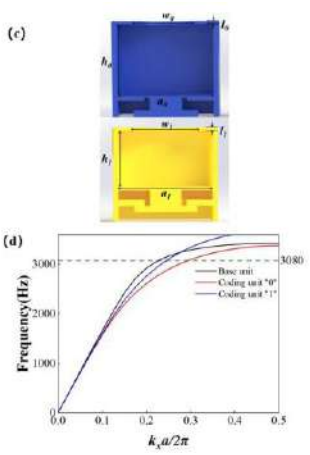
Abstract: In this paper, we design a tunable acoustic metasurface composed of Helmholtz-resonator-like digital-coding meta-atoms to realize the dynamic manipulation of spoof surface acoustic waves (SSAWs). By mechanically adjusting the resonator depth, we demonstrate a multifunctional and adaptive wavefront manipulation including acoustic focusing and Airy beam's generation.

Spoof surface acoustic waves (SSAWs), which is the direct acoustical analog of plasmon, can support strongly localized surface waves by metasurfaces and offer a toolset for acoustic imaging, communications, etc. For example, Liu manipulates two-dimensional acoustic vortices beyond the diffraction limit based on SSAWs. Li demonstrates the superwavelength self-healing of spoof surface sonic Airy-Talbot waves and realizes a high-quality, low-error, and high-capacity acoustic information transmission. However, the SSAWs cannot be controlled dynamically by these passive metasurfaces as the geometries of the unit cells are fixed, which restricts their application in emerging fields such as real-time signal encoding and adaptive wavefront manipulation. Here, we design a reconfigurable coding metasurface based on Helmholtz resonator unit cells, enabling flexible phase modulation of SSAWs through mechanical adjustment of the resonator depth. By selecting two units with a consistent transmission amplitude and a relative phase difference of 180° to construct a binary 1-bit encoding metasurface, we realize multiple functions of acoustic focusing and generation of Airy beam, as shown in Figs. 1(a) and (b).



Our metasurface comprises two independent coding units, as shown in Fig. 1(c). The neck length l=1mm, the opening diameter w=7mm, the length and width of the substrate cavity are both a=18mm. The depth of the cavity h can be adjusted, corresponding to the two states of the coding units, "0" and "1". In order to determine the value of h, it is essential to calculate the dispersion curve of the SSAWs. The dispersion relation reflects the relationship between its wave vector k_x and the angular frequency ω, which can be derived as:



$$k_x = \frac{\omega}{c_0}\sqrt{1+\frac{\omega^2}{\left(\omega_{\mathrm{HR}}^2-\omega^2\right)^2}\left(\frac{\rho_0 c_0}{M_{\mathrm{HR}}a^2}\right)^2} \tag{1}$$

where $\rho_0 = 1.21\,\mathrm{kg/m^3}$ is the mess density of the air, c_0=343kg/m^3 is the speed of sound in air, $\omega_{\mathrm{HR}} = \sqrt{(\pi w^2 c_0^2)/(4lha^2)}$ is the resonance angular frequency of the resonator cavity, $M_{\mathrm{HR}} = 4\rho_0 l/\pi w^2$ is the acoustic mass. As shown in Eq. (1), the wave vector of SSAW is determined by the cavity depth h. According to the equation $\varphi = kL$ where L is the propagation distance, we can select two types of units which result in a 180°

phase difference in the SSAWs. We calculate the dispersion relation in Fig. 1(d), where the black curve represents the substrate structure, which begins to deviate from the dispersion line of the background air when the frequency exceeds 3000 Hz. In order to avoid thermal viscosity and anisotropy, we set the operation frequency at 3080Hz, which is slightly off-resonance. The red and blue curves show the dispersion relations of the two selected coding units (h_1=17mm, h_2=15mm).

To validate the effectiveness of the designed coding unit, we use this programmable metasurface to realize the acoustic focusing, as shown in Fig. 2(a). To implement the designed acoustic lens, we fabricate a metasurface composed of 32×20 units using 3D printing with PLA materials and establish an experimental setup as shown in Fig. 2(b). The experimental results not only demonstrate excellent focusing capabilities but also allows for arbitrary control of the focal point's position. Furthermore, we change the structure to generate an Airy beam and demonstrate its non-diffracting property, as shown in Figs. 2(g)-(j).

Abstract

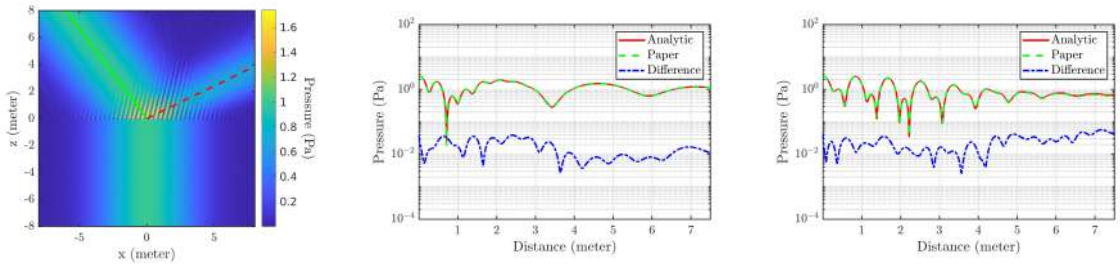
A surface integral equation with bianisotropic impedance boundary conditions is formulated and numerically solved using a Nyström method for simulation of acoustic metasurfaces. An acoustic splitter is simulated using the proposed method. Simulation results agree very well with analytic results demonstrating the method's validity and accuracy.

The rapid development of acoustic metasurfaces has generated significant interest in methods for simulation of acoustic metasurfaces. Direct simulation of a metasurface consisting of units cells in its native environment is challenging due to the difference of scale in the dimensions of propagation environment and the unit cell. To avoid this multiscale issue, in electromagnetics, the metasurface is replaced by a infinitesimally thin sheet with generalized sheet transition conditions (GSTCs) that enforce the response of the metasurface on the fields on the two sides of this sheet [1]. In acoustics, Willis coupling [2], which can be used for the same purpose, "connects" the velocity potentials on two sides of a metasurface, $\varphi_1(\mathbf{r})$ and $\varphi_2(\mathbf{r})$, using

$$\begin{bmatrix} \Delta\varphi(\mathbf{r}) \\ \Delta\partial_n\varphi(\mathbf{r}) \end{bmatrix} = \begin{bmatrix} b_{11}(\mathbf{r}) & b_{12}(\mathbf{r}) \\ b_{21}(\mathbf{r}) & b_{22}(\mathbf{r}) \end{bmatrix} \begin{bmatrix} \varphi_{\text{avg}}(\mathbf{r}) \\ \partial_n\varphi_{\text{avg}}(\mathbf{r}) \end{bmatrix}. \tag{1}$$

Here, $\Delta x(\mathbf{r}) = x_1(\mathbf{r}) - x_2(\mathbf{r})$, $x_{\text{avg}}(\mathbf{r}) = [x_1(\mathbf{r}) + x_2(\mathbf{r})]/2$, $\mathbf{r} \in S$, S is the surface of the infinitesimally thin sheet replacing the metasurface, ∂_n represents derivative along the direction normal to S (pointing from side 1 to side 2), and b_{ij}, $i, j = 1, 2$ are equivalent coupling coefficients. For a bianisotropic metasurface, one can easily derive the expressions for these coupling coefficients as

$$\begin{bmatrix} b_{11}(\mathbf{r}) & b_{12}(\mathbf{r}) \\ b_{21}(\mathbf{r}) & b_{22}(\mathbf{r}) \end{bmatrix} = \begin{bmatrix} 2\frac{Z_{11}(\mathbf{r})+Z_{12}(\mathbf{r})-Z_{21}(\mathbf{r})-Z_{22}(\mathbf{r})}{Z_{11}(\mathbf{r})+Z_{12}(\mathbf{r})+Z_{21}(\mathbf{r})+Z_{22}(\mathbf{r})} & \frac{4}{i\omega\rho_0}\frac{Z_{11}(\mathbf{r})Z_{22}(\mathbf{r})-Z_{21}(\mathbf{r})Z_{12}(\mathbf{r})}{Z_{11}(\mathbf{r})+Z_{12}(\mathbf{r})+Z_{21}(\mathbf{r})+Z_{22}(\mathbf{r})} \\ 4\frac{i\omega\rho_0}{Z_{11}(\mathbf{r})+Z_{12}(\mathbf{r})+Z_{21}(\mathbf{r})+Z_{22}(\mathbf{r})} & -2\frac{Z_{11}(\mathbf{r})-Z_{12}(\mathbf{r})+Z_{21}(\mathbf{r})-Z_{22}(\mathbf{r})}{Z_{11}(\mathbf{r})+Z_{12}(\mathbf{r})+Z_{21}(\mathbf{r})+Z_{22}(\mathbf{r})} \end{bmatrix}. \tag{2}$$



Here, Z_{ij}, $i, j = 1, 2$ are impedance matrix entries which relate the pressure and the normal component of the velocity on two sides of the metasurface, ω is the frequency, and ρ_0 is the density in the background medium where the metasurface resides.

Using the second Green identity, Kirchhoff-Helmholtz boundary integral equation can be formulated on S as [3]

$$\begin{aligned} \varphi^{\text{inc}}(\mathbf{r}) - S[\Delta\partial_n\varphi](\mathbf{r}) + D[\Delta\varphi](\mathbf{r}) &= \varphi(\mathbf{r}), \\ \partial_n\varphi^{\text{inc}}(\mathbf{r}) - D'[\Delta\partial_n\varphi](\mathbf{r}) + N[\Delta\varphi](\mathbf{r}) &= \partial_n\varphi(\mathbf{r}). \end{aligned} \tag{3}$$

Here, $\varphi^{\text{inc}}(\mathbf{r})$ is the incident potential, operators $S[x]$, $D[x]$, $D'[x]$ and $N[x]$ are given by

$$\begin{aligned} S[x](\mathbf{r}) &= \int_S G(\mathbf{r}, \mathbf{r}')x(\mathbf{r}')ds', \qquad D[x](\mathbf{r}) = \int_S \partial_{n'}G(\mathbf{r}, \mathbf{r}')x(\mathbf{r}')ds', \\ D'[x](\mathbf{r}) &= \int_S \partial_n G(\mathbf{r}, \mathbf{r}')x(\mathbf{r}')ds', \quad N[x](\mathbf{r}) = \int_S \partial^2_{nn'}G(\mathbf{r}, \mathbf{r}')x(\mathbf{r}')ds', \end{aligned} \tag{4}$$

(a) (b) (c)

Figure 1: (a) Pressure field on the $y = 0$ plane. Pressure field along (b) the green solid line and (c) the red dashed line.

and $G(\mathbf{r}, \mathbf{r}') = e^{ik_0|\mathbf{r}-\mathbf{r}'|}/4\pi|\mathbf{r} - \mathbf{r}'|$ is the Green function in the background medium with wave number k_0. By averaging Eq. (3) on two sides of S and combining resulting equation with Eq. (1), one can obtain

$$\begin{aligned} &\Delta\varphi(\mathbf{r}) - b_{11}(\mathbf{r})\tilde{D}[\Delta\varphi](\mathbf{r}) - b_{12}(\mathbf{r})N[\Delta\varphi](\mathbf{r}) + b_{11}(\mathbf{r})S[\Delta\partial_n\varphi](\mathbf{r}) + b_{12}(\mathbf{r})\tilde{D}'[\Delta\partial_n\varphi](\mathbf{r}) \\ &\qquad = b_{11}(\mathbf{r})\varphi^{\text{inc}}(\mathbf{r}) + b_{12}(\mathbf{r})\partial_n\varphi^{\text{inc}}(\mathbf{r}), \\ &\Delta\partial_n\varphi(\mathbf{r}) - b_{21}(\mathbf{r})\tilde{D}[\Delta\varphi](\mathbf{r}) - b_{22}(\mathbf{r})N[\Delta\varphi](\mathbf{r}) + b_{21}(\mathbf{r})S[\Delta\partial_n\varphi](\mathbf{r}) + b_{22}(\mathbf{r})\tilde{D}'[\Delta\partial_n\varphi](\mathbf{r}) \\ &\qquad = b_{21}(\mathbf{r})\varphi^{\text{inc}}(\mathbf{r}) + b_{22}(\mathbf{r})\partial_n\varphi^{\text{inc}}(\mathbf{r}), \end{aligned} \tag{5}$$

where '$\sim$' on the surface integral operators means the integration is evaluated in Cauchy principal value. Eq. (5) is a coupled system of equations in unknowns $\Delta\varphi(\mathbf{r})$ and $\Delta\partial_n\varphi(\mathbf{r})$. This system is discretized using a higher-order Nyström method [4].

The proposed method is used to simulate a metasurface that can split a normally incident beam into two directions θ_l and θ_r. The metasurface is a circular disk with a radius of 7 m located on the $z = 0$ plane and is excited by tapered plane wave at 689.8 Hz, and $\theta_l = 36.87°$ and $\theta_r = 64.16°$. S is discretized into a mesh of curvilinear triangular patches with an average edge length of 0.15 m, resulting in a total of 15 992 patches. On this mesh, unknowns $\Delta\varphi(\mathbf{r})$ and $\Delta\partial_n\varphi(\mathbf{r})$ are expanded using second-order basis functions. This results in a matrix system of dimension 191 904. An LU direct solver is used to solve this matrix system.

Fig. 1(a) visualizes the pressure field on the $y = 0$ plane. The splitting of the incident wave is clearly demonstrated. Fig. 1(b) and Fig. 1(c) plot the scattered pressure computed along the green solid and red dashed lines in Fig. 1(a). The proposed method achieves an error of 1.54% and 2.68% with respect to analytical results on these two lines, demonstrating its accuracy.

Abstract: We show that the collision dynamics of two pendulum-suspended mass-in-mass resonators, essentially a two "meta-atom" Newton's cradle, can be described using effective parameters. These effective parameters can assume non-conventional values compared to their conventional counterparts. This work paves the way for the development of new "collision-based metamaterial" structures.

While some aspects of collisions in metamaterials have been studied, e.g. [1], a common feature across previous work is a focus on multiple collisions and associated wave propagation. The fundamental processes involved in individual collisions in such metamaterials and their effect on the overall dynamics have not been extensively studied. We use the modified Newton's cradle as a suitable base system for our work. Assuming stiff shells and small angular displacements and ignoring effects such as acoustic waves in the supporting wires, we model a mass-in-mass locally resonant Newton's cradle as a one-dimension linear piecewise system. We show that the collision between two mass-in-mass resonators can be described using relevant effective parameters by defining the average velocities $\dot{x}_a$ of the two mass-in-mass spheres at the end of the collision as:

$$\dot{x}_{1,a} = \tfrac{1}{2}\left(CM_a \in CR_a\right)\dot{x}_{1,t_c}, \tag{1a}$$

$$\dot{x}_{2,a} = \tfrac{1}{2}\left(CM_a + CR_a\right)\dot{x}_{1,t_c}. \tag{1b}$$

We define an effective coefficient of restitution CR_a in the same manner as the conventional sense, but also an effective "coefficient of motion" CM_a as the ratio of the momentum after to that before the collision. $\dot{x}_{1,t_c}$ is the velocity of shell 1 at t_c the start of the collision. We derive the effective parameters by solving the linear equations for the collision, leading to:

$$CR_a = \tfrac{m}{m+m_r}\left(CR_e + \left(\hat{m}_{e,s}(t) * CR_e(t)\right)\big|_{t=t_s} \in \omega_r^2\left(\tfrac{d^2\hat{m}_{e,s}(t)}{dt^2}\tfrac{x_{r_1,t_c}}{\dot{x}_{1,t_c}} + \tfrac{d\hat{m}_{e,s}(t)}{dt}\tfrac{\dot{x}_{r_1,t_c}}{\dot{x}_{1,t_c}}\right)\Big|_{t=t_s}\right) \tag{2a}$$

$$CM_a = \tfrac{m}{m+m_r}\left(1 + \tfrac{m_r}{m}\tfrac{\dot{x}_{r,t_c}}{\dot{x}_{1,t_c}}\right). \tag{2b}$$

where

$$CR_e = \in \mathcal{L}^{-1}\left(\tfrac{\hat{m}_{e,s}s}{\hat{m}_e s^2+2\omega_c^2}\left(\tfrac{x_{r_1,t_c}}{\dot{x}_{1,t_c}}s + \tfrac{\dot{x}_{r,t_c}}{\dot{x}_{1,t_c}}\right) + \tfrac{s}{\hat{m}_e s^2+2\omega_c^2}\right)\Big|_{t=t_s},$$

$$CM_e = \mathcal{L}^{-1}\left(\tfrac{\hat{m}_{e,s}}{\hat{m}_e s}\left(s\tfrac{x_{r_1,t_c}}{\dot{x}_{1,t_c}} + \tfrac{\dot{x}_{r,t_c}}{\dot{x}_{1,t_c}}\right) + \tfrac{1}{\hat{m}_e s}\right)\Big|_{t=t_s},$$

$$\hat{m}_e = 1 + \tfrac{m_r}{m}\tfrac{\omega_r^2}{s^2+\omega_r^2} = 1 + \hat{m}_{e,s}.$$

Unlike effective parameters derived to understand wave propagation, these effective parameters are derived in the time domain since they are defined at the time t_s when the spheres separate.

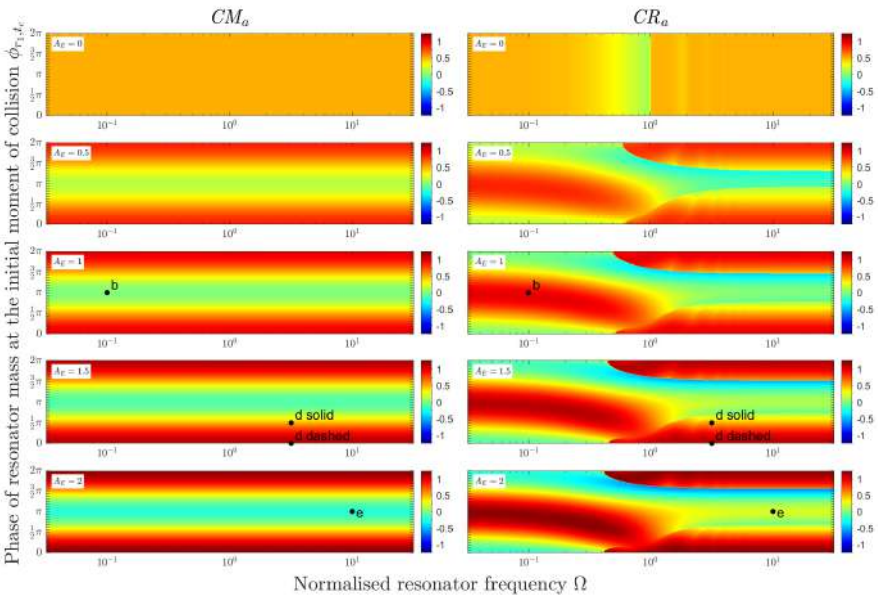

Figure 1: Density plots for the effective coefficients of motion, CM_a (left panels), and restitution, CR_a (right panels), for the mass-in-mass resonator system. Each plot represents the results for different initial conditions of the left-hand mass-in-mass system at the moment of collision.

The Laplace variable is s, $\mathcal{L}^{-1}$ the inverse Laplace operator, m and m_r the mass of the spherical shell and internal mass, ω_c and ω_r are the natural frequencies of the shell compression during collision and internal resonator respectively. The effective parameters are a function of the displacement x_{1,t_c} and velocity $\dot{x}_{1,t_c}$ of the resonant mass of shell 1 at the time of the impact.

Figure 1 shows density plots for the effective coefficients, with the horizontal axes showing the normalized frequency ratio $\Omega = \omega_r/\omega_c$. Conditions for a stiff shell are implemented using a steel shell with radius $R = 10$ mm and shell thickness $0.1R$, leading to $\omega_c/\omega_g = 4.7 \times 10^4$ for $m_r = m$, where ω_g is the pendulum frequency. The initial conditions of the internal resonator of shell 1 at the moment of collision are described in terms of A_E, the total energy of the resonator relative to the kinetic energy of a non-resonant shell of mass m (increasing down each column), and ϕ_{r_1,t_c}, the phase of the internal resonant mass relative to its undisturbed location (plotted on the vertical axis of each panel). It shows that CR_a can exceed 1, indicating that kinetic energy is being added to the spherical shells and also that it can take negative values. It shows that the CM_a, which is unity for conventional shells, can take positive/negative values associated with an effective addition/reduction of momentum to the system of spherical shells. This demonstrates that the mass-in-mass resonator system can exhibit a variety of responses depending on the resonator properties. As examples, the case indicated by the dot (b) is for approximately equal and opposite motion of the two outer spheres after collision, while (e) is a case when shell 1 bounces back and shell 2 remains stationary. Numerical simulations of the motion of the mass-in-mass resonators during and after collision verify these results.

Abstract: An underwater sensor positioning device was developed to control the hydrophone's location and the azimuth angle of tested metamaterial. Recently, a 3D underwater acoustic metalens was designed and fabricated using a 3D metal printing process. Basic performance tests with the positioning device in a tank showed a high focusing performance.

Various studies have been conducted on acoustic metamaterials for focusing underwater sound. Su et al. explored broadband underwater sound focusing using a 2D transparent pentamode lens [1], while Kim et al. investigated 3D acoustic metamaterial Luneburg lenses for broadband, wide-angle underwater ultrasound focusing [2]. In both cases, sound focusing was observed; however, in a water tank, the pentamode lens achieved an amplification of up to 4 dB, while Kim's study did not report the level of amplification achieved. Over the past decade, various experimental implementations of underwater lenses have emerged, driving further advancements in the acoustic field. However, despite their potential in the low-frequency range and the need for submerged applications, research remains limited, with most studies focusing on 2D lenses. To overcome low focusing efficiency and the limitations of 2D designs, a 3D Helmholtz resonator-based underwater acoustic metalens was recently designed and fabricated [3]. This paper presents the results of basic performance tests conducted in a large water tank ($35 \times 20 \times 9.6$ m^3).

A remotely operated underwater sensor positioning device was developed to control the location of a hydrophone along the x-, y-, and z-axes [4]. Additionally, a motor-driven rotator was incorporated to adjust the horizontal posture angle of the metamaterial being tested. Figure 1 presents a conceptual illustration along with a photograph of the device in a water tank. The device operates at depths exceeding 20 meters, with its position and angle automatically controlled by a PC. The measurement volume is approximately 1m × 1m × 1m, and the rotation angle spans a full 360 degrees.

Figure 1. Underwater sensor positioning device (a) conceptual illustration (b) photo

To verify the formation of plane waves in the water tank, sound field measurements were conducted. An omnidirectional transducer and a standard hydrophone were used to generate and measure the underwater sound

pressure. For the measurements, 2 ms-long burst tones ranging from 15 to 35 kHz were employed. Figure 2 presents an example of the measured magnitude and phase distribution at 25 kHz. The results confirm that the plane wave fields were successfully generated.

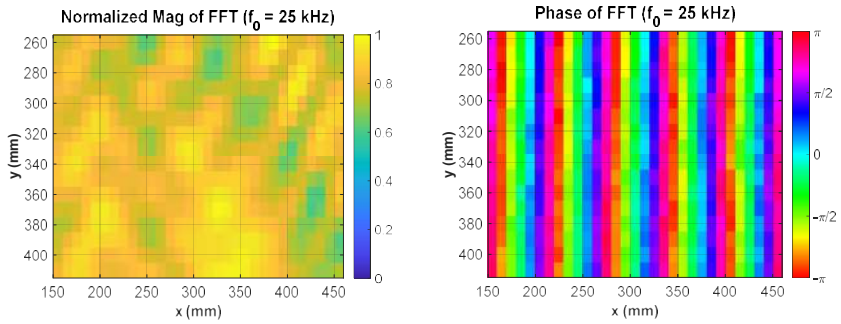

Figure 2. Measured underwater acoustic field in the water tank (a) normalized magnitude (b) phase

The 3D underwater acoustic metalens is fabricated using a 3D metal printing process, with a diameter of 240 mm. Its focusing performance is evaluated in a water tank using the same measurement techniques as those applied for plane wave analysis. Figure 3 illustrates the fabricated metalens mounted on the positioning device, along with an example of the measured sound distribution at 25 kHz. The results show that high sound focusing performance over 10 kHz band.

Programmable sound wave transmission by active acoustic meta-layers

Shoubo Dai[1], Hao Gao[1], and Yegao Qu[1*]

[1]State Key Laboratory of Mechanical System and Vibration, Shanghai Jiao Tong University, Shanghai 200240, China

Abstract: We have developed a programmable acoustic meta-layer that can precisely control sound waves transmission while meeting ventilation requirements. The acoustic meta-layer can realize non-reciprocal transmission and frequency conversion. Further, various functions such as tunable anomalous refraction, wave focusing and self-bending beam can be realized by adjusting the phase distribution.

Achieving precise and flexible control over sound waves have always been the main focus of engineering and science. Acoustic metamaterials provide a novel technical platform for sound wave control [1, 2]. However, the design of acoustic devices often needs to consider environmental requirements such as ventilation, and the demand for compact and multifunctional acoustic devices is also increasing, which poses challenges to the design of the structure [3].

Based on the active control strategy, we propose, design and demonstrate an active acoustic meta-layer that achieves programmable and precise control of the incident sound field while ensuring ventilation. As shown in Figs. 1(a) and (b), the meta-layer consists of a supporting frame, piezoelectric patches and a feedforward control loop. A charge amplifier is attached to the sensing patches to acquire the sensing voltage V_s. Based on the sensing signal V_s and the designed transfer function H implemented in the digital controller, antisymmetric potentials V_a and -V_a are generated and applied to the actuators. This configuration ensures the control loop feedforward [4].

Assume a plane sound wave varying harmonically in time and with an amplitude of P_0 is incident forward to the active acoustic meta-layer, the transmission coefficient can be expressed as

$$T_f = s_{21} + \kappa_a \kappa_s H\left(e^{-ika} + e^{ika}\right), \tag{1}$$

where s_{21} are the complex scattering coefficients of the acoustic meta-layer, representing its transmissive properties. κ_s is the sensing coefficient, κ_a is the actuation coefficient, and a represents the distance from the actuator to the center of the active acoustic meta-layer. Based on Eq. (1), the transmission characteristics of sound wave can be arbitrarily regulated by adjusting the transfer function H. However, when the sound wave is backward incident, the transmission coefficient is expressed as

$$T_b = s_{21} - \kappa_a \kappa_s H\left(e^{-ika} + e^{ika}\right). \tag{2}$$

Therefore, the active acoustic meta-layer is intrinsically non-reciprocal. As an example, consider the complete suppression of a 4000 Hz forward incident sound wave, where $T_f = 0$, the corresponding transfer function H_0 can be calculated according to Eq. (1). As shown in Fig. 1(c), a set of time-domain numerical simulations are conducted to further verify the non-reciprocal sound wave suppression property and the stability of the system. As shown in Figs. 1 (d) and (e), compared with the transmitted signal without control, the forward incident transmitted signal after the acoustic meta-layer control is almost zero, while the backward incident transmitted signal is twice as much. To achieve single-frequency conversion, further processing of the transfer function H is required. By adjusting the time-varying transfer function, the actuation voltage is made to satisfy

$$V_a(t) = H_0 V_s(t) + A_n\left[V_s(t)\cos(\omega_n t) + \dot{V}_s(t)\sin(\omega_n t)/\omega\right], \tag{3}$$

where A_n controls the emitted wave amplitude of the conversion frequency, ω_n is the modulation frequency. As an example, in Figs. 1(f) and (g), frequency up conversion is achieved by applying $\omega_n = 2\pi \times 1000$ Hz.

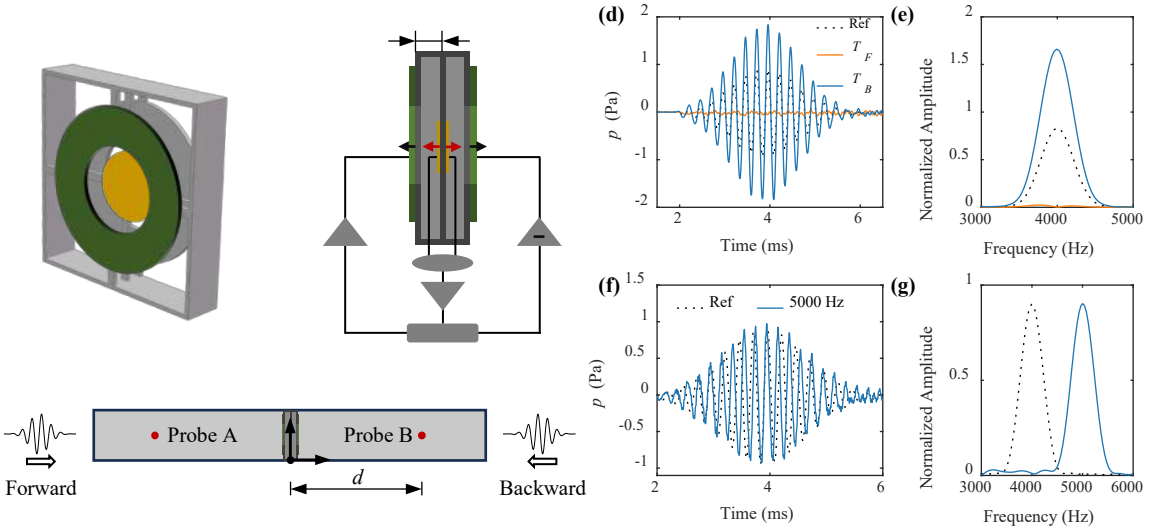

Figure 1. (a) Structural diagram of the active acoustic meta-layer; (b) design of the feedforward control loop; (c) schematic illustration of sound wave transmission modulated by the meta-layer; (d) time-domain transmission signals and (e) their spectra for non-reciprocal; (f) time-domain transmission signals and (g) their spectra after frequency conversion.

In addition, as shown in Fig. 2 (a), the meta-layer can also programmatically control the phase of the transmitted sound field. By distributing the array of meta-layers and individually programming the phase of each unit, tunable anomalous refraction, wave focusing, and self-bending beams can be achieved as shown in Figs 2 (b)-(c).

Abstract: This work proposes a polymer based acoustic metamaterial based on Lieb lattices, supporting energy localization at specific ultrasonic frequencies. The structure's tuneable bandgap and topologically-protected flat bands is demonstrated through simulations and experimental verification, leading to possible future applications in ultrasonic medical imaging, sensing, and acoustic manipulation.

The interaction of waves with periodic structures is a fundamental topic in physics [1]. In the context of acoustics, the periodic arrangement of materials gives rise to band structures that define the frequencies at which wave propagation is allowed or forbidden [2]. This phenomenon, known as band gaps, has been extensively studied in various wave systems, from photonic crystals to phononic crystals [3], where the periodicity of the material leads to the formation of band gaps that block wave propagation in specific frequency ranges. The discovery of such effects, initially explored for electronic waves in crystalline solids, has since been extended to mechanical and acoustic waves, providing significant insight into wave manipulation across a variety of systems [1].

In recent years, there has been an increase of interest in the development of acoustic metamaterials and phononic crystals, where the interplay between wave dynamics and the periodic structure can be exploited to control sound in novel ways [4]. In particular, the Lieb lattice has emerged as a key system due to its ability to support flat bands - frequency ranges where waves become non-dispersive. These flat bands are of great interest as they enable the localization of energy within specific regions of the material, often at particular lattice sites, due to interference effects. This phenomenon is especially significant in systems where energy localization can be selectively induced, such as in topologically protected states within the lattice structure.

In this work, we propose an acoustic metamaterial based on a Lieb lattice design, where the periodic arrangement of resonant cavities is tailored to support energy localization at specific frequencies. This structure consists of interconnected polymer cylinders with a diameter d = 1.079 mm. The length of the interconnections is set to be L = 1.079mm. The structure is designed for the wavelength λ = 6.075 mm such that the spacing between the diagonal sites is $\lambda/2$. These sites will act as defect sites for the formation of flat bands. We demonstrated the viability of the design through both numerical simulations and experimental verification. The initial numerical simulations were developed in COMSOL, followed by fabrication of the structure using a Digital Light Processing (DLP) 3D printer. We demonstrate that these localized modes occur at Lieb sites, where energy becomes confined within the structure. The geometrical

design of the unit cell plays a crucial role in tuning the bandgap and ensuring the desired frequency range for localization. Furthermore, the simulation results reveal that the energy localization is robust to perturbations in the lattice structure, suggesting the presence of topologically protected states.

Interestingly, the proposed design also allows for the adjustment of the bandgap through simple geometric modifications, which enables the system to be finely tuned for different frequencies of interest. This tunability presents an exciting opportunity for medical imaging, cloaking, lensing and further manipulation of localized signals [5].

In conclusion, this work introduces a new class of acoustic metamaterials based on the Lieb lattice, with potential applications in medical imaging, sensing, and other acoustic manipulation technologies. The combination of topologically protected flat bands, energy localization, and geometric tunability offers a promising avenue for advancing the capabilities of ultrasound and acoustic-based systems in various practical domains.

Abstract: In this work, an efficient meta-platform is proposed and experimentally demonstrated for high-resolution *vectorial* holography generation at the incidence of arbitrary polarization. Employing a series of highly-efficient and ultra-thin single-structure metaatoms with arbitrarily designated scattered phases and polarization-conversion capabilities, various vectorial holographic images are experimentally realized at 1064 nm.

Holography is an important technology in modern optics for information recording and reconstruction[1], yet traditional methods for holography generation face the problems of bulky sizes, complex setups and low efficiencies, and most holograms generated so far are typically scaler ones[2]. Recently, metasurfaces, highly-efficient and ultra-thin artificial materials have been widely employed for complex electro-magnetic wave manipulation, and introduced to holography generation. However, employing composite metaatoms, the meta -holograms realized so far are still scaler ones, with the few attempts on vectorial ones of low efficiencies[3].

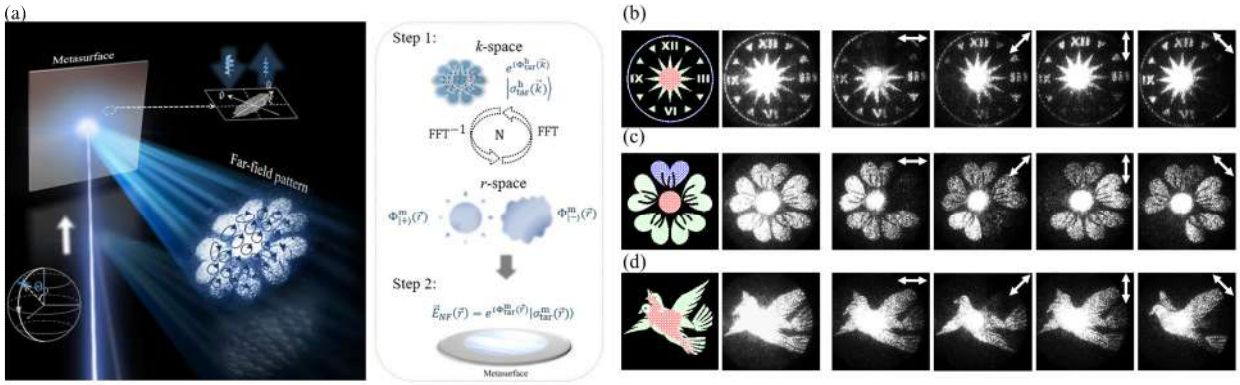

Fig. 1 The vectorial holography based on metasurface. (a) The schematics and design procedure of the vectorial meta-holograms. Experimental demonstrations of different vectorial holographic images and polarization filtered patterns for (b) a vectorial clock; (c) a vectorial flower; (d) a vectorial bird.

Here, by employing deep-subwavelength single-structure metaatoms, we propose and experimentally realize a general method for vectorial holography generation. As shown in Fig.1 (a), the method can be summarized as a two-step procedure: 1) firstly, decompose the target far-field vectorial holography into left-circular-polarized

(LCP) and right-circular-polarized (RCP) components, i.e. $A^{h}_{tar}(\vec{k})|\sigma^{h}_{tar}(\vec{k})\rangle = A^{h}_{tar,+}(\vec{k})|+\rangle_{\vec{k}} + A^{h}_{tar,-}(\vec{k})|-\rangle_{\vec{k}}$, here:

$$\begin{cases} A^{h}_{tar,+}(\vec{k}) = A^{h}_{tar}(\vec{k}) e^{-\frac{i\Psi^{h}_{tar}(\vec{k})}{2}} \cos\left(\frac{\Theta^{h}_{tar}(\vec{k})}{2}\right) \\ A^{h}_{tar,-}(\vec{k}) - A^{h}_{tar}(\vec{k}) e^{+\frac{i\Psi^{h}_{tar}(\vec{k})}{2}} \sin\left(\frac{\Theta^{h}_{tar}(\vec{k})}{2}\right) \end{cases} \quad (1)$$

then employ GS algorithm to retrieve the two nearfield planar sources (LCP and RCP sources) for generation of these two components; 2) secondly, construct the vectorial near-field planar source through the LCP and RCP components:

$$\vec{E}_{NF}(\vec{r}) = \frac{1}{\sqrt{I_+ + I_-}}\left[\sqrt{I_+}\, e^{i\Phi^{m}_{+}(\vec{r})}|+\rangle + \sqrt{I_-}\, e^{i\Phi^{m}_{-}(\vec{r})}|-\rangle\right] = e^{i\Phi^{m}_{tar}(\vec{r})}\begin{pmatrix} e^{-\frac{i\Psi^{m}_{tar}(\vec{r})}{2}}\cos\left(\frac{\Theta^{m}_{tar}(\vec{r})}{2}\right) \\ e^{+\frac{i\Psi^{m}_{tar}(\vec{r})}{2}}\sin\left(\frac{\Theta^{m}_{tar}(\vec{r})}{2}\right) \end{pmatrix}, \text{ where } \begin{cases} \Phi^{m}_{tar}(\vec{r}) = \frac{\Phi^{m}_{+}(\vec{r}) + \Phi^{m}_{-}(\vec{r})}{2} \\ \Theta^{m}_{tar}(\vec{r}) = 2\arctan\left(\frac{\sqrt{I_-}}{\sqrt{I_+}}\right) \\ \Psi^{m}_{tar}(\vec{r}) = \Phi^{m}_{-}(\vec{r}) - \Phi^{m}_{+}(\vec{r}) \end{cases} \quad (2)$$

Thus the Jones matrix for the target metasurface can be attained, and the geometric parameters of metaatoms for different vectorial meta-hologram design can be correspondingly retrieved from the FDTD simulated database.

Following this strategy, we design and experimentally demonstrate different meta-holograms. As shown in Fig. 1, at LCP incidence, the image directly collected by CCD [second panels of Fig.1 (b,c,d)] consist well with the target patterns [first panels of Fig.1 (b,c,d)]. Further placing a rotatable polarizer in front of the CCD as an analyzer, the filtered patterns illustrate the vectorial properties of the generated holography. Interestingly, the polarization filtered patterns of different images tell different stories. As shown in the third to sixth panel of Fig.1 (b), when the polarizer is tilted at 0° , 45° , 90° , 135° respectively, different parts of the vectorial holographic clock are "illuminated" in turn, as if the time passes. The third to sixth panel of Fig.1 (c) illustrate a vectorial holographic flower, the petals of which are "picked off" in turn as the analyser rotates to 0° , 45° , 90° , 135° respectively. As for the vectorial bird demonstrated in the third to sixth panel of Fig.1 (d), the bird is "flying" when the polarizer is rotated to different angles continuously.

To conclude, in this work, we establish a generic method to design meta-holograms employing ultra-thin single-structure metaatoms, which can generate designated vectorial holographic images under illuminations of light with an arbitrary polarization. Following this strategy, we experimentally illustrate different vectorial holographic images including vectorial clock, flower and bird, which exhibit interesting animations when the analyzer is continuously rotated to different angles.

Designing Temperature Invariant All-Dielectric Photothermal Metasurfaces

Gopal Narmada Naidu*, Can O Karaman, and Giulia Tagliabue

EPFL, Switzerland
*corresponding author: gopal.naidu@epfl.ch

Abstract: The diffusion-driven nature of temperature fields complicates spatial manipulation, making it challenging to achieve uniform or complex temperature distributions at the micro- and nanoscale. To address this, we developed an algorithm for designing temperature-invariant-all-dielectric photothermal metasurfaces, enabling precise, scalable thermal control and reconfigurable optical properties.

Shaping precise temperature fields at the micro- and nanoscales is a key challenge in nanotechnology, with applications in photonics, nanochemistry, biology, and microfluidics [1-4]. The diffusion-driven nature of temperature fields complicates spatial manipulation, posing challenges for applications requiring uniform or complex temperature distributions [5]. Thermonanophotonics, the study of photothermal effects in optical nanoantennas, has garnered significant attention in addressing this challenge. Moving beyond thermoplasmonic designs, all-dielectric nanophotonics has rapidly advanced in recent years, driven by resonant high-refractive-index dielectric and semiconductor nanostructures. These materials avoid the parasitic Ohmic losses inherent in plasmonics while offering strong optical nonlinearity and thermo-optical properties [6]. However, understanding and manipulating light-driven thermo-optical effects in large arrays of dielectric nanoantennas presents substantial challenges. Recent research, analyzed thermo-optical effects beyond a single nanoresonator, revealing that collective heating contributions in nanoresonator arrays strongly influence local absorption cross-sections and self-heating behavior. By optimizing nanoresonator size, array periodicity, and illumination wavelength, researchers demonstrated the ability to generate nontrivial spatial temperature profiles, including flat temperature distributions in 2D arrays of dissimilar silicon nanoresonators [7]. However, these studies primarily focused on silicon nanospheres embedded in uniform media, leaving substrate effects and non-spherical nanostructures as areas for further exploration.

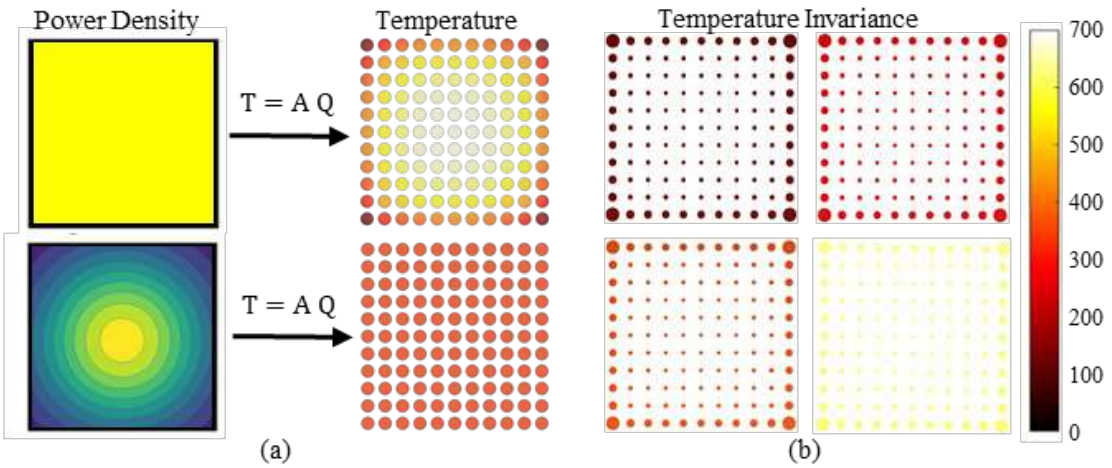

Fig.1(a) Power density distribution and the correspond temperature distribution over a 4μm x 4μm metasurface. (b) Temperature distributions over the designed metasurface under varying laser powers ($0.5 - 6$ mW/μm^2)

In this work, we developed an inversion algorithm to compute the thermal power density distribution for target temperature profiles on all-dielectric metasurfaces (Fig.1 (a)). Using a unit cell approach, we generated a library of optical absorption spectra for silicon nanodisks of varying radii and temperatures, accounting for the temperature-dependent refractive index of silicon [8]. The temperature field, modeled as a combination of self-heating and collective heating terms in a matrix formulation, was solved to determine the required thermal power distribution, which was then mapped to absorption cross-sections for a particle size distribution map. The study also addresses challenges posed by thermo-optical effects that impact the temperature-invariant performance of metasurfaces [9]. To mitigate this, we propose a design strategy for temperature-invariant all silicon metasurfaces, maintaining performance up to 600°C (Fig.1 (b)). Simulations validate our approach, demonstrating uniform and complex temperature distributions and reconfigurable optical properties, such as temperature-modulated transmission. This work combines thermal precision, scalability, and temperature stability, opening new avenues for nanotechnology and photonics.

Quantum Two-Photon Density-Matrix Holography with Metasurfaces

Abstract: We demonstrate quantum density-matrix holography by leveraging the interaction between a metasurface and entangled photon pairs. The entanglement property of this quantum hologram is further examined using quantum hologram tomography. By projecting onto different polarization-Bell states, we reveal distinct, tailor-made holographic patterns at the level of the photon density matrix.

The versatile spin-orbit coupling capability of metasurfaces has already advanced classical optics and is now becoming useful in quantum optics. They can enhance nonlinear crystals for quantum sources [1], facilitate the generation of entanglement [2], and improve quantum imaging [3]. Here, we propose a novel density-matrix holography technique that combines a two-photon entangled source and a polarization-multiplexed metasurface, as illustrated in Figure 1(a), to construct a quantum hologram. In the circular polarization basis, the two-photon entangled state can be expressed as: $\psi = (|L\rangle_i|L\rangle_s - |R\rangle_i|R\rangle_s)/\sqrt{2}$, where L and R denote left-handed and right-handed circular polarization, respectively, and the subscripts i and s represent the idler and signal photons. A metasurface placed in the signal arm generates distinct complex holographic fields under different input/output polarization combinations. We now outline the methodology for realizing density-matrix holography. A polarization-multiplexed metasurface needs to be designed to operate on circular polarizations as follows:

$$\hat{M}|L\rangle = \alpha|L,"="\rangle + \beta|R,"+" + " \times "\rangle, \;\; \hat{M}|R\rangle = \alpha|R,"="\rangle + \beta|L,"+" - " \times "\rangle, \quad (1)$$

where $\hat{M}$ represents the metasurface operator, with α and β denoting its co-polarization and cross-polarization conversion coefficients, respectively. This metasurface enables three distinct holographic patterns depending on the polarization pair. The LL and RR polarization pairs produce an "="-shaped pattern, while the LR polarization pairs generate a superposition of "+" and "×" patterns. Similarly, the RL polarization pairs also yield a superposition of "+" and "×" patterns but with a π-phase difference. After interacting with the metasurface, the two-photon quantum hologram becomes

$$\Psi = (\alpha(|L\rangle_h|L\rangle_s - |R\rangle_h|R\rangle_s)|"="\rangle_s + \beta(|L\rangle_h|R\rangle_s + |R\rangle_h|L\rangle_s)|" \times "\rangle_s + \beta|L\rangle_h|R\rangle_s - |R\rangle_h|L\rangle_s)|"+"\rangle_s)/\sqrt{2} \quad (2)$$

From this equation, it is evident that different Bell states correspond to distinct holographic patterns as our target. To further explore the entanglement properties of the quantum hologram, we perform quantum hologram tomography. This allows us to reconstruct the pixel-resolved density matrix, capturing its two-dimensional distribution, and project it onto specific Bell states using density matrix to reveal the corresponding holographic patterns.

On the other hand, the unit cell of our design consists of a SiO_2 substrate with an amorphous silicon nanopillar. The tunable parameters include the nanopillar width (W), length (L), and azimuthal angle (θ). When the nanopillars are rotated by an azimuthal angle θ and expressed in the circular polarization basis, the Jones matrix J_{CP} can be formulated as:

$$J_{CP} = \begin{pmatrix} t_{LL} & t_{LR} \\ t_{RL} & t_{RR} \end{pmatrix} = \begin{pmatrix} |t|e^{i\varphi} & |t'|e^{i(\varphi'-2\theta)} \\ |t'|e^{i(\varphi'+2\theta)} & |t|e^{i\varphi} \end{pmatrix}, \quad (3)$$

where t_{xy} represents the transmission coefficient for y-polarization input, x-polarization output. The diagonal terms are governed by the propagation phase $\varphi = \arg(t_{LL}) = \arg(t_{RR})$, while the off-diagonal terms include an additional propagation phase $\varphi' = \arg(\sqrt{t_{LR}}\sqrt{t_{RL}})$. From equation (3), it can be seen that the rectangular nanopillar is capable of generating three distinct holograms through the combination of geometric and propagation phases.

Next, quantum hologram tomography was performed using {H, V, D, L} as the basis. As shown in Figure 1(b), different columns correspond to distinct polarization states of signal photons, while different rows represent various polarization states of idler photons. By analyzing these sixteen raw holograms, we successfully reconstructed the two-dimensional distribution of density matrices in the Bell-state basis, pixel by pixel. The diagonal elements, which represent the projection weights onto different Bell states, are specifically visualized in Figure 1(c). Finally, three distinct holograms were obtained through projections onto different Bell states (diagonal of density matrix), obtaining "+","=" and "×" as in equation (2). Density-matrix holography holds great potential for advancing quantum communication and high-dimensional information encryption while also offering valuable insights into metasurface-driven quantum optics.

Abstract: We numerically demonstrate a dual Bound States in the Continuum metasurface operating in the Mid-IR region, with calculated Q-factors exceeding 10^5 and 10^6 and broad wavelength tunability. The choice of materials and structural dimensions makes our design a promising candidate for large-scale application as a highly efficient resonator.

Metasurfaces are engineered 2D nanostructures capable of manipulating light in ways that rarely occur in nature. Structurally, metasurfaces consist of a periodic or aperiodic arrangement of subwavelength elements that manipulate light at the nanoscale through the collective resonant behavior of individual meta-atoms. This characteristic has drawn the attention of researchers worldwide, leading to the exploration of metasurfaces in diverse applications including amplitude and phase control [1], focusing [2], enhanced light-matter interaction [3], sensing and spectroscopy [4], selective color reflection [5, 6], and high reflectivity mirrors [7, 8].

In recent years, a new kind of metasurface exploiting the Bound States in the Continuum (BICs) phenomenon has emerged, offering unprecedented light-mater interaction capabilities [9]. BICs were initially studied in quantum mechanics as a mathematical curiosity, however, only in recent years have they been explored in wave physics and photonics. By definition, BICs are non-radiating dark states that coexist within the radiative continuum while remaining fully decoupled from it [10].

In its "pure" form, a BIC has limited use in practice since it cannot couple with free-space light., However, by perturbating the meta-atom's symmetry, a controlled energy leakage can be achieved, enabling the excitation of super high Q-factors Fano resonances. These resonances are characterized by strong near-field enhancement and localization. In this contribution, we numerically investigate the influence of the asymmetry in a square block nanoresonator. Figure 1(a) shows the sketch of the proposed meta-atom. It consists of a square germanium (Ge) block with a single tapered side, positioned on a sapphire (Al_2O_3) layer and supported by a calcium fluoride (CaF_2) substrate. We selected Ge and CaF_2 for their wide transparency range in the Mid-IR region and we incorporate a thin Al_2O_3 layer to preserve CaF_2 from etching. The unit cell's symmetry is broken via the asymmetry parameter α, which controls the tapering angle on one side of the block.

We employed the 3D Rigorous Coupled-Wave Analysis (RCWA) method to simulate the unit-cell response. Periodic boundary conditions were applied along the *x*- and *y*-directions. A normally incident plane wave polarized along the y-axis excited the metasurface from the top. The transmitted power was measured. All materials were modelled as dispersive and lossless materials, given their minimal absorption in the Mid-IR region.

Figure 1 (b) – (c) reveal the excitation of two ultra-narrow Fano resonances, whose linewidth and spectral position depend on the degree of asymmetry. Particularly, Figure 1 (c) – (d) confirm that the Q-factor follows the expected α^{-2} power law, widely reported in literature, reaching values above 10^5 and 10^6 and asymptotically tending to infinity when the asymmetry parameter approaches to zero. Furthermore, extended simulations were performed to account for the smoothing of corner shapes observed in ongoing fabrication trials.

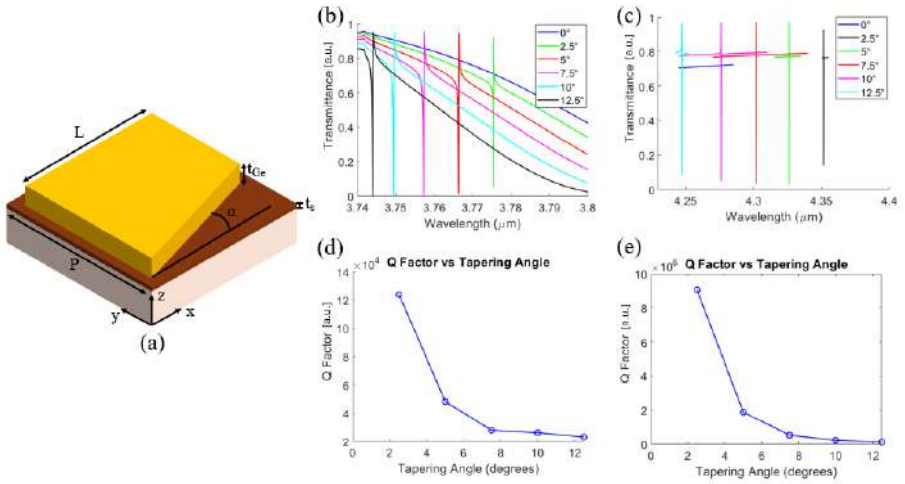

Fig. 1: (a) Sketch of the unit cell. The geometric parameters are $P = 2.65\ \mu m$, $L = 1.65\ \mu m$, $t_{Ge} = 0.2\ \mu m$ and $t_s = 0.011\ \mu m$. (b) – (c) Transmittance as a function of the asymmetry parameter α for both the excited resonances. As the asymmetry increases, the resonances exhibit blue-shift and broadening. (d) – (e) Q-factor as a function of α for both the excited resonances. As expected, Q-factor diverges as the asymmetry approaches to zero, following the α^{-2} power law.

This work presents a novel metasurface design capable of achieving dual band high-Q Fano resonances. The combination of tunable spectral response and Q-factor as well as the material selection and dimensions render our design an excellent candidate for large-scale application as a highly efficient Mid-IR Fano resonator.

Abstract: Temperature measurement is crucial for energy transfer, particularly in extreme high-temperature environments. Traditional radiation thermometry struggle with bulky optical systems. We introduce Dispersive Meta-lens Temperature Detector (DMTD), which uses dispersive meta-lens to achieve miniaturized, high-precision temperature measurements with a reduced error (<0.32%), compared to state-of-the-art multi-spectral light-field thermometry (MSLF, <2%).

Our presentation will introduce the DMTD system, designed for high-precision temperature measurements. The performance of the DMTD system was validated through experiments on a high-temperature blackbody furnace. The experimental setup and captured dispersion image are shown in Figures 1(a), (b).

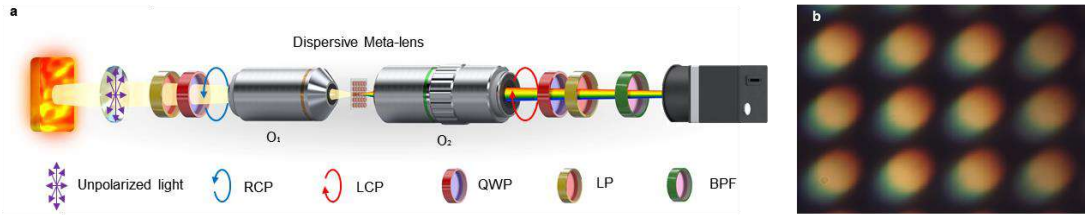

Figure 1. Experimental setup and local captured dispersion image.

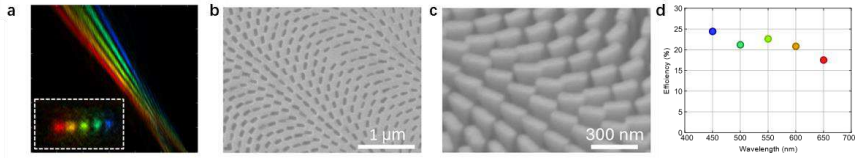

Figure 2. Meta-lens dispersion calibration results and SEM image.

The system consists primarily of a dispersive meta-lens array, an RGB image sensor, two objective lenses (10X and 20X), quarter-wave plates, and linear polarizers. The meta-lens is designed to cover the visible spectrum (450 nm to 650 nm) with a phase profile that disperses broadband light with the following phase profile:

$$\Phi(x, y, \lambda) = -\frac{2\pi}{\lambda}\left(\sqrt{(x-x')^2 + (y-y')^2 + f^2} - \sqrt{(x')^2 + (y')^2 + f^2}\right) \quad (1)$$

The focal spots (x', y') of long and short wavelength are designed at different lateral position.

The meta-lens was fabricated with TiO_2 rectangular nanopillars on a sapphire substrate, with a radius of 30 μm. Scanning electron microscope (SEM) images of the meta-lens are shown in Figures 2(b) and (c), and the efficiency and dispersed focal spots are measured and shown in Figure 2(d). For calibration, the DMT system was verified by switching filters at wavelengths (450, 500, 550, 600, and 650 nm in Figure 2(a)) to ensure precise wavelength decoding. The system was experimentally validated by capturing dispersed light-field images from a blackbody furnace, ranging from 1673K to 1873K in 10K intervals. The captured compressed images were decoded using Convex Spectral Compressive Sensing (SCS) and Reverse Dispersion Network (RDN) algorithms.

These methods allow the construction of hyperspectral images **V** from the compressed RGB information **S**. The basic reconstruction model is as follows:

$$\underset{\mathbf{V}}{\operatorname{argmin}} \| \boldsymbol{\Psi X V} - \boldsymbol{S} \|_2^2 + \alpha_1 \left\| \nabla_{xy} \boldsymbol{V} \right\|_1 + \beta_1 \| \nabla_{\lambda} \boldsymbol{V} \|_1 \tag{2}$$

Where **Ψ** and **X** are the shift and mapping operators. The reconstructed hyperspectral images for 21 wavelengths at 1873K are shown in Figure 3(a ~ d). Figure 3(e) displays well-matched spectral data for four temperature points. Comparisons of intensity profiles with the theoretical Planck's radiation law show that the SCS and RDN results correlate strongly with theoretical values, with correlation coefficients greater than 0.97 and 0.99, respectively.

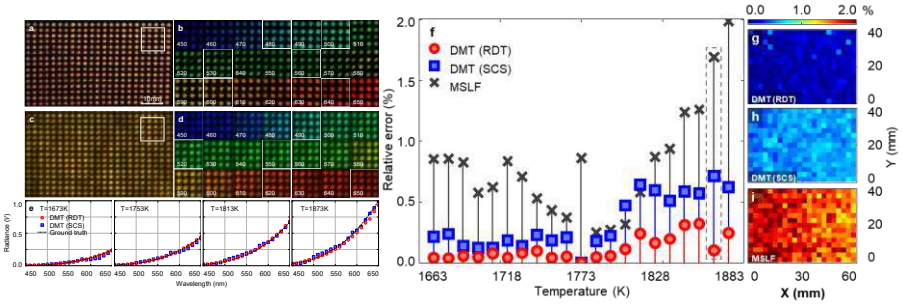

Figure 3. Reconstructed spectral intensity and temperature measured results of blackbody furnace.

Since each channel corresponds to the same temperature but different emissivity, temperature solving references the spectrum intensity of blackbody furnace at 1873K, and the optimization problem is defined as:

$$\min f(x) = \sum_{i=1}^{n} [T_i - E(T)]^2 \to 0 \tag{3}$$

Which can be solved using the Chameleon Swarm Algorithm (CSA) and compared with the state-of-the-art MSLF. As shown in Figure 3(f), the average relative error of DMT (RDN) (<0.32%) and DMT (SCS) (<0.7%) is much lower than that of state-of-the-art MSLF (<2%). What's more, the measured temperature of the blackbody shows a consistent distribution (as illustrated in Figure 3(g–i) which is recorded at 1863 K). This improvement is due to the hyperspectral radiation sampling, which leads to more accurate temperature and emissivity calculations.

In conclusion, the DMTD system offers an efficient and accurate method for measuring high-temperature radiation, with potential applications for infrared dispersive meta-lenses to achieve similar performance in low-temperature measurements.

Green Metasurface for Wearable ETA Radar Antenna Protection

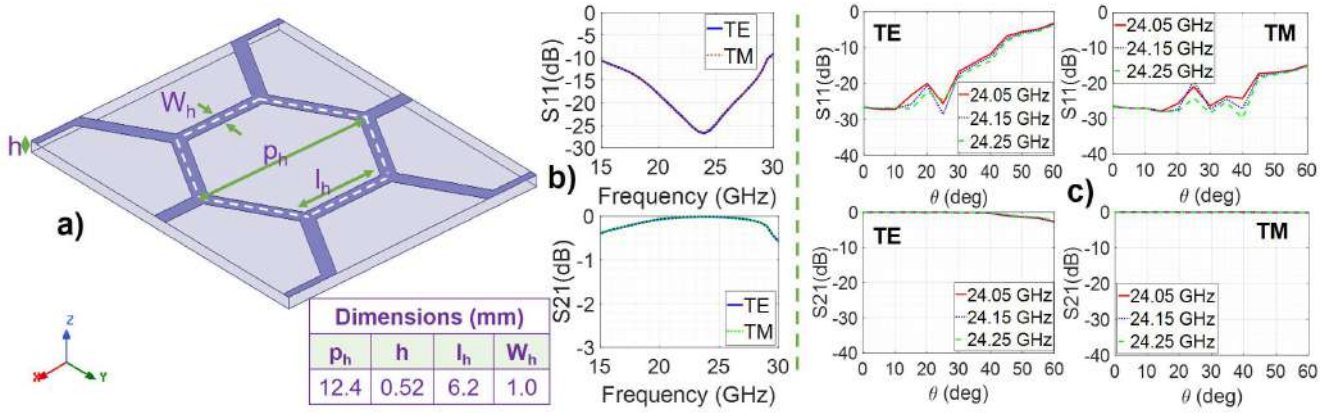
M. E. de Cos Gómez[1*], Alicia Flórez Berdasco[1] and F. Las-Heras Andrés[1]

[1] TSC, Electrical Engineering Department. Universidad de Oviedo. Gijón, Spain
[*]corresponding author: medecos@uniovi.es

Abstract: An Eco-friendly metasurface solution to protect a wearable grid array antenna in 24.05-24.25 GHz band is designed. The overall device' size is 40 x 40 x 1.94 mm^3. The target application is collision avoidance to assist visually impaired individuals at short-medium distance.

The antenna is a key part of Electronic travel assistance (ETA) radar systems to assist visually impaired people. Wearable antennas must be compact, lightweight, comfortable to wear and not radiate towards the body. Moreover, they should be protected from impacts and inclement weather. To avoid degrading antenna performance, radomes should be transparent, i.e. provide high transmission and low reflection and absorption in the antenna operating band. Metasurfaces have been proposed to be used as radomes [1]. At 24 GHz the metallization designs of the unit cells must remain simple, allowing them to be fabricated using standard microwave circuit techniques. To contribute to circular economies and achieve sustainable development goals, electronic device designs must be based on green materials. Figure 1 shows the metasurface unit cell geometry and dimensions on eco-friendly polypropylene (PP) dielectric [2] and Aluminium (Al), the retrieved reflection and transmission coefficients for both TE and TM polarized incident plane waves. It is noteworthy that very high transmission and very low reflection is achieved within the target band (24.05-24.25GHz).

The angular stability of the metasurface to be used as radome is of prime importance. The designed metasurface is fully stable across the target frequency band (24.05- 24-25 GHz) under oblique incident TM polarized waves (see Figure 1 c)) for Phi=0º and almost fully stable (up-to θ=45º) for TE polarized waves.



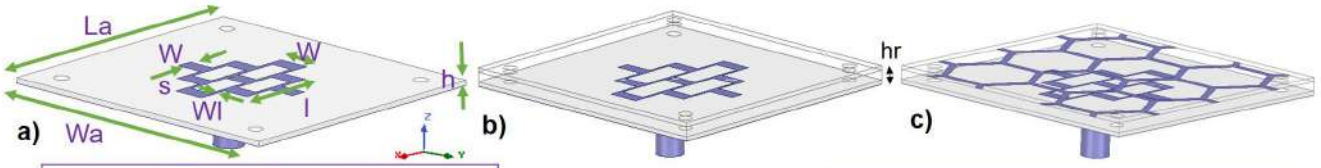


Figure 1. Metasurface: a) Unit cell; b) Reflection (S_{11}) and Transmission (S_{21}) coefficients; c) Angular stability.

Grid array antennas (GAA) [3] surpass conventional patch-type radiator arrays in terms of gain, cross-polarization control and bandwidth. A suitable GAA was designed on Al-cladded PP (Figure 2 a) and d)). According to Figure 3 e) the hexagonal metaradome (MTR-Hexagon) considerably overcomes a thin PP radome in terms of front to back ratio (FTBR) and radiation efficiency (η) at short distances from the GAA (hr= 0.7 and 0.9 mm) while provides similar peak realized gain (G). Prototypes of the GAA, the radome and MTR-hexagon

have been fabricated based on eco-friendly PP and Al using conventional milling machining (see Figure 3 a))

Dimensions (mm)

Abstract: A wearable artificial magnetic conductor backed dielectric resonator antenna array is designed for operation in 24.05-24.25 GHz band. The overall device' size is 24 x 24 x 7.37 mm^3. The target application is collision avoidance in aid to visually impaired people at short-medium distance.

Electronic travel assistance (ETA) radar systems are valuable for assisting visually impaired individuals by providing accurate and real-time environmental awareness, enhancing their mobility and safety. The antenna is a key element in radar's operation. For the target application, to alert of obstacles within a short to medium range (up to 2 meters), antenna radiation pattern beam-widths of 30-40 degrees are recommended [1]. In addition, to be wearable, the antenna must be compact, lightweight, comfortable to wear and not radiate towards the body. Dielectric resonator antennas (DRAs) offer high efficiency, wide bandwidth, and compact size, making them ideal for millimeter-wave frequency applications [2]. An artificial magnetic conductor (AMC) metasurface can be used to isolate a person's body from the wearable antenna and vice versa, so that neither the antenna's performance is degraded by the presence of the body, nor does the user receive high levels of radiation from the antenna [3], to comply with ICNIRP exposure guidelines. At such high frequencies, the metallization geometries of the unit cells cannot be very complex, so they can be manufactured using conventional microwave circuit techniques. Figure 1 shows the metasurface unit cell geometry and dimensions on RO3003 dielectric, the simulation set-up and the retrieved reflection coefficient phase and surface impedance for both TE and TM polarized incident plane waves. It is worth noting the wide AMC operating bandwidth achieved (29%), which includes the target band 24.05-24.25 GHz, and the high surface impedance at the 23.95 GHz resonant frequency.

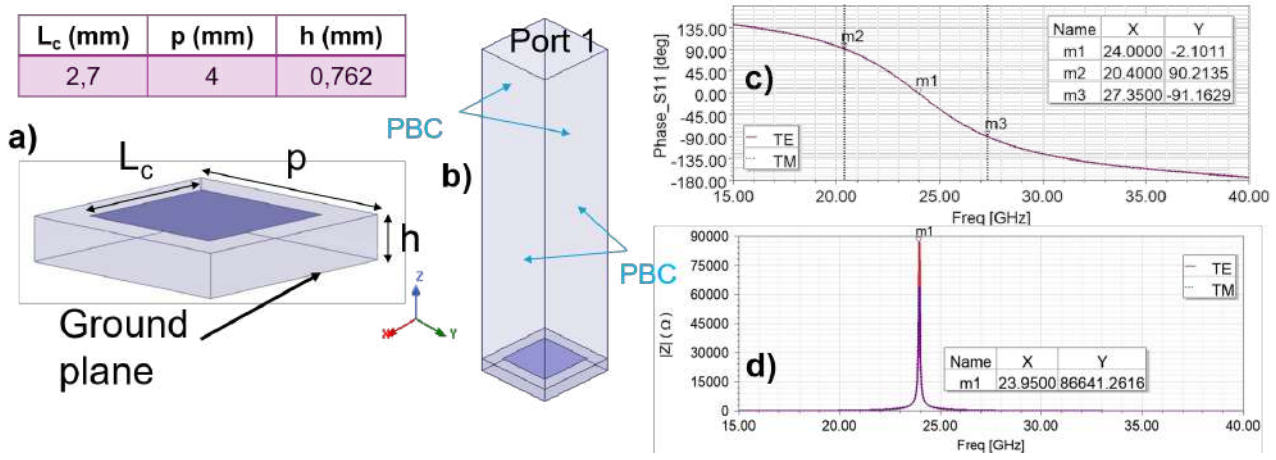

Figure 1. Metasurface: a) Unit cell; b) Simulation set-up; c) Reflection coefficient; d) Surface impedance.

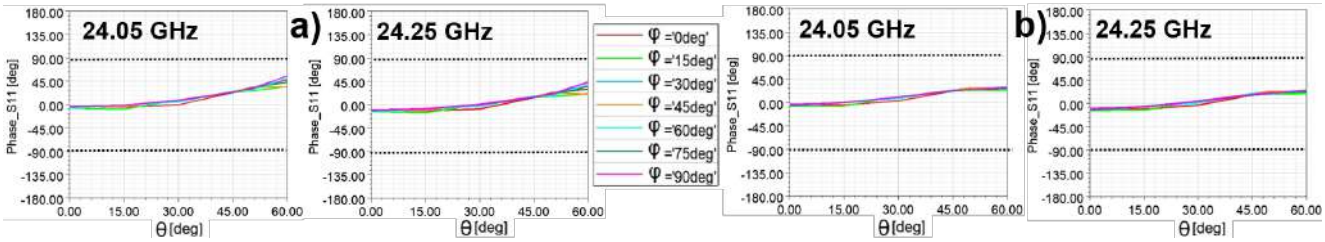
The angular stability of the AMC to be combined with an antenna is of major importance. The designed AMC is fully stable under oblique incident TE and TM polarized waves (see Figure 2) throughout the target frequency band (24.05- 24-25 GHz).



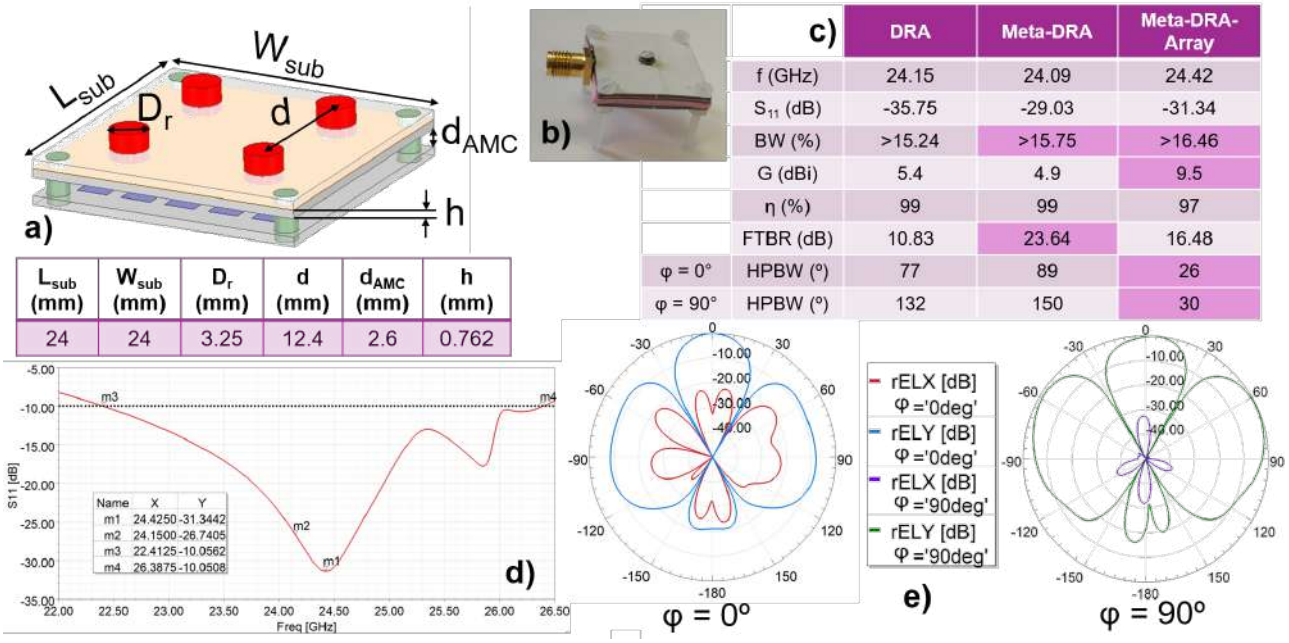


Figure 2. Metasurface angular stability under a) TE and b) TM polarized incident plane waves at the band edges.

A single element DRA provides wide bandwidth (BW) and high radiation efficiency (η) (Figure 3 c)), but exhibiting low front to back ratio (FTBR) level and not meeting the half-power bandwidth (HPBW) requirements. Adding an AMC to the DRA greatly improves the FTBR in the MTR-DRA, while preserving η, BW and gain (G), but slightly worsening the HPBW. Finally, Meta-DRA array (an AMC backed 2 x 2 element array) meets all the target application requirements, although the FTBR is reduced with respect to Meta-DRA.

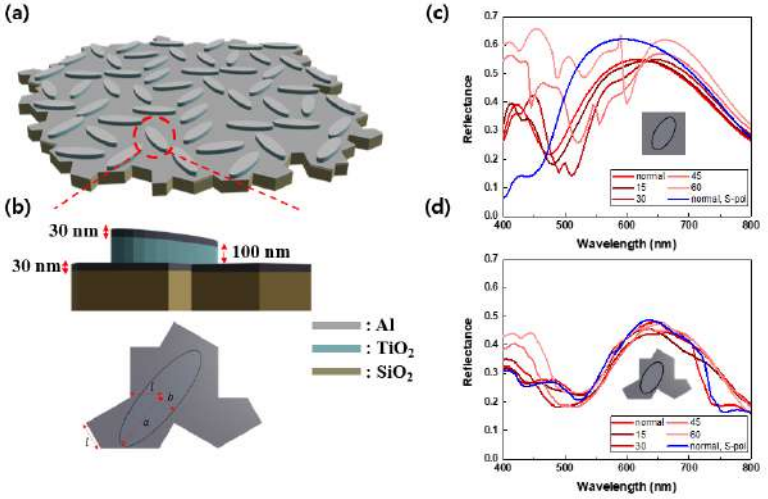
Abstract: In this study, we present a novel metasurface design based on the 'Einstein' tile for achieving robust structural color under varying incident light conditions. Simulation results demonstrate that the aperiodic metasurface based on aperiodic unit cell exhibits improved incident angle and polarization tolerance compared to periodic metasurface.

Metasurface-based color generation offers advantages such as resistance to chemical discoloration and high resolution. However, structural colors from metasurfaces are often affected by different incident light conditions. Conventional periodic-array metasurface designs are sensitive to incident angle and polarization due to some phenomena from periodicity, such as diffraction, lattice resonance, and asymmetric resonance.

In this work, the 'Einstein' tile, which can cover a surface completely without periodicity [(1)], is introduced into the metasurface design to mitigate incident angle and polarization sensitivity. By breaking the periodicity of the metasurface through the 'Einstein' tile, this design induces enhanced incident angle and polarization tolerance.



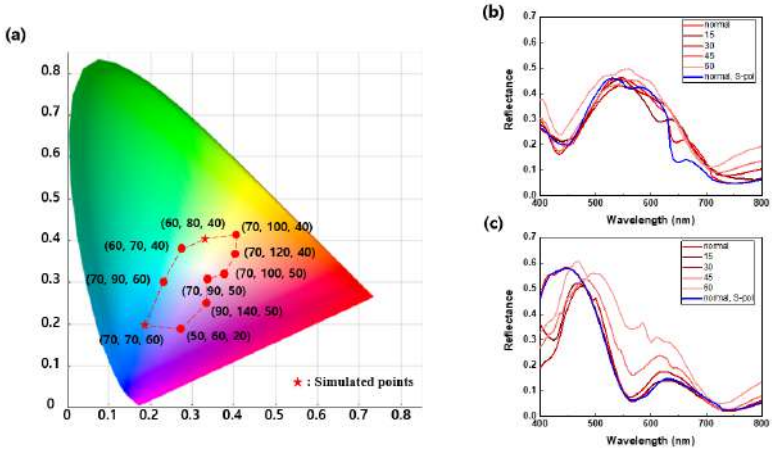


Figure 1. Schematic of the aperiodic metasurface for the structural color and the comparison between periodic and aperiodic metasurface. (a) The entire structure and (b) the aperiodic unit cell design of the aperiodic metasurface. Spectral reflectance of (c) periodic and (d) aperiodic metasurfaces with the same scatterer design.

Figure 1 depicts the schematic of the aperiodic metasurface and the comparison between a periodic and an aperiodic metasurface. As illustrated in Fig. 1(a), the scatterers are aperiodically arranged on the metasurface due

to the ‘Einstein’ tile. The aperiodic unit cell design for this aperiodic metasurface is shown in Fig. 1(b). The internal scatterer, a commonly used plasmonic resonator for the structural colors, is embedded within the ‘Einstein’ tile. This aperiodic unit cell induces aperiodicity and orientational randomness into the metasurface, like Fig. 1(a), and such properties contribute to improved tolerance under varying incident light conditions.

The simulation results of periodic and aperiodic metasurfaces with the same scatterer design are shown in Fig. 1(c-d). Conventional periodic metasurface exhibits high sensitivity under different incident angle and polarizations due to its periodic arrangement and anisotropic scatterer shape. In contrast, the proposed aperiodic metasurface effectively suppresses additional diffraction peaks near the 450 nm range, which appear in the periodic case, and achieves improved polarization tolerance. Thus, this aperiodic metasurface enhances incident angle and polarization tolerance by utilizing the aperiodic tile with conventional scatterer designs.

[Fig.2] (a) Color map of aperiodic metasurface with different structural parameters and (b-c) spectral reflectance under various incident light conditions for green and blue metasurfaces.

Figure 2 demonstrates the expandability of the aperiodic metasurface with different designs of the inside scatterer. Inset numbers are (*l, a, b*) structural parameters explained in Fig. 1(a). As shown in Fig. 2(a), the aperiodic metasurface can exhibit diverse structural colors by changing structural parameters of the aperiodic unit cell. This result shows the flexibility of the aperiodic metasurface so that we can simply design the aperiodic unit cell for diverse purposes, as we did in the periodic case.

The incident angle and polarization tolerance of two different structural parameter sets are also investigated and depicted in Fig. 2(b-c). The aperiodic metasurface for green and blue colors still exhibit tolerant spectral reflectance, similar to previous result in Fig. 1(d). This result represents that the aperiodic metasurface can be applied with various shapes or materials of scatterers for the proper performance with the additional incident angle and polarization tolerance.

Abstract: This study introduces a low-cost, single-layer unit cell for reconfigurable reflectarray effectively targeting the frequency bands from 90 GHz to 120 GHz. The results demonstrate a reflection phase tunability of 208^{0} and low loss of 3.9 dB. The reflectarray is simulated as proof of concept for 1-D beam-steering applications.

Reconfigurable intelligent surfaces (RIS) have gained significant interest in both academia and the industry in recent years, as they offer a wide range of advantages for modern millimeter-wave (mmWave) wireless communication systems. To achieve electronic reconfigurability, the meta-atoms that make up these RIS have to be loaded with active elements such as PIN diodes, varactors, MEMs, transistors, graphene, phase-change materials, etc. Alternatively, tunable substrates such as liquid crystals (LCs) enable reconfigurability in reflectarrays (RAs), offering low power consumption, low insertion loss, continuous tunability, scalability, reliability, and cost-effectiveness. One of the pioneering liquid crystal (LC)-based reflectarrays (RA), consisting of a square patch at 35 GHz, was proposed in 2006 [1]. Following this work, several studies have explored the use of LC as a tunable substrate material capable of modifying the reflective phase of the unit cell (UC) when a quasistatic electric field is applied. Over the past two decades, after these initial pioneering efforts, LC compounds specifically designed for microwave and millimeter-wave frequencies have been developed. Some notable examples include GT3-230001 [2], GT5-26001 [3], GT7-290001 [4], C–09–2 [5], and LCM-1 [6], whose electrical parameters have been measured and extracted accordingly.

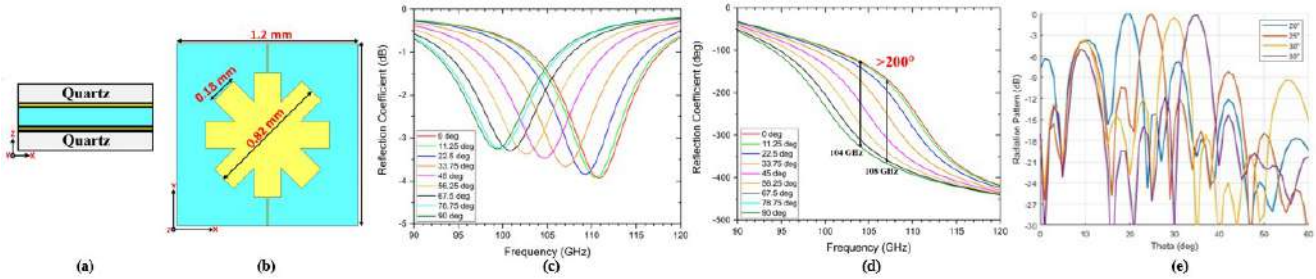

Figure 1: (a) Schematic View of the LC-based RA cell, cross-sectional view (b) Front View (c) Reflection coefficient magnitude in dB (d) Reflection phase in degrees (e) Simulated 1D radiation patterns at 105 GHz, illustrating beam steering to reflection angles of 20^{0}, 25^{0}, 30^{0}, and 35^{0}.

We analyze the performance of an LC-based RA using various LC formulations. The UC configuration consists of two parallel 400 µm quartz plates separated by a cavity filled with the LC, with a thickness of 40 µm, as shown in Figure 1 (a-b). The quartz plates act as the dielectric material, with a relative permittivity (ε_r) of 3.78 and dielectric loss tangent (tanδ) of 0.002. The UC is illuminated by a normally incident plane wave in the

transversal magnetic (TM) mode, with the electric field polarized along the x-axis. Its electromagnetic performance is analyzed and optimized using CST Microwave Studio™.

Our findings indicate a trade-off between reflection loss (RL) and maximum phase excursion (PE), as shown in Table 1. Among the tested compounds, LCM-1 and GT5 emerge as the most favorable options for applications requiring low RLs (< -2.2 dB), coupled with a maximum PE of approximately 188^0. On the other hand, GT7 and C-09-2 provide the best PE exceeding 200^0 but at the cost of a higher RL, around -4 dB. Therefore, if a RL of around -4 dB is acceptable and maximizing PE is a primary objective, GT7 and C-09-2 are the most suitable choices for such applications. Hereafter, the GT7-29001 is finally adopted in this work to achieve improved phase ranges and low RLs.

Table-1: Summary of performance evaluations for various LC compounds in RA based on an asterisk-shaped UC

	GT3-23001	**GT5-26001**	**GT7-29001**	**C–09–2**	**LCM-1**
Resonance Shifted from to (GHz)	110.9 to 102.3	110.8 to 100.5	110.8 to 99.4	99.3 to 112.4	109.2 to 100.5
Maximum loss (dB)	-4	-2.2	-3.9	-4	-1.76
Maximum Phase Excursion	175° at 106 GHz	188° at 106 GHz	208° at 105 GHz	217° at 104 GHz	168° at 106 GHz

To give an idea of the operation of the designs, Figure 1 (c-d) shows the reflection coefficient magnitude for different biasing states, particularized to the GT7-29001 LC compound. To capture all possible intermediate orientations of LC molecules, the LC tensor (α) is rotated incrementally from $\alpha = 0^0$ to 90^0. The resonant frequency shifts from 110.8 GHz to 99.4 GHz and maximum PE of 208^0 is obtained at 105 GHz. In the numerical analysis of a 1D beam steering scenario, a single row consisting of 1 × 33 UCs was considered. The design demonstrated the ability to steer the reflected beam to an angle of E_r=35^0, while the main reflection beam (specular reflection) remained at E_r=10^0, as shown in Figure 1 (e).

In summary, LC-based RA cell simulations demonstrated a wide 12 GHz bandwidth, with a maximum RL of -3.9 dB and a maximum PE of 208° at 105 GHz, showing a phase variation over 200° between 104 and 108 GHz. These findings highlight the potential of LC technology to enable reconfigurable devices for both mmWave and sub-mmWave applications, offering an effective solution for the demands of emerging technologies.

This project has received funding from the European Union's Horizon 2020 research and innovation programme under the Marie Sklodowska-Curie grant agreement No 101034285.

Polarization-Independent Huygens' Metasurfaces based on Split Ring Resonator for Highly Efficient Wavefront Formation at sub-THz bands

H. Kagami*, D. Kitayama, A. Pander, H. Matsunaga, and H. Takahashi

[1]NTT Device Technology Labs., NTT Corporation, 3-1 Morinosato-Wakamiya, Atsugi, Kanagawa, 243–0198, Japan

Abstract: A polarization-independent design for Huygens' metasurfaces at sub-THz bands is proposed. Metasurfaces designed using an electric LC resonator exhibited 2π phase controllability and low transmission loss. With a cell size below 0.5λ even for polarization-independent design, a 38° beam deflection angle with 2-bit wavefront formation was achieved.

In response to the continuously increasing volume of wireless traffic, frequency bands above 100 GHz have been discussed to enable high-speed and high-capacity wireless communications. However, radio waves above 100 GHz exhibit high linearity that results in the formation of blind zones due to shielding effects in obstacles, which creates a significant challenge in practical applications. To solve this problem and provide a highly efficient polarization-independent performance that can accommodate polarization multiplexing and mitigate polarization fluctuations, propagation control using metasurfaces is required [1]. Since metasurfaces are formed by unit cells with a finite size, quantization of the gradient phase profile is necessary; however, the occurrence of phase quantization errors can lead to a decrease of the diffraction efficiency. To keep the diffraction efficiency degradation low (below 1 dB), a quantization number of 4 (0, π/2, π, 3π/2) or more is required [2]. Huygens' metasurfaces, which can exhibit a full 2π phase control with a small number of metallic layers, are suitable to keep the diffraction efficiency high. For the same quantization number, metasurfaces with smaller unit cells allow for larger deflection angles and fewer sidelobes. One way to reduce the cell size is to use split ring resonators (SRRs). While a few reports on SRR-based Huygens metasurfaces can be found, the distinctive features of SRRs make them difficult to use in polarization-independent designs. In this study, we investigate SRR-based Huygens' metasurface unit cells (size <0.5λ) that exhibit polarization-independent characteristics for future applications to polarization-multiplexed communication in the sub-terahertz band.

The basic metasurface unit cell used in this study is based on an SRR and features an electric LC (ELC) resonator (marked by a red contour line in Fig. 1(a)). By stacking two layers of ELCs, an electric dipole (ED) and magnetic dipole (MD) can be excited. However, simply stacking two layers of ELCs does not match the

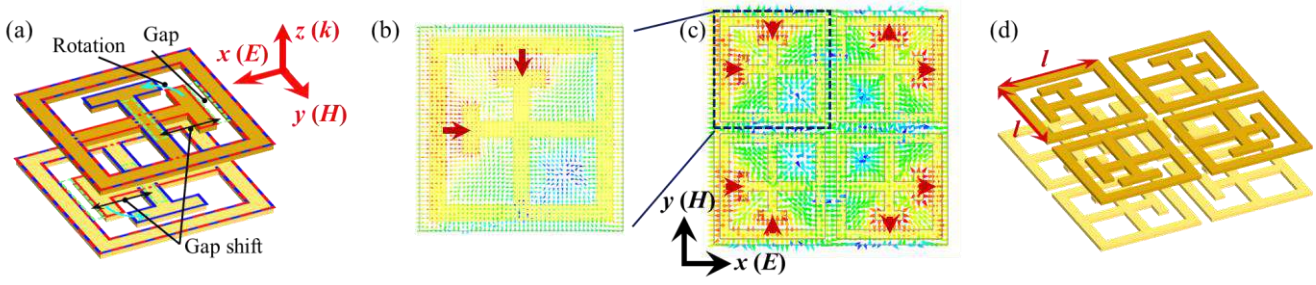

Fig. 1. (a) Geometry of ELC resonator unit cell. Red and blue regions correspond to *x*- and *y*- polarization. (b) ***E*** vector when *x*-polarization is incident on a basic unit cell synthesized to respond to both polarizations. (c) ***E***-field vector diagram for ***E***-field polarization along the *x*-axis of the unit cell, where the ***E*** fields in the *y*-direction cancel each other out. (d) Polarization- independent unit cell based on 4-fold rotational symmetry of ELC unit cell.

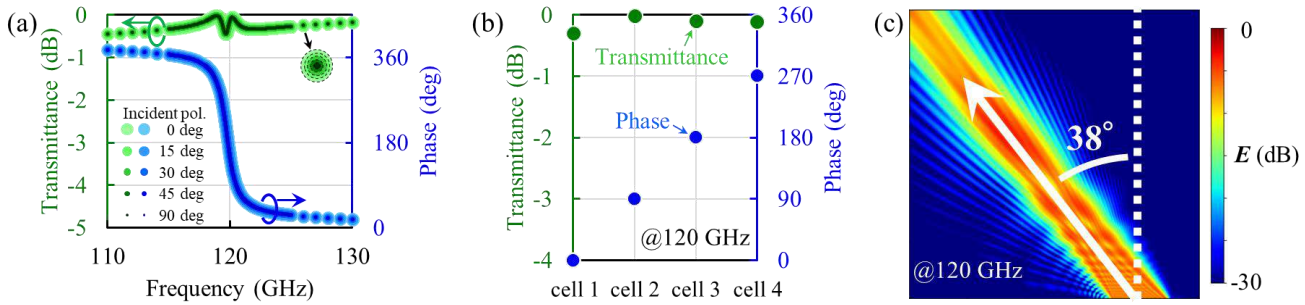

Fig. 2. (a) Transmission characteristics for the direction of the incident ***E*** field varied in 15° steps. (b) Unit cell transmission characteristics for π/2 phase variation caused by the change of parameter *l*. (c) Simulated near-field patterns of electromagnetic waves transmitted through a four-step phase-gradient metasurface.

frequencies of ED and MD. Therefore, offsetting the split part (gap) in both layers in the opposite directions (marked by arrows in Fig. 1(a)) is necessary so that the ED/MD resonance frequencies can be matched to form a Huygens' metasurface [3]. This structure correlates to a single polarization (*x*-polarization) where the electric field (***E***) vector aligns with the *x*-axis.

By 90° orthogonal rotation of basic ELC (red contour into blue contour cell in Fig. 1(a)) and a combination of both cells, an additional response can be obtained for vertically polarized (*y*-polarization) waves. However, as shown in the ***E*** field distribution (see Fig. 1(b)), when the electromagnetic wave is incident to the *x*-polarized wave, the local ***E*** field is excited in both orthogonal sections, and the polarization of the transmitted wave is rotated with respect to the incident wave. Therefore, we considered a unit cell (Fig. 1(c), (d)) structure obtained by a 4-fold rotational symmetry of the cell in Fig. 1(a). The EM simulation shows that the local ***E*** fields in the *y*-direction that are orthogonal to the incident ***E***-plane cancel each other in the entire unit cell (Fig. 1(c)). Similar EM field responses can be expected for both *x*- and *y*-polarized incident waves without polarization rotation. Simulation results of the transmission characteristics of this unit cell are shown in Fig. 2(a), where we can see that a phase shift of 2π is obtained with a transmission loss below 1 dB. The case where the incident polarization varies in 15° steps from 0° (*x*-pol.) to 90° (*y*-pol.) is also shown, demonstrating that the transmission characteristics remain the same regardless of the input polarization angle.

In this work, the change in transmission characteristics of the unit cell at 120 GHz to achieve four phase steps, as shown in Fig. 2(b), was obtained by the variation of the length *l* in Fig. 1(d). Next, we constructed a phase gradient metasurface using the discussed cell. The near-field simulation results shown in Fig. 2(c) confirm that small cells with a quantization number of 4 can produce a 38° beam deflection angle.

In conclusion, the proposed Huygens' metasurface structure can realize a low-loss polarization-independent transmissive metasurface with a quantization number of 4 or higher (phase change of 3π/2 or higher). The detailed experimental data analysis will be presented at the conference.

Designing Impedances Surfaces for Simultaneous Anomalous Reflection and Polarisation Conversion

Abstract: We present a method for deriving the tensorial impedance distributions required for arbitrary anomalous reflections, with polarisation conversion. We demonstrate this by converting a normally incident Transverse Magnetic polarised plane wave into a 30° anomalously reflected plane wave that is also polarisation converted to both Transverse Electric and Circular polarisations.

Anomalous reflection metasurfaces are surfaces patterned on the order of the diffraction period [1,2], with a sub-patterning within this period that is graded to select a direction for the incident wave to be reflected into. Anomalous reflection metasurfaces have attracted attention for their applications in 5/6G communications and their ability to redirect signals in increasingly dense environments.

Previous research has shown that an optimal tensorial susceptance distribution for simultaneous anomalous reflection and polarisation conversion can be found through the matching of Floquet modes, however this method can be rather complex and has only been demonstrated with total polarization conversion [3].

In this work we present a novel alternative method of calculating the family of tensorial impedance distributions for any given field transformation, and apply it to the case of simultaneous anomalous reflection and polarisation conversion. This method can be applied to any field transformation, directly from expressions for the desired incident and reflected fields. We begin our design process by extending the equation presented in [4], finding the tensorial impedance required to satisfy the total incident and reflected fields to be

$$\boldsymbol{Z} = \frac{|\vec{E}|}{|\vec{H}|}\{e_1\left[\hat{h} \otimes \left(\hat{n} \times \hat{h}\right)^* + \left(\hat{n} \times \hat{h}\right)^* \otimes \hat{h}\right] + e_2\left(\hat{n} \times \hat{h}\right)^* \otimes \left(\hat{n} \times \hat{h}\right)^* + \alpha\hat{h} \times \widehat{h}\}. \quad (1)$$

Here $\hat{e}, \hat{h}$ are the unit vectors of the Electric and magnetic fields respectively, $\hat{n}$ is the surface normal of the impedance surface, e_1 and e_2 are the defined by $\vec{E} = e_1\hat{h} + e_2\left(\hat{n} \times \hat{h}\right)$, and $\vec{\mathrm{E}}, \vec{\mathrm{H}}$ are the electric and magnetic fields respectively. In the case of lossless problems the circle collapses to a point, retrieving a specific passive solution. However, in cases of partial polarization conversion and anomalous reflection where loss is required, we gain a range of solutions of $\boldsymbol{Z}$. In this talk we will show the test cases of anomalous reflection at $30°$ converting an incident TM polarised wave to either a TE or circularly polarized waves. We then verify the performance of this impedance distribution in 2D FEM modelling [5] before approximating the impedance distribution, for a frequency of 31 GHz, using a repeated supercell design formed of 10 dodecagonal copper patches of various sizes and rotations on a grounded dielectric [6]. The performance of the metasurfaces design can be seen in Fig 1. We chose a test case of TM to TE polarisation conversion similar to [3] as a demonstrator of "perfect" anomalous reflection, allowing for the maximum amount of power to be sent in the desired direction [7]. The reflectance magnitudes for this case are shown in Fig 1a with a peak in the m=-1 TE mode at the design frequency of 31 GHz

with corresponding nulls in the other reflected orders.The second case is chosen as a demonstration of the ease of control over the level of polarisation conversion that can be achieved with this method, where loss is now required due to the partial interference of the incident and reflected waves [7]. This case is shown in Fig 1b, where the reflected TE/TM m = -1 modes show a near equal proportion of around the design frequency of 31GHz. Fig 1c shows the phase difference between the m = -1 TE and TM modes π radians with an approximately 1GHz

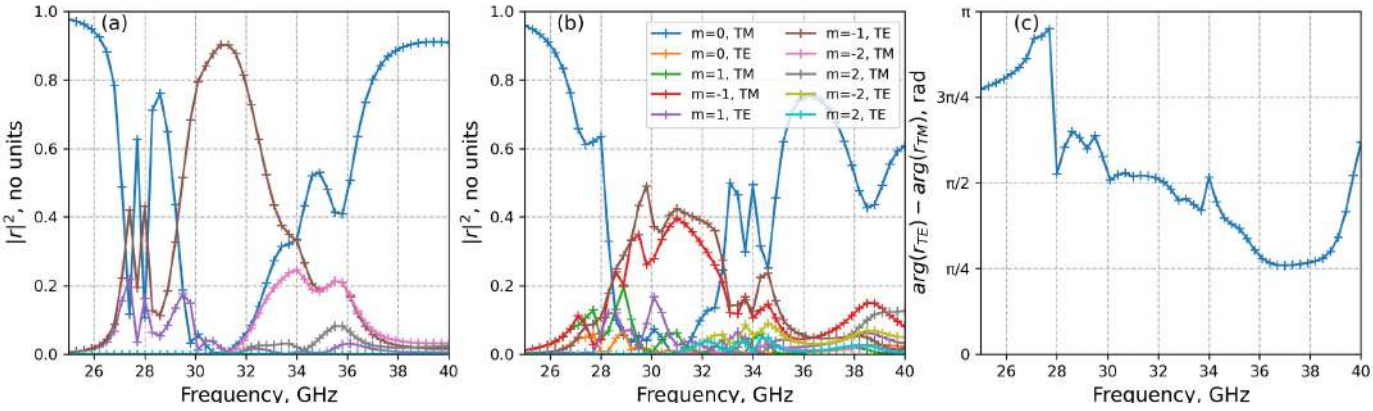

Figure 1 (a): Reflectance of the supercell design required for converting a Transverse Magnetic incident plane wave to a Transverse electric plane wave with a reflection angle of $\theta_r = 30°$ (b): Reflectance of the supercell design required for converting a Transverse Magnetic incident plane wave to a Circularly polarised plane wave with a reflection angle of $\theta_r = 30°$. (c) shows the phase difference between the TE and TM components of the -1 diffracted order modes of the surface shown in (b).

Abstract

By benchmarking two Topology Optimization (TO) strategies, a metasurface grating is presented, developed using a 3D Finite Element model based on open-source softwares. It exhibits nearly 60% of average diffraction efficiency on the $\in 1^{\text{st}}$ diffraction order in reflection between 400 and 1500 nm.

1 Introduction

For Earth and Universe observation purpose, a new generation of compact spectro-imagers is being developed [1]. To efficiently disperse the incident light on a given diffraction order for a wider range of wavelengths than a grating with a sawtooth profile, a metasurface configuration is proposed. We have generalized our 2D conical code [2] to the 3D case using two approches. First, a natural development is the TO of the distribution of the relative permittivity ε_r into the design region based on the Finite Element mesh generated by the resolution of the Maxwell's Equations; ε_r is considered constant by part in each tetrahedron. Second, a pillar-based permittivity distribution is presented for a fabrication purpose; ε_r is considered constant by part inside manufacturable cuboids.

2 Theoretical model

The function of merit in the optimization process is the diffraction efficiency of the grating in reflection on the $\in 1^{\text{st}}$ order, for a plane wave incidence. This quantity is computed with an open-source code that solves the Maxwell's Equations in the frequency domain. Then, the Jacobian of this merit function is calculated using an adjoint method. The latter Jacobian is applied in a gradient descent to optimize the permittivity distribution that maximizes the objective. Finally, a binarization and a connectedness filter are added to obtain a readable shape. The theory, the in-house developed code and all the tools used are detailed in Ref. [2] for the conical incidence, namely for a mono-periodic grating with a 3D incident plane wave. However, the Partial Differential Equation (PDE) remains the same in 3D, namely for a bi-periodic pattern. The weak formulation is even simpler to write, nevertheless more costly to solve [3].

3 Pillar-based bi-periodic pattern

Though the mesh-based algorithm is an interesting proof of concept for the TO process – it provides very high-efficiency gratings – a pillar bi-periodic pattern is hereby presented, for it can be manufactured. As illustrated in Fig. 1a on a single period, it is made of 200 nm-high elementary pillars of Si_3N_4 (in blue) or air with 82.5 nm-long edges, deposited on a 50 nm

stopping layer of aluminum oxide (Al_2O_3, in orange). Such dimensions have already been etched with adjusted e-beam lithography [4].

Fig. 1b shows the spectral response of the proposed pattern on the [400,1500] nm wavelength range (two octaves), with an oblic incident plane wave which wavevector is not coplanar with (Oxz) nor (Oyz). It is moreover compared to the best spectral responses obtained with topology optimized, mesh-based, mono-periodic structures. Starting from a 1300 nm-high design region using the mesh-based algorithm with SiO_2, the average diffraction efficiency reaches 81% (red dashed graph). With a 300 nm-high design region and Si_3N_4, this value drops to 65% (black dotted graph). Finally, with the 200 nm-high Si_3N_4 pillars, the average efficiency is 58% (blue graph). As compared to the efficiency of the sawtooth profile of 46% (grey graph), a 26% improvement in relative terms is achieved.

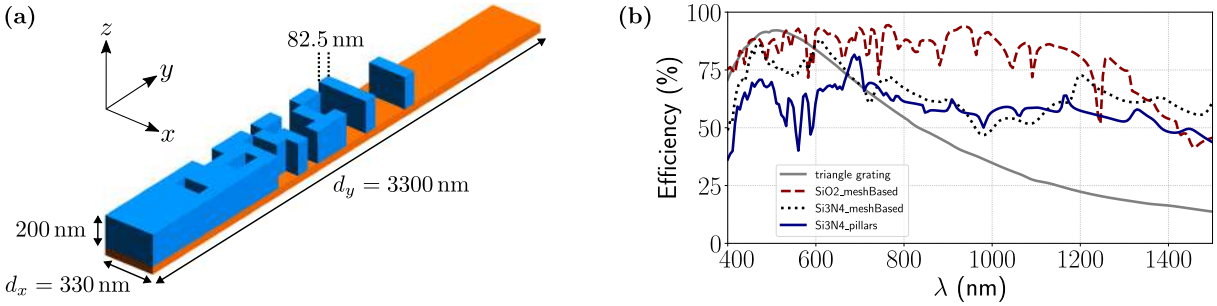

Figure 1: **(a)** Single period of the 3D structure. **(b)** Spectral responses on the $\in 1^{st}$ diffraction order for different structures.

4 Conclusion

The theoretical optimization of blazed metasurface gratings in broadband (two octaves, between 400 and 1500 nm) has led to a pillar-based design that can be manufactured. This structure exhibits a 58% of average diffraction efficiency on the $\in 1^{st}$ order, which is 26% higher than the sawtooth design in relative terms.

The next step of this project is to actually manufacture this structure using adjusted e-beam lithography and to analyse the feedback on the models, using far- and near-field characterization techniques.

Discrete multilevel metasurfaces for absorbers and antireflective layers

M. Kusko[1] and C. Kusko[1*]

[1]National Institute for R&D in Microtechnologies – IMT Bucharest , Romania

[*]corresponding author: cristian.kusko@imt.ro

Abstract: We numerically investigate dielectric nonresonant metasurfaces consisting in periodic arrays of blocks with different sizes and heights placed one on the top of the other. By adjusting the features of the blocks one can find enhanced functionalities of these metasurfaces such as absorbers or antireflecting layers.

Metasurfaces are two dimensional metamaterials, being essentially, periodic array of micro/nano antennas or resonating elements with subwavelength features, such that one can apply homogenization describing their properties in terms of effective material parameters. With applications ranging from antireflective layers and absorbers to metalenses or optical devices for wavefront control and manipulation, metasurfaces emerged as an important research direction in the field of flat optics [1].

One road to add another degree of freedom for increasing the possibility of tailoring the electromagnetic properties of the metasurfaces is to consider a multilayered metasurface by stacking arrays of elements with different geometric parameters one on the top of the other [2].

In this work, we perform a numerical analysis of multilevel dielectric metasurfaces consisting of a series of 2^N blocks with different sizes and heights placed one on the top of the other. We consider this number of levels since they can be practically realized by N standard photolithographic processes each of the followed by a etching process. The features of the blocks are much smaller than the wavelength such that the metasurface can be considered homogeneous. Also, the features of the blocks are chosen such that for the range of wavelengths of interest, the Mie resonances do not appear, the metasurfaces being non – resonant. In this quasi – static approach, we calculated the effective dielectric permittivites of each layer of blocks employing the circuit model [3,4]. By applying the transfer matrix method algorithm and the finite difference time domain method, we explore the potential of these configurations to be used as absorbers and antireflective layers.

Incoherent digital holography using multilayer metasurfaces for zeroth-order-light-free recording

T. Nobukawa*, R. Higashida, K. Imamura, Y. Maeda, and K. Hagiwara

Japan Broadcasting Corporation (NHK), Japan
*Corresponding author: nobukawa.t-eq@nhk.or.jp

Abstract: We propose and experimentally demonstrate an incoherent digital holography (IDH) system using multilayer metasurfaces. Unlike conventional IDH systems using a geometric-phase metalens, which suffer from noise caused by the zeroth-order light of the metalens, our proposed system exhibits exceptional robustness to such noise owing to its multilayer geometry.

1. Introduction

Incoherent digital holography (IDH) is a technique for recording holograms through the self-interference of a spatially incoherent light source [1]. To implement IDH, generating two beams with different defocus phases from the object light is necessary. One approach for generating two beams involves using a geometric-phase metalens [2] that generates two beams with the same intensities and opposite-sign defocus phases based on the geometric-phase. However, practical metalenses exhibit fabrication errors, leading to the generation of zeroth-order light. In IDH, zeroth-order light introduces undesired interference in the holograms, thereby degrading the quality of the reconstructed images. Optimizing the metalens fabrication process can help minimize zeroth-order light. However, even a few percent of zeroth-order light remain problematic in IDH due to the inherently low contrast of holograms.

Therefore, to address this issue, we propose a novel IDH system using multilayer metasurfaces. The proposed system effectively filters out zeroth-order light by incorporating geometric linear phases on each metasurface. Proof-of-principle experiments were conducted to prove that this system can successfully record holograms without the effect of zeroth-order light.

2. Principle of an incoherent digital holography system using multilayer metasurfaces

Figure 1 illustrates the schematic of the proposed IDH system, which comprises three geometric-phase metasurfaces. The spatially incoherent light from the object is first polarized using a polarizer. The polarized light is then divided into two parts with orthogonal circular polarizations by the first metasurface, which functions as a geometric-phase prism. If a fabrication error occurs in the first metasurface, zeroth-order light propagates along the optical axis. The second metasurface comprises three subregions. The center region filters out on-axis zeroth-order light, whereas the two outer regions function as geometric-phase prisms. The grating period of these outer regions is half that of the first metasurface. The divided beams are incident on the third metasurface that has the functions of the geometric-phase prism and geometric-phase metalens. The modulated light follows a common optical path, exhibiting different defocus phases and orthogonally circular polarization states. A polarization-sensitive image sensor captures the hologram with four-step phase shifts determined by the geometric-phase [1, 2]. From the captured image, the three-dimensional information of the object can be reconstructed using the phase-shifting method and diffraction calculations.

3. Proof-of-principle experiments

We used three metasurfaces composed of silicon nitride meta-atoms for the proof-of-principle experiment. The meta-atoms are designed to be nearly ideal half-wave plates with 120 × 240 × 700-nm^3 dimensions. The metasurfaces were fabricated using a multistep process, including plasma-enhanced chemical vapor deposition of a silicon nitride layer on fused glass, nanopatterning via electron beam lithography, and dry etching with a Cr hard mask. During dry etching, we intentionally under-etched samples to generate zeroth-order light. The diffraction efficiencies for the zeroth-order light of the fabricated metasurface were 78 % in average, which generally cannot be used in conventional IDH systems. To demonstrate the IDH functionality using the imperfect metasurfaces, we used a USAF test chart as the object and illuminated it with LED light. A bandpass filter with a center wavelength of 633 nm and a bandwidth of 10 nm was applied to enhance the temporal coherence of the light. The three metasurfaces modulated the transmitted light, and a polarization-sensitive image sensor captured its self-interference hologram. Figure 2(a) shows the captured hologram. By demosaicking the hologram and applying the phase-shifting and angular spectrum methods, we successfully reconstructed an image of a portion of the USAF test chart (Fig. 2(b)). These results show that the proposed system can successfully implement the IDH functionality without the effect of zeroth-order light of the imperfect metasurfaces.

4. Conclusions

We proposed and demonstrated IDH systems using multilayer metasurfaces. The proof-of-principle experiments show the proposed system is highly robust against zeroth-order light. In future work, we will evaluate the robustness of the system against zeroth-order light and optimize its geometry to improve image quality.

Angle independent enhancing and diminishing metasurface with susceptibility-driven inverse design

S. Y. Golla*, Jian Cao, S. Salhi, Paula Nuño Ruano, Carlos Alonso-Ramos, Daniele Melati

Centre de Nanosciences et de Nanotechnologies, CNRS, Université Paris-Saclay, 91120 Palaiseau, France

sandeep-yadav.golla@universite-paris-saclay.fr

Abstract: This study presents metasurfaces for angle independent enhancement and diminution, designed and fabricated using analytical target phases derived from susceptibilities via generalized sheet transition conditions. Electric filed and far-field simulated results demonstrate precise doubling/halving of angular patterns even at extreme angles, enabling applications in beam shaping and steering.

1. Introduction

Achieving precise beam steering without losing directivity at higher angles has long been challenging in optics [2]. While metasurfaces have driven significant advancements, their performance is limited, especially at smaller pixel sizes, due to restricted numerical apertures. Angle-enhancing devices address wide-angle beam steering but face notable shortcomings. Passive metasurfaces perform optimally only within narrow design ranges, as their phase profiles approximate target phase maps rather than using rigorous analytical solutions, leading to limited efficiency and steering angles. Active metasurfaces offer tunability but face challenges like complexity, energy use, and dependence on actuation, limiting their practicality for compact applications. Current methods struggle to combine the flexibility of active metasurfaces with the simplicity of passive ones, especially for wide-angle beam steering and imaging. This paper presents an inverse design for angle-enhancing and -diminishing metasurfaces, starting with engineered susceptibility, converting it into the target phase, and using a lookup table method to design nano-pillars.

2. Susceptibilities of angle enhancing and diminishing metasurfaces

Electromagnetic wave propagation in a medium is governed by Maxwell's equations. For interfaces with metasurfaces (engineered arrays of nanoscale meta-atoms), the Generalized Sheet Transition Conditions (GSTCs) [1] describe the discontinuity:

$$n \times [\![\mathbf{E}]\!] = -i\omega\mu_0 \overline{\overline{\chi}}_{mm,0} \{\mathbf{H}_{\parallel}\}, \quad n \times [\![\mathbf{H}]\!] = i\omega\varepsilon_0 \overline{\overline{\chi}}_{ee,0} \{\mathbf{E}_{\parallel}\}. \tag{1}$$

where n is the vector normal to the surface of the interface, satisfying local orthonormal curvilinear basis (τ^1, τ^2, n) with tangential vectors τ^1 and τ^2. ω, μ_0 and ε are frequency , permittivity and permeability for free space. The $[\![\mathbf{A}]\!] = \mathbf{A}_+ - \mathbf{A}_-$ and $\{\mathbf{A}\} = (\mathbf{A}_+ + \mathbf{A}_-)/2$ are the difference, mean of the $\mathbf{A}_+, \mathbf{A}_-$ with $\mathbf{A} = \mathbf{E}, \mathbf{H}$. $\mathbf{A}_{pm}$ is the filed before and after the metasurface. On inverting the above equations and solving for the susceptibilities, we obtain

$$\chi_{ee,0}^{\tau^1\tau^1} = \frac{-1}{i\omega\varepsilon_0} \frac{[\![\mathbf{H}^0 \cdot \tau^2]\!]}{\{\mathbf{E}^0 \cdot \tau^1\}}, \chi_{ee,0}^{\tau^2\tau^2} = \frac{1}{i\omega\varepsilon_0} \frac{[\![\mathbf{H}^0 \cdot \tau^1]\!]}{\{\mathbf{E}^0 \cdot \tau^2\}}, \chi_{mm,0}^{\tau^1\tau^1} = \frac{1}{i\omega\mu_0} \frac{[\![\mathbf{E}^0 \cdot \tau^2]\!]}{\{\mathbf{H}^0 \cdot \tau^1\}}, \chi_{mm,0}^{\tau^2\tau^2} = \frac{-1}{i\omega\mu_0} \frac{[\![\mathbf{E}^0 \cdot \tau^1]\!]}{\{\mathbf{H}^0 \cdot \tau^2\}}. \tag{2}$$

By carefully selecting the injected and transmitted electromagnetic fields,$\mathbf{E}_{\pm}^0, \mathbf{H}_{\pm}^0$, the desired functionality of the metasurface can be inverse designed. For Transverse Electric (TE) $(\mathbf{E}_x, \mathbf{H}_y, \mathbf{E}_z)$ mode interacting with a metasurface designed to enhance or diminish the propagation angle, one possible configuration for the injected and transmitted electromagnetic fields is given by:

$$\mathbf{E}_{0,-}(x,y,z) = (1,0,1)\exp\left(-ik_0(x\sin(\theta_i) + y\cos(\theta_i))\right), \tag{3}$$

$$\mathbf{E}_{0,+}(x,y,z) = (1,0,1)\exp\left(-ik_0(x\sin(m\theta_t) + y\cos(m\theta_t))\right). \tag{4}$$

For angle doubling and halving, m takes the values 2 and $1/2$, respectively. The remaining field components can be derived using the corresponding Maxwell curl equations. The final expressions for the electric and magnetic susceptibilities are obtained by substituting the input/output fields from Eqs. (**??**)- (**??**) into Eqs. (2), and are as follows:

$$\chi_{\mathrm{ee}} = \frac{2\sqrt{\varepsilon_0/\mu_0}(1-t_{e/d}-r)}{\mathrm{j}\omega(1+t_{e/d}+r)}, \chi_{\mathrm{mm}} = \frac{2\sqrt{\mu_0/\varepsilon_0}(1-t_{e/d}+r)}{\mathrm{j}\omega(1+t_{e/d}-r)},$$

Here, $t_{e/d}$ and r represent the transmission and reflection coefficients, respectively, for the angle-doubling and angle-halving metasurfaces. For the case where $r = 0$ t is given by:

$$t_d = \frac{2\pi}{\lambda}\left(\frac{1}{2} - 2\left(\frac{n_t}{4n_i}\right)^2 \mp \frac{n_t}{4n_i}\left(\left(\frac{n_t}{2n_i}\right)^2+2\right)^{1/2}\right)^{1/2}\left(n_t - 2n_i\left[\frac{n_t}{4n_i} \pm \frac{1}{2}\left(\left(\frac{n_t}{2n_i}\right)^2+2\right)^{1/2}\right]\right),$$

$$t_e = \frac{2\pi}{\lambda}\left(\frac{1}{2} - 2\left(\frac{n_i}{4n_t}\right)^2 \mp \frac{n_i}{4n_t}\left(\left(\frac{n_i}{2n_t}\right)^2+2\right)^{1/2}\right)^{1/2}\left(-n_i + 2n_t\left[\frac{n_i}{4n_t} \pm \frac{1}{2}\left(\left(\frac{n_i}{2n_t}\right)^2+2\right)^{1/2}\right]\right)$$

The refractive indices of the incident and transmitted media at the metasurface interface are denoted by $n_{i/t}$. Angle-independent susceptibilities are achieved using generalized Snell's law, ensuring accuracy. These susceptibilities, including $t_{e/d}$ for the required phase profile, are used for inverse designing the metasurface.

Finite Difference Time Domain (FDTD) simulations of the metasurface were performed to analyze its angle-enhancing and angle-diminishing functions. Electric field maps and far-field patterns for incidence angles of 0 to 45 degrees are shown in Fig. 1. The refractive indices of SiO_2 (input medium) and air (output medium) are 1.48 and 1.0, respectively, with simulations over a $10\lambda \times 10\lambda$ region at a wavelength of $1.5\mu m$.

The far-field patterns show the metasurface maintains beam directivity at higher angles, with reduced intensity due to complex susceptibilities and partial transmittance. It effectively doubles the angle in the enhancer configuration and halves it in the diminisher configuration. The design performs reliably even at extreme angles, and no side lobes are present except at 90 degrees, confirming its ability to suppress unwanted scattering.

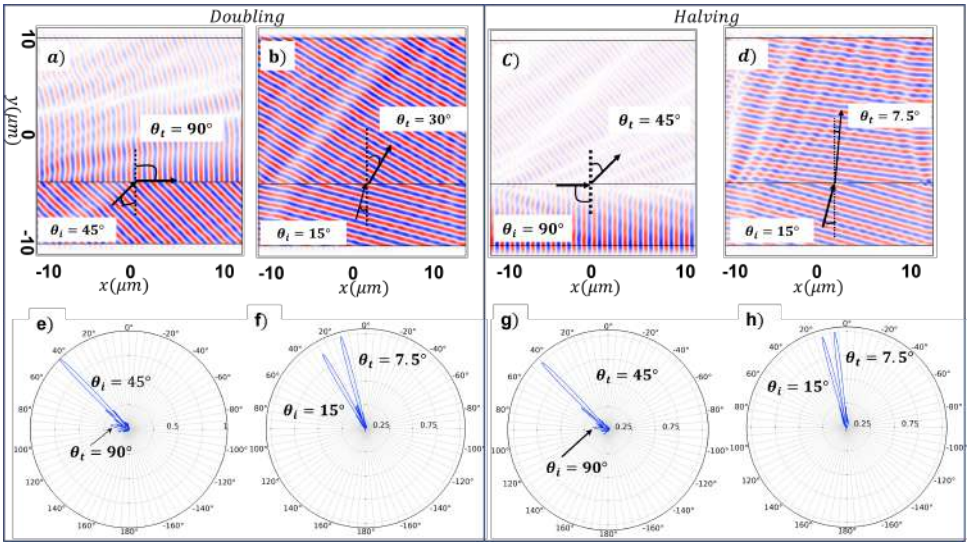

Fig. 1. Numerical simulations of the angle enhancing metasurface: a-d) Electric filed component of angle doubling metasurface for incidence range of ∠0 to ∠45; e-h) The associated farfield radiation pattern of angle doubling metasurface.

Conclusion. In conclusion, we designed an angle-doubling and halving metasurface that is independent of propagation angle, performs effectively at extreme angles, and offers a passive alternative to active metasurfaces.

Acknowledgments. This work has been supported by the European Research Council (ERC project BEAMS, grant agreement No. 101041131).

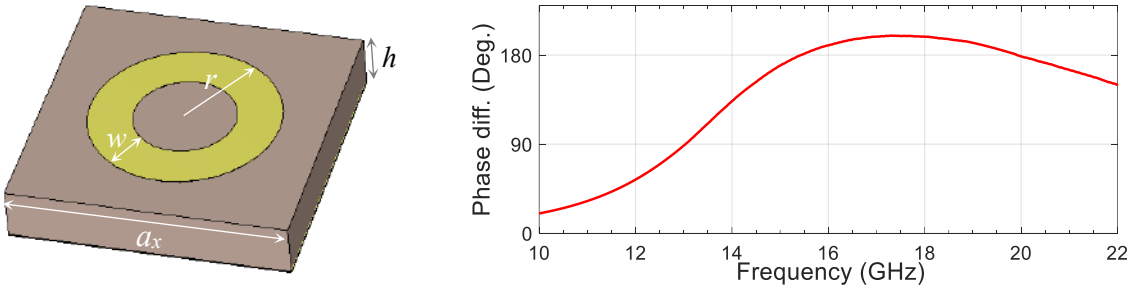
Ring distributed metamaterial with phase cancellation for RCS reduction

O. Fernández[1*], R. Gonzalez[1], A. Gómez[1] and I. Barba[2]



[1]Departamento de Ingeniería de Comunicaciones, Universidad de Cantabria, Santander, Spain.
[2]Departamento de Electricidad y Electrónica, Universidad de Valladolid, Valladolid, Spain
[*] corresponding author: fernanos@unican.es

Abstract: In this communication a phase cancellation metasurface is presented. The novelty of the proposed design resides on the combination of 4 structures based on the same unit cells but with slight modifications. This metasurface is designed to reduced monostatic RCS but also improve the diffuse scattering taking advantage of secondary lobes.

In electronic warfare applications, radar cross-section reduction is of vital importance to protect the integrity of fleets and infrastructures. Traditionally, techniques such as structural design with "special" geometries or the use of Radar absorbing Materials (RAM) have been used to reduce the radar signature. In recent years, metamaterials have been shown to be a good alternative to overcome the limitations of these traditional techniques, providing lighter structures (as opposed to RAM) and geometries suitable for the low observability of some parts of the infrastructures as antennas.

Phase-cancellation metasurfaces are one of the most commonly used techniques in the literature. The simplest structure combines two different types of cells which have a modulus reflection coefficient close to 1 and a phase offset of 180°. Each type of unit cell is grouped into tiles and both types of tiles are distributed over the metasurface. This technique significantly reduces the RCS for monostatic radar. However, it appears secondary lobes that represent a handicap for bi-static radar. In this paper, we focus on evaluating the impact of the type of tile distribution on the metasurface. Different approaches can be found in the literature. We start from the chessboard distribution [1] where two squared tiles (one of each type) are alternately distributed. The resulting bistatic RCS has four lobes. In [2] triangular tiles are used alternately distributed in a hexagonal supercell and its RCS has 6 lobes. Non-periodic distributions as in [3] with the tiles aligned without any specific pattern (i.e. random) can reduce the RCS by means of diffuse scattering thus reducing the bistatic radar.

In this communication we analyze a hybrid distribution that combines the advantages of different arrangements. This metasurface is based on the ring unit cell presented elsewhere [4]. Fig. 1a presents the main geometrical parameters of the Ring unit cell. We have selected a ring width of 1 mm and for the two-unit cells outer radius of

(a) (b)

Figure 1.- (a) Representation of the unit cell with the main parameters, a_x = 6 mm, w = 1 mm, substrate Rogers 4003C with h = 1.524 mm and cladding 35 μm. (b) Phase difference between the reflection coef. of unit cells with r = 1.6 and 2.4 mm.

2.4 and 1.6 mm. The phase difference between the two types of structures is represented in Fig. 1b. A 180º phase difference is obtained at about 15.5 GHz and 20 GHz.

The type of distribution provides a different interaction between the tiles thus affecting to the resultant phase cancellation. In this communication we propose a ring distributed metasurface that reduces the bistatic RCS in comparison with the chessboard and the random distribution. The proposed metasurface is formed by four structures distributed in rings as detailed in Fig. 2 a. In each structure a small variation of the generic unit cell or the default tile is done to provide whether a reduction of the broadside RCS or an increase of the diffuse. Fig 2b presents a comparison of the monostatic RCS for the three structures.

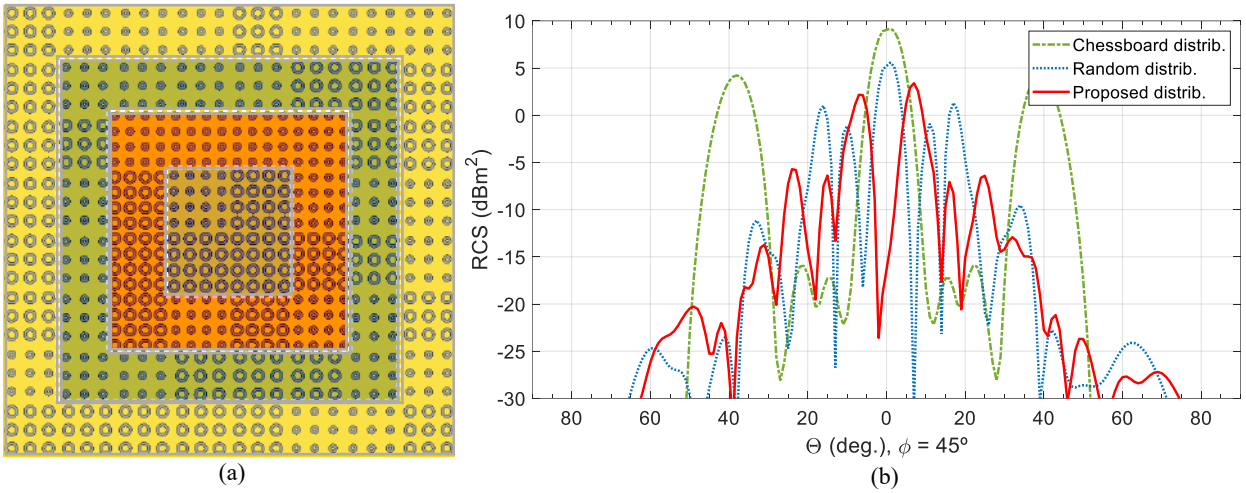


Figure 2.- (a) Proposed metasurface (b) Monostatic RCS of the proposed distribution compared with the chessboard and the random distribution.

Numerical investigation of Transverse-Mode Theory for Strongly Coupled Periodic All-Dielectric Metasurfaces

Pooja Uday Naik[1] **and Massimiliano Guasoni**[1*]

[1]Optoelectronics Research Centre, University of Southampton, United Kingdom.
[*]corresponding author: m.guasoni@soton.ac.uk

Abstract: Transverse mode behaviour has been investigated by modelling strongly coupled periodic nanoantenna array. Our study, unlike the Mie theory and look-up table approach—where individual nanoantenna modes and their interference are studied—considers the effect of coupling strength on the supermode of the array, offering new insights into light-matter interaction.

Metasurfaces have been widely studied as a powerful platform for manipulating light at the subwavelength scales, enabling applications in beam shaping, metalenses, and holography[1,2]. While traditional metasurface designs rely on localized Mie resonances, lattice modes, quasi-modes description, and look-up table approach[3-5], the models fail to capture the collective optical behaviour in the strong coupling regime, where interactions between neighbouring meta-atoms become significant. In this work, we numerically investigate the transverse-mode behaviour in periodic metasurfaces and introduce a 3-layer equivalent model that accurately predicts the phase response in the strong coupling regime.

The study models the periodic metasurface as an effective three-layer system, where the metasurface can be interpreted as a homogenized anisotropic slab. By analysing the forward and backward propagating waves and their interactions, the analytical formulation captures the behaviour of strongly coupled meta-atoms in a more intuitive manner than conventional scattering-based models. In the linear regime, the incident plane wave can be further decomposed as a combination of transverse modes, providing a simplified approach to predict the near-field and by extension shape the phase-coherent far-field response of the densely packed nanoantenna array.

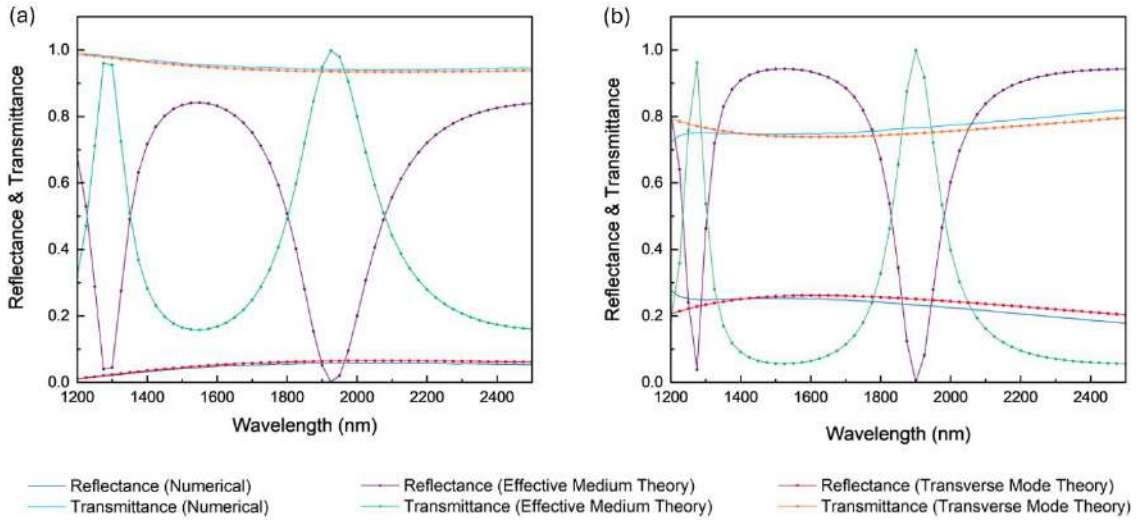

Figure 1: Transmittance and reflectance spectra of a periodic Si-air hollow-core nanoantenna array with period (P) = 1.5 as a function of incident wavelength for (a) normal incidence and (b) 55° incidence. The graphs compare numerical simulation results with EMT and the proposed transverse mode theory.

The transverse-mode approach differs fundamentally from standard effective medium theory (EMT) in how it treats light-matter interactions in metasurfaces. EMT homogenizes the structure, assuming the meta-atoms act independently and can be replaced by an averaged refractive index, which works well when particles are subwavelength and weakly interacting. However, in the strongly coupled regime, where meta-atoms are closely spaced, near-field interactions become significant, and the metasurface

behaves collectively, supporting lateral waves propagating along its plane[6]. Rather than treating the metasurface as a uniform bulk medium, the transverse-mode model views it as an effective thin slab that guides these lateral waves. This approach captures the phase-coherent nature of strongly coupled metasurfaces, enabling accurate descriptions of their phase response.

The predictions are verified using COMSOL Multiphysics by performing full-wave simulations and comparing it against the proposed transverse mode theory as shown in Figure 1. Here, silicon (Si) hollow-core nanoantennas filled with air with diameter and height of 400 nm are modelled. The optical response of the periodic array with period (P) = 1.5 has been investigated as a function of incident wavelength from 1200 nm to 2500 nm. A comparison between EMT and transverse mode theory has been made to showcase the accuracy of the proposed transverse mode theory model. In the case of EMT, the effective refractive index (n_{eff}) was determined using a weighted index approach, which fails to accurately capture the underlying physics of mode confinement and coupling. In contrast, transverse mode theory provides a more rigorous description of the system even with the change in the incident angle from normal incidence to 55° incidence, yielding results that exhibit strong agreement with numerical simulations, thereby offering a more precise characterization of the modal behaviour.

Our findings provide an alternative perspective on metasurface physics, offering a more unified framework for designing highly efficient wavefront-control devices. The proposed transverse mode theory can also be further extended to study aperiodic metasurfaces since the theory fundamentally depends on the coupling strength rather than the geometry of the individual meta-atom. By bridging gaps in existing theories, this work opens new avenues for inverse-designed metasurfaces and even nonlinear nanophotonics applications.

Polarization-multiplexed vectorial OAM holography based on dielectric metasurfaces

Joonkyo Jung[1], Hyeonhee Kim[1], and Jonghwa Shin[1,*]

[1]Department of Materials Science and Engineering, KAIST, Daejeon 34141, Republic of Korea

Abstract: We propose novel metasurface holograms, where multiple vectorial holographic images can be encrypted into the polarization state and orbital angular momentum (OAM) of incident light. By expanding the multiplexing capability, we anticipate that our approach can find various applications such as optical information storage, secure encryption, and optical communications.

Metasurfaces, which are two-dimensional arrays of subwavelength nanostructures, have attracted tremendous interests by virtue of their versatile controllability over various characteristics of light such as amplitude, phase, and polarization. This controllability has made metasurfaces promising platforms for optical holograms. In addition, metasurfaces can be designed to operate differently depending on the states of incident light, e.g., polarization and wavelength. This multiplexing capability of metasurfaces has significantly increased the amount of information that can be encoded in a single metasurface.

The OAM of light has emerged as a new degree of freedom for augmenting the multiplexing capability of metasurface-enabled holograms [1, 2]. Since OAM is not bounded theoretically, it is expected to dramatically boost the information capacity. In an OAM-preserving hologram, the OAM of incident light is preserved at each pixel of the target images. By imposing an additional helical phase, this hologram becomes an OAM-selective hologram, where only incident light with the opposite helical phase can generate the target images with the fundamental Gaussian modes; by applying a fundamental Gaussian filter, only incident light with the desired topological charge can generate holographic images.

Even though there have been many studies related to OAM holograms, almost all of these studies are limited to intensity-only holographic image, which represent only a small portion of the information that the electric field can convey. Recently, based on polarization-multiplexed metasurfaces, a vectorial OAM hologram was suggested in [3]. However, in [3], both input polarization channels are exhausted to generate the vectorial holographic images because the polarization controllability of metasurfaces has not been fully utilized.

In this study, we propose a novel approach to encode different vectorial OAM holograms in different polarization-OAM channels with the desired topological charges as schematically represented in Figure 1. As numerically demonstrated in Figure 1, the proposed metasurfaces can generate three distinctive target images for each polarization-OAM channel, where the first one is corresponding to the amplitude and the second and third ones are corresponding to the polarization state. We believe that our approach overcoming the current limitations of OAM holography can pave a way toward further improved optical communications, optical encryption, and data storage.

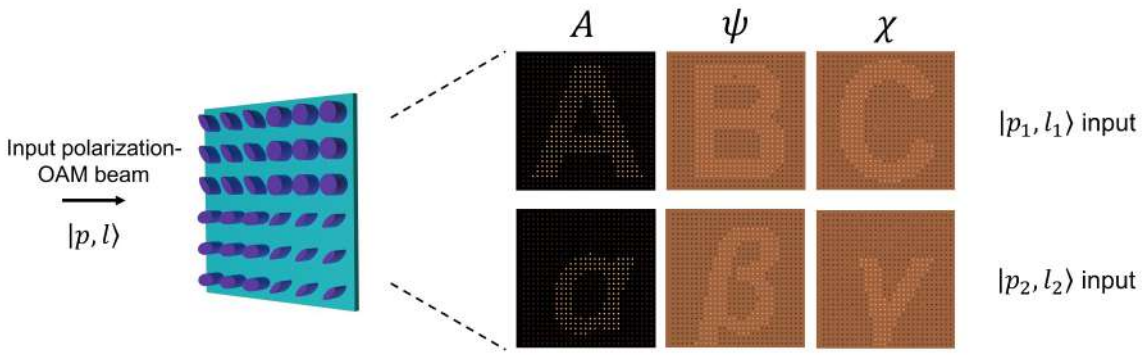

Figure 1. Schematic representation of polarization-multiplexed vectorial OAM holography. The state of an input OAM beam is defined by polarization states p and topological charge l. The right panels show the numerically calculated results of the amplitude A, and two angular values of ψ and χ, defining polarization state of the resulting vectorial field profile.

Characterization of flat optical devices in a transformation optics context

M. Giloan

MG Data, Romania
corresponding author: mircea_giloan@yahoo.com

Abstract: Optical devices are mainly based on wave path and wave vector manipulation. This can be obtained by specifically designing the surface of the interface between two media. In the last years flat optical devices have been intensively studied. In this study flat optical devices are characterized as transformation optics media.

This theoretical study shows a general method for designing flat optical devices based on transformation optics. Optical devices consisting in flat media obtained by transforming only one coordinate of the free space have been considered. A proper control of the wave path and wave vector can provide a specific wave vector distribution at the output plane of the flat device [1]. This method can be used to design lenses, optical connectors and wave-shape transformers [2, 3]. Numerical computations consisting in Finite-Difference Time-Domain (FDTD) simulations confirm the proposed theoretical model. Figure 1 shows the FDTD simulation results for a designed flat optical device. This device transforms the wave generated by a dipole in a plane wave (see fig. 1(a)). The designed device has a square shape which can be observed in figure 1(b) which depicts the *xy* component of the electric permittivity tensor.

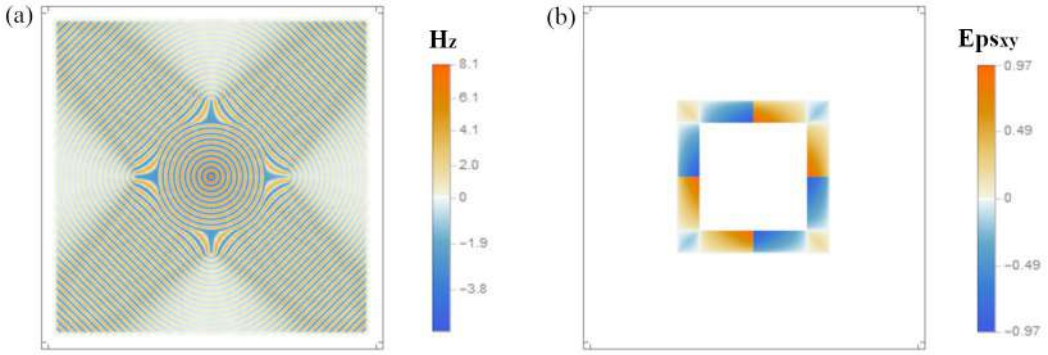

Figure 1. (**a**) Distribution of the magnetic field intensity (**Hz**) generated by a dipole source, transformed into plane waves after passing through a flat optical device. (**b**) Distribution of the *xy* component of the electric permittivity tensor of the transformation optics medium corresponding to the flat optical device.

Abstract: A novel unit cell for broadband microwave absorber is proposed. This polarization insensitive absorber exhibits more than 90% absorption for (8.04 –19.30) GHz, covering X, and Ku bands. The absorption is maintained till incident angle 30° for both TE and TM modes. The absorption remains significant for higher angles, also.

1 Introduction

Microwave absorbers are strengthening their grip among the RF-Microwave research community. With diverse range of applications from strategic to civil domain, they are motivating quality research in the field. The applications range from RCS reduction, EM interference and shielding, clean anechoic chambers, to RF sensors, energy harvestors and solar cells. With increasing use of electromagnetic technologies in day to day lives, the demand for a high functioning low profile microwave absorber has also become significant. Multiple researches have been reported focusing on low profile, high transparency, high robustness, high environmental resilience, and easy fabrication processes.

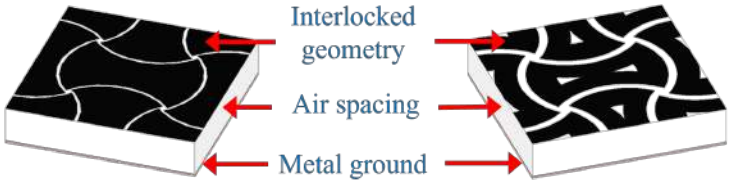

Figure 1: Interlocked unit cell based microwave absorber.

In this work, a novel unit cell is proposed with an improved absorption profile and miniaturized dimensions. This was achieved by fragmenting a patch-based geometry into interlocking tiles. Fragmentation of patch-based geometry gives rise to increased intra unit cell capacitance and helps in achieving the miniaturization of unit cell. Here, two unit cell designs are proposed and studied. One is interlocking loop-based geometry, and the other is interlocking patch-based geometry. Both the proposed absorbers exhibit more than 90% absorption for complete X and Ku band, and partial C and K bands. The proposed designs are insensitive to polarization due to 4∈fold geometrical symmetry of the unit cells. With stable TE mode performance upto 30°, and TM mode performance upto 45°, the proposed structure is reasonably stable against varying incident angle values.

2 Design and Analysis

In the presented work, two unit cell geometries are proposed and studied based on interlocking geometry. A typical absorber unit cell consists of a patterned resistive layer, backed by a thick air spacer and metal ground.

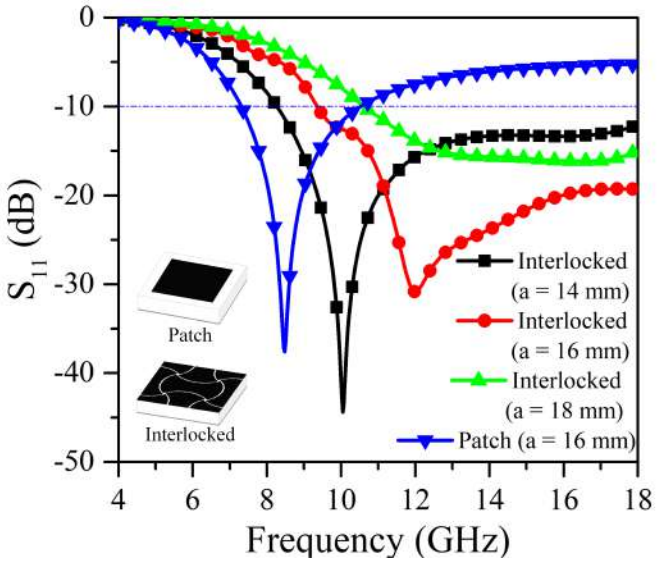

Figure 2: Comparative absorption profile of a resistive patch absorber against fragmented and interlocked geometry.

The design was achieved by fragmenting a square patch into 4 interlocked dumblelike structures. This is reflected and studied in Fig. 2. From the given plot, the two schemes are compared. This was done keeping the thickness, $t = 3mm$, constant for all the schemes. For interlocked schemes, the periodicity is also altered. It is inferred that most optimized performance is achieved for interlocked scheme with period, $a = 16mm$. However, all the interlocked schemes are better in terms of performance against square patch.

Further, two design schemes are proposed based on the interlocking scheme. The first one is interlocked loop-based unit cell geometry and the other one is interlocked patch-based geometry.

3 Conclusion

Wide-band resistive ink based novel absorber for C, X, Ku and K- bands is designed and studied. The possible applications of the proposed structure is in the RCS reduction of the structures where thin absorber profile is required. The proposed absorber is also conformable by the properties of the material choice made for the same.

Abstract: We propose liquid crystal metasurface using split ring resonators for tunable polarization conversion in the terahertz band. The device achieves a polarization conversion ratio ranging from 98.7% to 4.8% and maintains high stability at incident angles from -30° to 30°, making it suitable for various terahertz applications.

Introduction

The polarization of electromagnetic waves is a fundamental property. The manipulation of polarization influences the anti-interference ability and quality of the signal. Conventional methods for terahertz (THz) polarization manipulation are based on natural materials that exhibit optical effects such as birefringence, total internal reflection, or magneto-optical rotation. Metasurfaces-based polarization converters[1,2] can achieve flexible and effective control of THz waves with advantages such as compact size, low profile, and low cost.

In this work, we present a novel device that can dynamically manipulate the polarization state of electromagnetic waves by integrating the liquid crystal layer into the metasurface. Liquid crystal is a tunable dielectric material that can change its orientation under an electric field. The unit cell has a metal-insulator-metal (MIM) structure. The liquid crystal layer is sandwiched between two metallic layers. By applying different voltages to the liquid crystal layer, we can switch the device between two states: the initial state (OFF) and the bias state (ON). The device can achieve a high polarization conversion ratio (PCR) 98.7% and a large modulation depth of 95.1% in the THz band.

Design of unit cell

As is shown in Fig. 1, the two metallic layers are made of 200 nm-thick gold film. The dielectric layer is liquid crystal. The upper metallic layer has a SRR pattern etched on it, and the lower metallic layer serves as the ground plane. The two metallic layers are separated by quartz glass, and the dielectric layer has a liquid crystal with a dielectric constant of 2.49 and a loss tangent of 0.06. The geometric parameters of the device are as follows: R_1 = 165 μm, R_2 = 107 μm, L = 360 μm, t_1 = 445 μm, t_2 = 500 μm, h = 25 μm.

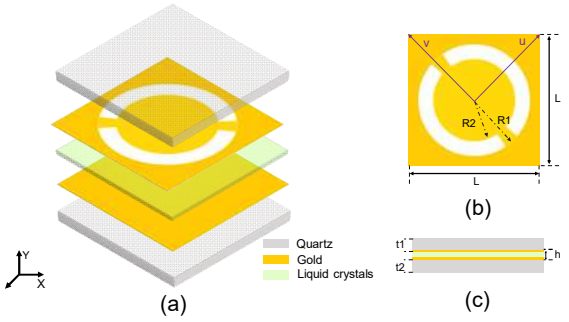

Fig. 1. Schematic of unit cell structure of the proposed tunable polarization converter. (a) 3-D view, (b)top view. (c)side view of the unit cell.

Simulation Results

As shown in Fig. 1b, the structure has a resonant ring with anisotropy, which creates a difference in the resonant frequency points of the electromagnetic waves along the U and V directions. This leads to a resonant phase difference. The MIM structure, filled with liquid crystal, acts as a variable capacitor. By rotating the liquid crystal molecules, the capacitance value of the capacitor changes, which alters the resonant frequency point and produces a tunable phase difference. We combine the ability of metasurface to manipulate electromagnetic waves with the tunable characteristics of the liquid crystal to achieve a tunable polarization converter device.

The reflection coefficient of a metasurface is defined as: $r_{xx} = \left|E^r{}_{xx}\right| / \left|E^i\right|, r_{xy} = \left|E^r{}_{xy}\right| / \left|E^i\right|$, where x and y are the polarization directions, and i and r represent the incident and reflected waves, respectively. The PCR of the converter is defined as $PCR = \frac{r_{xy}{}^2}{r_{xx}{}^2 + r_{xy}{}^2}$.

The device demonstrates broadband polarization conversion and large modulation depth, as shown by the simulation results. The co-polarized and cross-polarized reflection amplitudes in different liquid crystal states are presented in Fig. 2. In the frequency range of 0.380 -0.415 THz, the cross-polarized reflection amplitude is higher than the co-polarized reflection amplitude in the initial state of liquid crystal (OFF), with a maximum value of 0.77 at the center frequency. In the full-bias state of liquid crystal (ON), the cross-polarized reflection amplitude reaches a minimum value of 0.16, indicating that the reflection coefficient is inverted by switching the liquid crystal states. The PCR curve in the figure further illustrates the high modulation performance of the device. At 0.415THz, the PCR amplitude decreases from 98.7% to 4.8% by switching the liquid crystal states, achieving a modulation depth of 95.1%.

Complete asymmetric polarization conversion through zero-eigenvalued exceptional points of non-Hermitian metasurfaces

Abstract: We propose a non-Hermitian metasurface that achieves complete asymmetric polarization conversion at an exceptional point with a zero eigenvalue by introducing gain. Numerical verification confirms this design, which converts right to left circular polarization, blocks the opposite conversion, and eliminates co-polarized transmission.

Non-Hermitian physics provides a unique avenue to reinterpret polarization optics [1-3]. At exceptional points (EPs), the eigenpolarization states merge into a single eigenpolarization, revealing the singular and topological polarization phenomena. To achieve a comprehensive understanding of these phenomena, it's essential to consider both the coalesced eigenpolarization and the eigentransmission. Here, we propose a non-Hermitian metasurface to achieve complete asymmetric polarization conversion (CAPC) at a chiral EP. In this work, the CAPC refers to the phenomenon of conversion from right (or left) to left (or right) circular polarization while blocking the opposite conversion and eliminating co-polarized transmission. The design exploits both zero eigentransmission and a coalesced circular eigenpolarization state at the chiral EP, which highlights an intriguing feature of eigenvalue-dependent polarization phenomena at the EP. Moreover, we demonstrate that the CAPC can enable achieving the highest level of circular dichroism in transmission, even without a three-dimensional helical chiral arrangement.

To verify the CAPC at the chiral EP, we performed a numerical simulation of a non-Hermitian metasurface composed of two orthogonally oriented nano-rod resonators on a gain substrate, designed for near-infrared operation. The resonators are designed to have the same resonance frequency under polarization along their major axes (Fig. 1A). In Fig. 1B, the numerically-extracted eigentransmission is plotted as a function of the input frequency and the imaginary part of the substrate permittivity. The zero-eigentransmission chiral EP gives rise to CAPC, validated by the near-vanishing of all Jones matrix elements except t_{LR} (Fig 1C).

Notably, this CAPC mechanism achieves a maximum circular dichroism in transmission (CDT), as indicated by the value nearing -1. This behavior is qualitatively different from the CDT observed in three-dimensional helical structures, which typically show differences in co-polarized transmission between RCP and LCP

incidence and zero-valued cross-polarized transmission. Furthermore, our planar design exhibits chirality by breaking in-plane mirror symmetry, yielding different responses to circularly polarized light incident from opposite directions. Consequently, asymmetric CAPC is observed, where incident light is converted to LCP for forward propagation and RCP for backward propagation, with the sign of maximal CDT being inverted for forward and backward propagation (Fig. 1D, E).

In conclusion, we propose an approach to achieve CAPC by leveraging a gain-integrated metasurface with zero-eigenvalued chiral EP. Our method numerically substantiates CAPC from a non-Hermitian perspective and provides a novel pathway to achieve asymmetric maximal CDT without the requirement for extrinsic chirality. This non-Hermitian approach opens up new possibilities for polarization optics, offering a powerful way to engineer polarization-dependent light matter interactions.

Singular Flat Band in Metallic Kagomé Lattice

Dongho Lee[1], Hyeon Gi Park[2], Donghak Oh[1], Yung Kim[2], Soojeong Baek[3], and Bumki Min[1,3*]

[1]Department of Physics, Korea Advanced Institute of Science and Technology, Republic of Korea
[2]Department of Physics, University of Ulsan, Republic of Korea

Abstract: Our study focuses on reconstructing the singular flat band structure of a THz metallic Kagomé lattice, analyzing transmission spectra and eigenmodes, and confirming a singularity through quantum distance calculations.

Recent investigations into topological characteristics of quantum systems have increasingly centered on the quantum geometric tensor [1], with particular attention given to its real component, the quantum metric [2]. In this context, singular flat bands—characterized by discontinuous eigenstates at band touching points [3]—have emerged as a compelling platform for probing quantum metric-related phenomena. These bands, previously studied in phononic crystals [4] and waveguide arrays [5], are now gaining traction. Notably, the Kagomé lattice inherently supports such singular flat bands due to its distinct geometric structure [2]. In this study, we extract and investigate the singular flat band structure of a metallic Kagomé lattice, or Kagomé metasurface.

Drawing inspiration from the Kagomé lattice architecture [6], we developed a terahertz (THz) metasurface design (Fig. 1(a)) comprising thin gold disks arranged on a polyimide substrate, interconnected by gold bars. This metallic layer serves a pivotal role in our investigation—not merely as a static framework, but as a dynamic system wherein each disk accumulates an oscillating electric charge under electromagnetic wave excitation, alternating periodically between positive and negative values. To analyze the resulting complex band structure, we employed a coupled oscillator model integrated with the Euler–Lagrange formalism. The governing coupled charge equation is expressed as follows:

$$(\omega/\omega_0)^2\mathbf{q} = (4-\mathbf{A})(1+\kappa\mathbf{A})^{-1}\mathbf{q} \tag{1}$$

where $\mathbf{A}$ denotes the adjacency matrix of the Kagomé lattice in momentum space, $\mathbf{q}$ represents the vector of stored charge amplitudes, and κ is the coupling coefficient. Solving the resulting eigenvalue equation yields a three-band model (Fig. 1(b)), comprising a flat band, a parabolic band, and a lower-energy band. Notably, the parabolic band touches the flat band at the Γ point. The quantum distance of the flat band, measured from the propagation angle of 0°, is calculated as follows:

$$d^2 = 1 - \left|\left\langle q_0^{\mathrm{FB}} \middle| q_\varphi^{\mathrm{FB}} \right\rangle\right|^2 \tag{2}$$

where $\left|q_\varphi^{\mathrm{FB}}\right\rangle$ denotes the flat band eigenstate (Fig. 1(c)). The analytical expression for the quantum distance, derived from Eq. (2), yields a sinusoidal function with a maximum value of 1 and a periodicity of π.

Figure 2(a) presents the transmission spectra as functions of wavenumber and frequency, based on linearly polarized transverse input waves—TE_{00} and TM_{00} modes. Each polarization mode gives rise to distinct resonant frequencies. The combined spectral response reveals the presence of both flat and parabolic bands across all propagation angles. Owing to the C_6 rotational symmetry at the center of the hexagon, the transmission characteristics remain invariant under azimuthal rotation $\varphi \rightarrow \varphi + 60°$. By analyzing the transmission spectra with angular and polarization resolution, the full band structure can be reconstructed.

In summary, we have demonstrated the presence of a singular flat band structure in metallic Kagomé lattices engineered for terahertz-frequency operation. The extracted quantum distance near the singularity approaches unity, highlighting the promise of metallic Kagomé lattices as a viable platform for exploring unconventional phenomena linked to the quantum metric. The eigenstates of flat band can also be reconstructed via transmission intensities measured across six polarization states—horizontal–vertical (HV), diagonal–antidiagonal (DA), and right–left circular (RL) [7]. This enables experimental confirmation of the singular flat band, providing a reliable foundation for subsequent investigations into the system's quantum geometric and topological properties.

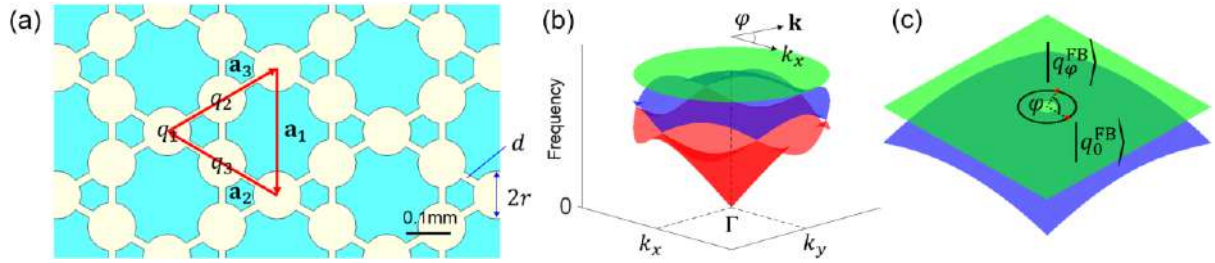

Fig.1. (a) Schematic illustration of the gold Kagomé lattice. The 200nm gold structure is on the 2μm polyimide substrate. $\mathbf{a}_i$ are unit-lattice vectors. Disk radius $r = 55\mu$m, bar width $d = 17\mu$m. (b) Analytical band structure of gold Kagomé lattice. Upper two bands are flat band and parabolic band, degenerating at the Γ point. $\mathbf{k}$ is parallel component of wavenumber of the incident wave, and φ is propagation angle of the incident wave. Design of a metasurface deflector integrated with a grating coupler to collimate a Gaussian beam from an optical fiber for vertical coupling

Suhee Shin[1], Jaewon Jang[1], Minsu Park[1], Yeonsang Park[12*]

[1]Department of Physics, Chungnam National University, Daejeon, Republic of Korea
[2]Institute of Quantum Systems, Chungnam National University, Daejeon, Republic of Korea
[*]corresponding author: yeonsang.park@cnu.ac.kr

Abstract: The light from an optical fiber has a very high divergence angle. We propose a metasurface that collimates the Gaussian beam and at the same time deflects it into a grating coupler. This enables the vertical coupling of the optical fiber and enhances the coupling efficiency.

In photonic integrated circuits (PICs), optical and electrical components are placed on a single substrate, which is called co-packaged optics (CPOs). Since CPOs are constructed on a low-loss substrate and are very compact, transmission power loss and delay time in CPOs can be decreased remarkably. Eventhough their advantages, the dimension of waveguides on the chip and a fiber core are very different in physical scale and therefore an interface structure to connect two components without the coupling loss is required. Since the emergence of metasurfaces, various practical photonic systems with high-performance such as a lens, a polarizer, and a spectrometer etc have been reported based on the advantage of dielectric metasurfaces that can freely control electromagnetic fields at the nanoscale.

Here, we propose an integration of a metasurface, working at 1550 nm, with a grating coupler to increase the coupling efficiency between a photonic integrated chip and an optical fiber. The metasurface collimates the light emitted from the fiber and enables vertical coupling. By executing finite difference time domain(FDTD) solver simultaneously, we found out that the light passing through the grating coupler is transmitted well into the waveguide. We expect that this technology will open new application of metasurfaces and give efficient solution for PICs that require high coupling efficiency between waveguides and optical fibers.

(a) (b)

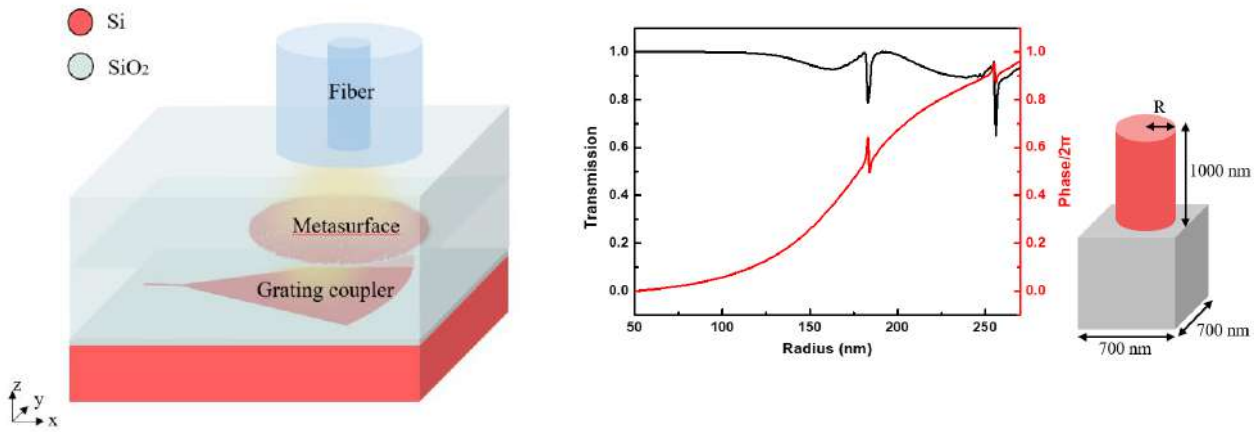

Figure 1. (a) Schematic of the metasurface integrated with a grating coupler. (b) Transmission and phase of the p eriodic Si nano-posts for different radius.

The emitted light beam from single mode optical fiber (SMF) has significant divergence. we used a single-

mode fiber, SMF-28e, manufactured by Thorlabs, which has a divergence of 5.44°, which is almost identical to the divergence of the fundamental Gaussian mode. we design for 1550 nm light with transverse electric field (TE) polarization of the waveguide, i.e., polarized along the y-direction.

We designed the silicon nano-posts with a height of 1000 nm on the SiO_2 background material and substrate, with a lattice constant of 700 nm. We performed the calculation using FDTD method and analyzed the transmission coefficient and phase of silicon nano-posts by varing the unit cell size a from 50 nm to 275 nm.

The phase profile that flattens the Gaussian wavefront is given as

$$\phi(x,y) = -\left[k\left(z + \frac{x^2+y^2}{2R(z)}\right) - \arctan(z/z_R)\right] \quad (1)$$

where z_R is the Rayleigh length and R(z) is the radius of curvature of the Gaussian wavefront and (x, y) is the Cartesian coordinate of the spatial phase profile.

The diffraction angle of the gradient metasurface can be obtained by following the Snell's law,

$$n_t sin\theta_t - n_i sin\theta_i = \frac{\lambda}{2\pi}\frac{d\phi}{dx} \quad (2)$$

Where n_t and n_i are the refractive index of the surrounding medium on the transmitted and incident siedes, in our design $n_t = n_i = 1.44$, θ_t is the deflection angle, θ_i is the incidence angle. According to the information of the well-known grating coupler, when the deflection angle is 9.7°, it is coupled to the grating coupler. The final phase profile of the metasurface can be obtained by linearly combining Equations (1) and (2).

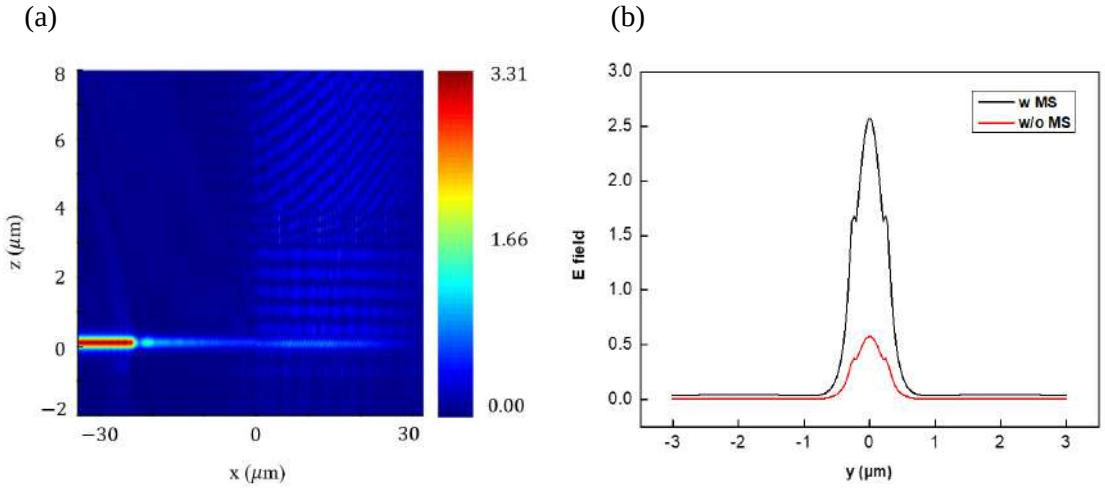

Figure 2. (a) xz-plane field profile showing transmission through the metasurface integrated grating coupler. (b) Waveguide E field magnitude with and without metasurface.

Abstract

We report on spin-decoupled metasurfaces for compact generation of vector beams with non-separable polarization and spatial profiles, enabling three-dimensional light shaping along customizable spirals for applications in optical manipulation and quantum photonics.

Structured light has transformed optical beam shaping, enabling advanced control over phase, polarization, and orbital angular momentum (OAM). However, the generation of non-separable spin–orbit states often relies on bulky and complex optical setups. Metasurfaces overcome these limitations, offering compact, planar devices with full phase and polarization control. Here, we introduce a dual-functional metalens (DFML) paradigm that exploits spin-decoupled design to independently tailor right- and left-handed circular polarizations. This strategy paves the way for compact generation of complex 2D and 3D vector beams with arbitrary polarization structures.

Dual-functional metalenses are well-suited for structured vector beam generation, as they can impart distinct phase delays $e^{i\Phi^{\pm}}$ to orthogonal circular components. [1] A linearly polarized input state can be expressed as$|\vartheta\rangle = \frac{1}{\sqrt{2}}\left(|R\rangle e^{i\vartheta} + |L\rangle e^{-i\vartheta}\right)$ which, after passing through the metasurface, becomes:

$$J|\vartheta\rangle = \frac{1}{\sqrt{2}}\left(e^{i\vartheta}e^{i\Phi^{-}}|L\rangle + e^{-i\vartheta}e^{i\Phi^{+}}|R\rangle\right)$$

This spin-decoupled transformation enables the independent shaping of each polarization component, resulting in vector beams with non-separable spatial and polarization degrees of freedom. By engineering the phase profiles $\Phi^{\pm}$, arbitrary wavefront manipulation is possible. We demonstrate this concept through two representative cases: **3D helico-conical vector beams (HCVBs**, where the polarization pattern follows a spiraling intensity profile and evolves along the propagation axis due to the beam's caustic nature and **azimuthally-variant vector beams (AV-PVBs**, characterized by ring-shaped intensity profiles with spatially varying polarization and tunable phase gradients. 3D helico-conical vector can be obtained by imposing the following phase profiles to the experimental metasurface phase profile:

$$\Phi^{\pm}(r,\theta) = -i\left[a\left(\frac{r-r_0}{R}\right)(m\vartheta+\vartheta_0) \pm n\vartheta - \frac{kr^2}{2f}\right] \tag{1}$$

composed by an helico-conical $(a\left(\frac{r-r_0}{R}\right)(m\vartheta+\vartheta_0))$ and a focusing polarization independent $(-\frac{kr^2}{2f})$ phase terms plus an additional conical-independent but polarization-dependent phase gradient $(\pm n\vartheta)$. To demonstrate the versatility of the dual-functional metalens platform, we also investigated the generation of azimuthally-variant vector beams, characterized by structured polarization and phase profiles varying along a ring. To further enable this, the spin-dependent

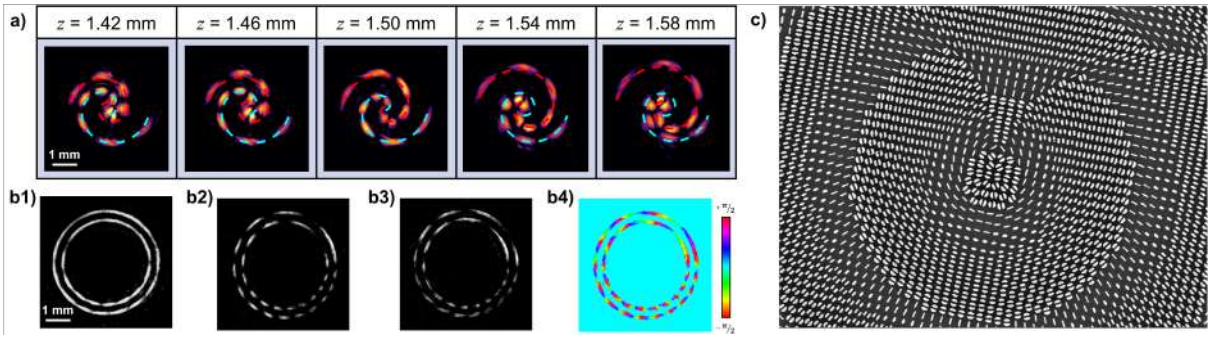

Figure 1: a) Measured double-arm helico-conical vector beam after filtering using a linear polarizer. Both the vectorial and 3D caustic nature are confirmed. b1) Intensity of generated double-ring azimuthally-variant perfect vector beam with linear phase gradient and encoding opposite vector states in the two annuli. Filtered acquisition of AV-PVB using a polarizer rotated by $+\pi/4$ (b2) and $-\pi/4$ (b3) shows both the azimuthally-variant nature of the beam and the different vector states of the annuli. b4) Reconstructed polarization state of the generated AV-PVB; colors refers to the local orientation of the polarization. c) SEM image of a fabricated DFML.

phase term $\Phi_{\pm\ell}$ is generalized to a more complex form $\Phi^{\pm}_{m,\ell_0,\ell_1}$, designed to impart an azimuthally varying phase gradient across the beam cross-section:

$$\Phi^{\pm}_{m,\ell_0,\ell_1}(r,\theta) = -\alpha r - k\sqrt{(r^2+f^2)} - f + \sum_{j=1}^{m}(-1)^{H_C^j}\left[\pm(\ell_0 + H_G^j\ell_1) \pm (-1)^{H_G^j}(\ell_1-\ell_0)\beta(m\cdot\varphi)\right]\varphi \tag{2}$$

where $\varphi \in \left((j-1)\frac{2\pi}{m}, j\frac{2\pi}{m}\right)$, for all $j = 1,\ldots,m$. $-\alpha r$ describes the phase profile associated with an axicon, while $\Phi_{lens} = -k\sqrt{(r^2+f^2)} - f$ provides the geometrically aberration-free focusing phase profile, where f is the focal length and $k = 2\pi/\lambda$ is the wavenumber. In addition, the function $\beta(\cdot)$ introduces a smoothly varying azimuthal phase gradient within each of the m sectors into which the ring is divided where, m defines the azimuthal sectors over the ℓ_0 the background topological charge, ℓ_1 controls the strength of the gradient and H_G^j and H_C^j are Heaviside-like binary functions that control the gradient sign and the local charge inversion within each sector. In both cases, it is possible to generate multiple beams using the same metalens using the phase equalization method. [2] Two DFML were fabricated using electron-beam lithography and inductive-coupled plasma reactive ion etching processes. The optical characterization their output field generating two-arm helico-conical vector beam and double-ring azimuthally-variant vector beams with linear phase gradients are depicted in Figure 1. The reported findings showcase the transformative potential of metasurfaces for generating complex structured light fields, specifically through meticulous design and nanofabrication that offers unprecedented control over the phase and polarization patterns in both two and three dimensions.

Abstract: We demonstrate a compact flat-optics (metasurface) platform for generating and dynamically controlling hybrid grafted vortex beams and azimuthally tailored multispectral OAM combs. By superposing multiple helical phase profiles, beams with precisely customized topological charges and multispectral OAM spectra are achieved, offering new avenues for optical encryption, communications, and particle manipulation.

This work presents a novel metasurface-based approach for generating and controlling hybrid grafted vortex beams (GPVBs) and azimuthally tailored multispectral orbital angular momentum (OAM) combs, addressing key limitations in conventional optical systems. Grafted vortex beams [1], formed by combining multiple helical phase profiles, exhibit unique optical properties and offer promising applications in fields such as singular optics and quantum science. However, current methods for generating GPVBs rely on complex and bulky setups. Our approach utilizes a single metasurface to generate various superpositions of GPVBs with different topological charges, enabling the formation of asymmetric singularity distributions. The design allows the modulation of singularity positions via an initial phase difference, eliminating the need for intricate optical configurations.

In addition, we explore the generation of hybrid perfect vector vortex beams (GPVVBs) [2], which are produced by superimposing grafted vortex beams using a multifunctional metasurface. These hybrid beams have spatially variant polarization characteristics, providing enhanced design flexibility with multiple topological charge combinations. A rotating half-waveplate is introduced to dynamically control the hybrid beams, opening new possibilities for dynamic applications such as optical encryption and dense data communication.

Furthermore, the metasurface platform is extended to create multispectral OAM combs with customized mode spacings, enabling a compact and efficient solution for generating OAM spectra in multiple dimensions, and enhancing information capacity for optical communication and other emerging applications [3].

Abstract

Tamm Plasmon (TP) modes, formed at the plasmonic layer-DBR interface, enable strong light confinement and coupling. This work explores TP modes ability to detect and modulate phenomena at the biotic-antibiotic interface, demonstrating their potential for advanced photonics and biological applications.

Introduction

Tamm Plasmon (TP) modes are a form of Surface Plasmon Resonance (SPR) that can be excited at the interface between a plasmonic layer and a distributed Bragg reflector (DBR). In recent years, interest in TP-based devices has significantly increased due to their unique properties, such as strong confinement of electromagnetic fields and efficient coupling of incident light to localized surface modes. These features make TP devices an ideal platform for the development of novel optoelectronic and photonics applications [1,2]. Previous studies [3] have demonstrated that introducing nanoscale corrugations on the free surface of the plasmonic layer can enable interactions between the confined electromagnetic field and the external interface of the device.

Here, we exploit these capabilities of TP modes to modulate phenomena at the biotic-abiotic interface. So, I discuss the TP-driven enhancement of the phototransduction activity of conjugated polymers at the interface with living cells, enabling photostimulation of biological signaling.

Abstract: We utilize mechanically compliant materials in a nanophotonic resonator designed to trap light at dimensions comparable to gigahertz-scale acoustic displacements. This configuration enables rapid modulation and sculpting of optical fields, paving the way for fast, adaptable metasurfaces poised to advance future photonic technologies.

Mechanical approaches to controlling light remain among the most reliable methods and have been widely employed since optics began. Typically, such methods rely on physically shifting sizable optical parts, which inherently restricts the modulation speed. Reducing the scale of these movable components can help increase their speed. While significant progress in Micro-Electromechanical Systems (MEMS) has been made thanks to modern nanofabrication techniques [1,2], these systems generally cap out at only a few megahertz. Conversely, acoustic waves are among the fastest mechanical modulation schemes, but the small displacements involved have traditionally been insufficient to considerably affect optical fields.

In this work, we introduce a novel nanoscale opto-mechanical resonator that confines light to dimensions comparable to the typical displacements of gigahertz acoustic waves. By using mechanically compliant materials in tandem with an optical plasmon mode, we exploit surface acoustic waves to reshape the amplitude and phase of the optical field. Our results illustrate a notable resonance shift—extending from approximately 700 nm to 600 nm—and confirm modulation rates beyond 1 GHz. Furthermore, by tailoring the excitation profile of these acoustic waves, we achieve dynamic control of optical amplitude and phase distributions across the device surface, enabling beam steering and lensing without large-scale moving parts.

These findings mark a significant breakthrough in the field of acousto-optic modulation by proposing a flexible platform for high-speed modulation and precise manipulation of materials at nanometer and nanosecond scales. By designing mechanical components that match gigahertz acoustic displacements, we open new possibilities for advanced, dynamic optical metasurface technologies.

Abstract: Nanoparticle on a slit (NPoS) is a nanometer cavity for extreme light confinement. In this work we present the simulation and characterization of a NPoS to work in the visible and infrared range with polarization-insensitive fashion for surface enhanced Raman spectroscopy (SERS).

In this work we present a new configuration for surface enhanced Raman spectroscopy with dielectric waveguides. The studied cavity is called nanoparticle on a slit. It is made of three structures, the first one is two patches of gold separated by a narrow slit of 120 nm, on top of the two patches a dielectric layer of a 1 nm thickness of a certain molecule is functionalized. The last part is a gold nanoparticle placed in the middle of the slit. Light is coupled in and out of the cavity by using a silicon nitride slot waveguide with a 200 nm air gap. A microscope image and a scanning electron image (SEM) of the studied structure are shown in Figure 1 b).

For the fabrication process, first, a gold infrared/visible light antenna made of two rectangular slits with 2500 nm length, 100 nm width and 50 nm thickness are deposited by metal evaporation. Then, the gold surface is functionalized with a self-assembled monolayer of Biphenil-4-thiol (BPT) [1], creating a dielectric interface with a nano-meter gap. In the slit between the two gold patches is placed accurately a gold spherical nanoparticle with 150 nm diameter. The nanoparticle is placed using a soft-lithography method. The method consists of using a PDMS stamp with micropillars to transfer the nanoparticle by capillarity onto the slit, as it is shown in Figure 1 a) [2].

Finite-difference time-domain simulations show that both TE and TM can excite the surface plasmon resonance of the nanoantenna at wavelengths around 750 nm. This resonance can be pushed towards the infrared region by changing the length of the strips. Furthermore, simulations show that the localized field in the BPT monolayer between the gold nanoparticle and the slit is perpendicular to the gold surface, independently of the polarization of the excitation mode. So, the excited vibrational states of the BPT molecule will remain the same.

The sample was characterized using a commercial Raman setup at an excitation wavelength of 633 nm. The light is coupled into the waveguide by means of a 50x objective, the incident mode excites the NPoS cavity and the Raman scattering of the BPT is propagated backwards by the slot waveguide and collected by the objective, as it is shown in Figure 1 c). BPT presents three main vibrational resonances related to the chemical bonds of the elements that compose the molecule. That vibrational resonance produces a certain Raman shift at 1090, 1280 and 1580 cm^{-1}, respectively. A typical Raman spectrum of BPT for bulk or Nanoparticle on a mirror (NPoM) cavity is plotted in Figure 1 d). Finally, in Figure 1 e) it is shown the measured Raman scattering of the BPT molecules that comprises the NPoS cavity. It can be noticed in Figure 1 f) that the signal measured for TM is more intense than that for the TE mode caused by the difference in the coupling efficiencies. Even though both

Raman scattering signals have the same order of magnitude, in contrast to other configurations, in which the Raman scattering signal for TE or TM will have different order of magnitude.

Abstract: Subwavelength Gratings (SGs) support Bound States in the Continuum (BICs), enabling high-quality factor resonances. To improve mechanical stability, vertically nonsymmetric SGs (VN-SGs) are formed by placing a GaAs membrane on an AlAs substrate. We demonstrate the first experimental observation of BICs in GaAs-AlAs SG, advancing toward future electrically pumped devices.

Subwavelength gratings (SGs) are periodic structures composed of high-refractive-index grating slabs, surrounded by lower-refractive-index material on both sides. When the material beneath the grating is air, the structure is referred to as a "membrane." In this configuration, it is possible to achieve an infinite quality factor (Q), indicating the presence of bound states in the continuum (BICs) [1]. A similar behavior is observed in vertically symmetric subwavelength gratings (VS-SGs), where the grating is symmetrically embedded in a low-refractive-index material. However, VS-SGs pose fabrication challenges and are mechanically fragile, particularly in the case of membranes.

To enhance mechanical stability, the vertical symmetry of the structure must be broken by placing the membrane onto a solid substrate, forming a vertically nonsymmetric subwavelength grating (VN-SG, Fig. 1). For practical applications, these structures are often envisioned for electrically pumped devices, requiring both high electrical and thermal conductivity of the membrane and substrate. In [2] we demonstrated that despite the low refractive index contrast (as small as Δn=0.04) between the membrane and the substrate, BICs can still emerge in VN-SGs. Furthermore, we showed that in finite structures, the localization of BICs in an infinite system corresponds to local maxima of the quality factor. In a system composed of a GaAs membrane on an AlAs substrate, quality factors on the order of 10^4 were observed in 2D simulations.

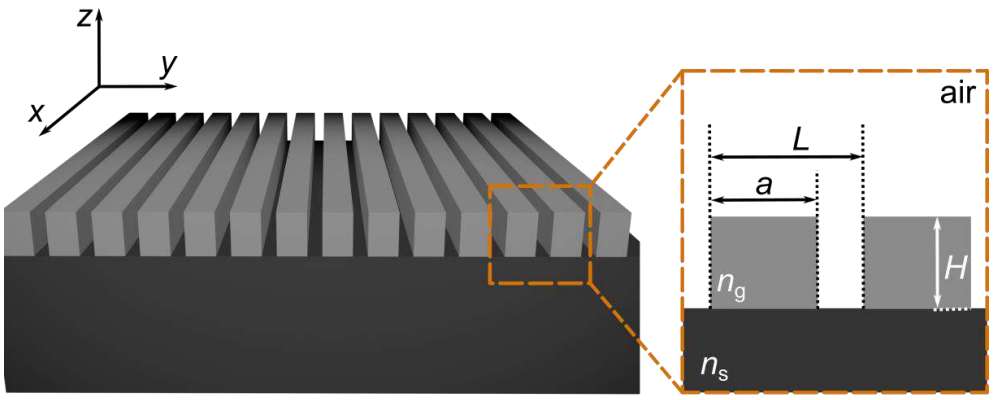

Figure 1. Vertically nonsymmetric subwavelength grating made of high refractive index grating (light gray) and bulky substrate (dark gray) with coordinate system (top panel). Bottom panel presents key parameters of a VN-SG namely refractive index of grating and substrate – n_g and n_s respectively, H – etching depth, a – width of a single stripe, L – period of the grating. In our work we demonstrate results for GaAs grating (n_g=3.52) and AlAs substrate (n_s =2.95).

In this study, we report the first experimental demonstration of BICs in real-world SGs that have been fabricated from GaAs grown on AlAs substrate. This configuration results in a fully monolithic semiconductor subwavelength grating, offering a robust and scalable platform for photonic applications. Our findings provide direct evidence of BIC formation in practical device structures, highlighting their potential for enhancing optical confinement and control in semiconductor-based systems. The successful realization of BICs in these structures represents a significant step toward achieving efficient light emission from SGs. Furthermore, these results open new possibilities for the integration of subwavelength gratings with electrically pumped devices, paving the way for the development of compact and high-performance semiconductor light sources.

Abstract: The latest progress of piezoelectric MEMS tunable multifunctional optical metasurfaces (OMS) for advanced imaging is presented. Switching between different imaging modes can be achieved by varying the MEMS actuation voltages.

Optical metasurfaces (OMS) have emerged as transformative platforms for next-generation compact imaging systems by enabling precise light manipulation at subwavelength scales[1]. Among these, dynamic metasurfaces hold immense potential for realizing intelligent imaging devices with adaptive functionalities, such as tunable focal lengths and steerable focal spots. Recent advances leverage active materials like liquid crystals (LCs)[2] or phase-change materials (PCMs)[3] to achieve reconfigurability, yet fundamental limitations remain. LC-based systems suffer from polarization dependence and slow response times, while PCMs lack reversibility and speed. Conversely, approaches using 2D materials, though faster, exhibit weak modulation strength. To address these challenges, we propose a MEMS-integrated optical metasurface (MEMS-OMS) platform that combines a piezoelectric MEMS mirror with a plasmonic metasurface for dynamic wavefront shaping. Here, building on our developed MEMS-OMS platform, we designed a MEMS tunable bilayer metasurfaces as a varifocal lens operating at 800 nm wavelengths, under circularly polarized incidence.

Our MEMS-OMS design features a bilayer metasurface fabricated on a glass substrate assembled with a piezoelectric MEMS mirror (Fig.1). By applying an actuation voltage, the MEMS actuator induces out-of-plane nanoscale displacement of the mirror, thereby modulating the two-dimensional phase profiles of the reflected light. This tuning mechanism bypasses material limitations due to accessible refractive index changes, resulting in high efficiency and response speeds up to the MHz range. As a proof of concept, we demonstrate a metasurface that can switch the reflected light focusing at two distinct positions (i.e., different focal lengths and lateral shifts) by switching between two voltage sets. These functions are achieved by leveraging the design flexibility offered by the bilayer metasurface, where the displacement of the MEMS driven mirror is directly mapped to a customized phase distribution. Finite-difference time-domain (FDTD) simulations reveal that by switching the MEMS-OMS separation between 350 nm and 500 nm, varifocal lenses are achieved, indicating the distinct wavefront modulation encoded in the reflected light, which validates our design.

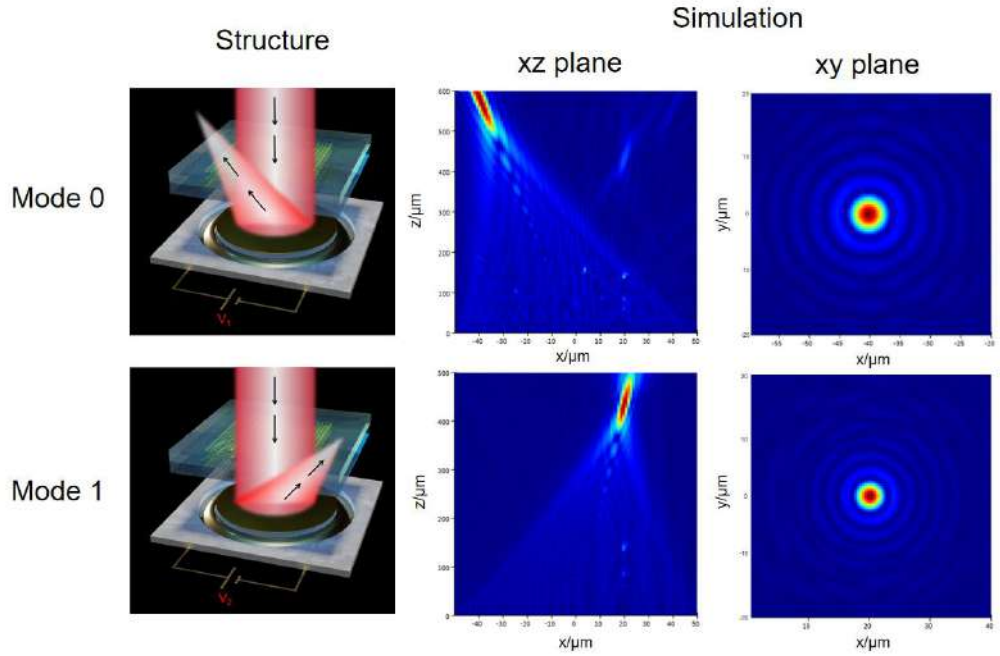

Fig.1 MEMS-OMS varifocal lens.

Looking ahead, this MEMS-OMS platform opens avenues for compact, multifunctional imaging systems. Applications span miniaturized endoscopic probes with adjustable focus, LiDAR systems with dynamically programmable scanning foci, and augmented reality (AR) displays requiring real-time aberration correction. We are also attempting to implement reconfigurable optical computing functions based on this configuration. This work emphasizes the synergistic effects between MEMS and meta-optics, which could potentially serve as a reliable platform for high-performance, adaptive optical systems.

Evolution of Quantum Plasmonics in Relatively Large Doped Quantum Dots

D. Subedi, D. Dada and M. Mochena*
Florida A&M University
Tallahassee, FL, USA
***Corresponding author: mogus.mochena@famu.edu

Abstract: Two model Hamiltonians have been employed to investigate the evolution of plasmonics as a function of the number of electrons confined in a potential well in the first case[1] and a jellium model[2] in the second case. Here, we present results of DFT+U[3,4] as well as TDDFT studies on discrete crystal lattice.

Summary
The evolution of quantum plasmonics has been studied with two model Hamiltonians. In the first case, the conduction electrons are confined within a potential box and their oscillatory behavior was studied as a function of the number of electrons. In the second case, TDDFT study was applied to electrons distributed uniformly through a sphere or on the surface, confined by the jellium positive background charge. The jellium model is argued to apply in the highly doped limit. While these studies establish the evolution of plasmonics, in order to apply the findings, structural dependent studies must be performed to determine what materials manifest strong plasmonic behavior and why they do it. In particular, there are intriguing photodoping experimental results by two groups[5,6] that claim excitations of few electrons can lead to quantum plasmonics. This finding was only addressed at qualitative level in the jellium model by extrapolating the computational results obtained for highly doped QDs for which the jellium model is applicable. The model, however, cannot be justified in the limit of low level of doping where the discreteness of the lattice must be taken into account. Such findings are exciting on their own right from magneto-opics point of view as it is well established in diluted magnetic semiconductors, very few dopants lead to ferromagnetism. Thus, there is a potential to couple plasmonics with magnetism in the low doping limit.

Initially, we performed first principles calculations of density functional theory, with the Hubbard U correction, to see if localized surface plasmonic resonances can be sustained by doping a wide bandgap ZnO with few shallow donors of Ga. We distributed 3–6 dopants approximately uniformly, due to quasi-spherical geometry of the quantum dot, in the dilute doping limit. The uniform distribution of dopants in quantum dots has been reported experimentally. Although the dopant configurations are limited due to computational cost, our findings shed light on absorption trends. Results for quantum dots of 1.4 nm, passivated with pseudo-hydrogens, show that localized surface plasmonic resonances can be generated in the near infrared range. The absorption linewidths for such small-sized quantum dots are broad. We find that the resonance linewidth depends on the orientation of surfaces and the number of secondary peaks on the concentration of dopants. The absorption coefficients, as functions of the principal values of the dielectric tensor, indicate that an electric field with orientation parallel to that of the most symmetric surface will produce localized surface plasmonic resonances with high quality factors.

The broadness of the absorption spectral lines for a small QD led us to look into a larger ZnO QD. There are no studies of quantum plasmonics of large quantum dots of the size of Bohr excitonic radius

or less that take electronic and geometric structure of the quantum dots. In this work, we studied extensively the absorption spectra of a protype quantum dot of sizeable ZnO of approximately 3.0 nm in diameter consisting of 1580 atoms, doped with Ga, and Al in diluted limit with density functional theory (DFT) plus Hubbard corrections (U). The localized surface plasmon resonances (LSPRs) were then determined from the real part of the dielectric function by correlating the negative portion of it to resonant spectral lines. Our results show the sensitivity of the spectral lines to distribution of the dopants, the electronic structure of the dopants, the polarization of the electric field, and size of the quantum dots. Even though our findings are based on stoichiometrically simple ZnO, it shows that the DFT + U method with numerical atomic basis can be used at reasonable computational cost, in contrast to time dependent DFT, to study quantum plasmonics of few electrons taking into account electronic and geometric structures, which is currently missing.

Recently, we have extended our research to include the TDDFT approach to study the whole spectrum of doping and examine the evolution of quantum plasmonics. Our current computations of DFT+U of the 3.0 nm QD was studied with SIESTA code which can handle large QDs of the sizes used in experiments. SIESTA has recently incorporated capabilities to compute TDDFT, as a result we will be able to compare the DFT+U results with DFT + U ones. In addition, we are beginning to work with the Octopus code which is geared to studying TDDFT properties of large systems. The octopus code uses the real space grid to perform the computations unlike the reciprocal space commonly used in most codes. By attacking the quantum plasmonics problem from two different approaches, we hope to gain a comprehensive understanding of the phenomena. We will present our current findings in the talk.

Rainbow Trapping with Graded Triangular Grooves for Enhanced Raman Spectroscopy of Biomolecules

Yi Loh[1]

[1]National University of Singapore, SHINE Centre, Block E6, 5 Engineering Drive 1, Singapore

Abstract: Graded triangular gratings can be used for rainbow trapping biosensors. Wavelength-dependent phase reflection requires precise corrections to groove depths to achieve adiabatic condition. Optimized tapered grooves enable superior multiwavelength trapping and localized field intensities, boosting SERS sensitivity with enhancement factors up to 10^{10} for >10 nm molecules.

Summary: The concept of rainbow trapping, wherein different wavelengths are spatially localized at different positions along the graded structure, can enable broadband hyperspectral amplification of biomolecule model signals[1]. This can achieved by narrow slit grooves of high aspect ratios and graded depth over the grating length, in order to achieve adiabatic condition and field localization as well as multiwavelength trapping, yet the poor access of biomolecules to reach the bottom of these grooves is a major limitation. We show that graded triangular grooves (**Figure 1**) can achieve both adiabaticity[2,3] and sensing of large >10 nm sized molecules. Narrower grooves confine the plasmonic modes more tightly, while deeper grooves support multiple resonant modes.

One of the key findings is the significant influence of groove angle (**Figure 2**). Groove angles ~17.5°, 20°, and 25° were found to be critical in shaping the phase response and confinement characteristics of surface plasmon polaritons (SPPs) within the grooves. These angles determine the effective metal-insulator-metal (MIM) waveguide geometry that the groove forms and thus the propagation constant of the SPPs along the groove depth. The total reflection phase at the groove terminus is not constant in triangular grooves unlike slit grooves, which requires a wavelength-dependent phase shift correction to the groove depth. Theoretical estimations based on fixed parameter often underestimate the actual depth required for accurate resonance. Adjusting the groove depth by 10–20 nm across the visible to near-infrared spectrum brings theoretical predictions into better alignment with simulation and experimental data.

The triangular grooves are especially suitable for label-free biosensing applications. With groove widths on the order of 10 nm, these structures can effectively trap and enhance signals from small biomolecules, including hemoglobin, Rhodamine 6G, and lipid molecules (**Figure 3**). We report SERs enhancement factors as high as 5×10^{9}, which exceed those typically achieved with rectangular or cylindrical groove designs

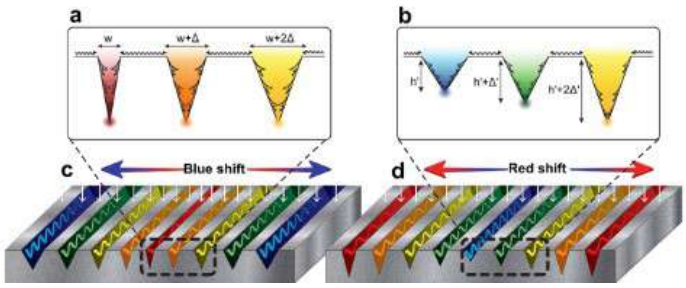

Figure 1. Schematic diagram of graded triangular gratings. (a) and (c) show that width-graded gratings undergo a blue shift, while conversely, (b) and (d) show that a depth graded grating undergoes a red shift. Nano-focusing at the top of the grating and intra-groove coupling are illustrated with arrows.

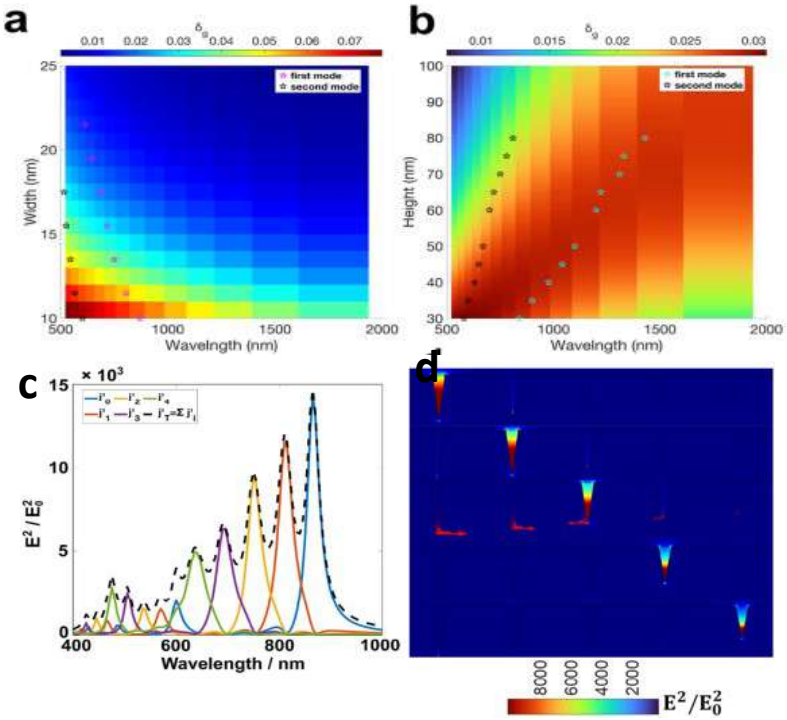

Figure 2. Variation of the adiabatic parameter for (**a**) width-graded gratings where the depth of the central grating is 30 nm, Δ = 5 nm, and w = 10 nm, and (**b**) depth-graded gratings where the width of the central grating is w' = 10 nm, Δ' = 2 nm, and d' = 50 nm. (**c**) Design of graded triangular gratings: localized field intensity inside depth graded grating: j_i, j'_i resembles the i-th groove inside the grating and j_T, j'_T is the total field intensity of all grooves. (**d**) COMSOL simulations of the electric field intensity inside the resonating groove. In addition, the E_x field is plotted with red arrows as an indication of the adiabatic mode transformation.

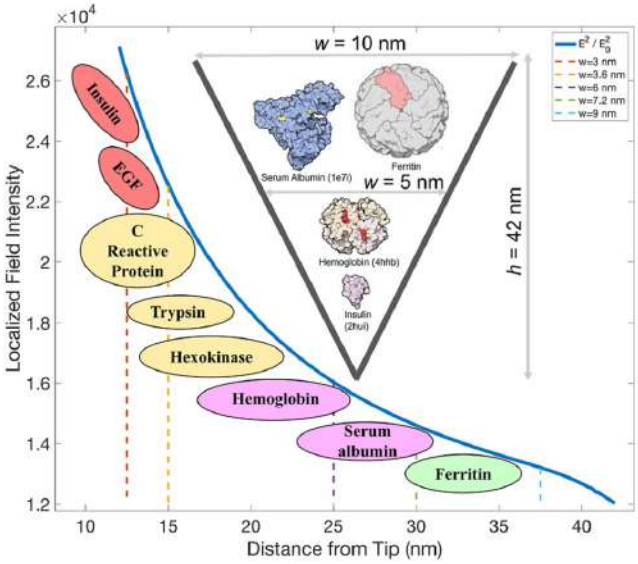

Figure 3. Various small and large bio-molecules fit within the triangular nano-groove with a width of 10 nm and a depth of 42 nm. Molecules smaller than 6 nm, which include hemoglobin, are likely to be detected under a high field greater than 1.5×10^4.

Magnetic field induced shift in LSPR of photochemical synthesized ZnO/Ag nanocomposites

R. A. Redko[1], V. V. Shvalagin[2], G.V. Milenin[1], S.M. Redko[1]

Abstract: The influence of the ZnO nanoparticles magnetic field pre-treatment on the position of the plasmon resonance peak in ZnO/Ag nanocomposites was detected. "Memory effect" during 30 days after magnetic field pre-treatment was observed. Possible physical mechanism related to feromagnetic-like behaviour of ZnO nanoparticles is discussed.

The ethanol solutions of the ZnO nanoparticles were placed in a constant and homogeneous weak magnetic field (B = 60 mT). Exposure time in the field was: 1 hour, 1 day and 5 days. These solutions were used for photocatalytic formation of ZnO/Ag nanoheterostructures under the action of UV irradiation. The production cycle was repeated during 30 days. During this time, the evolution of the obtained optical absorption spectra of solutions containing ZnO/Ag nanoparticles were measured on a Specord 210 spectrophotometer (relative to a cuvette with pure ethanol) and SEM microscopy data. For reliability of the received results the solution which was not exposed in magnetic field, but stored together with all samples at the same temperature conditions was used as a reference. Under the UV action, photocatalytic reduction of Ag (I) and the formation of a ZnO/Ag colloidal heterostructure occurs, which is characterized by an absorption maximum at 400–460 nm.

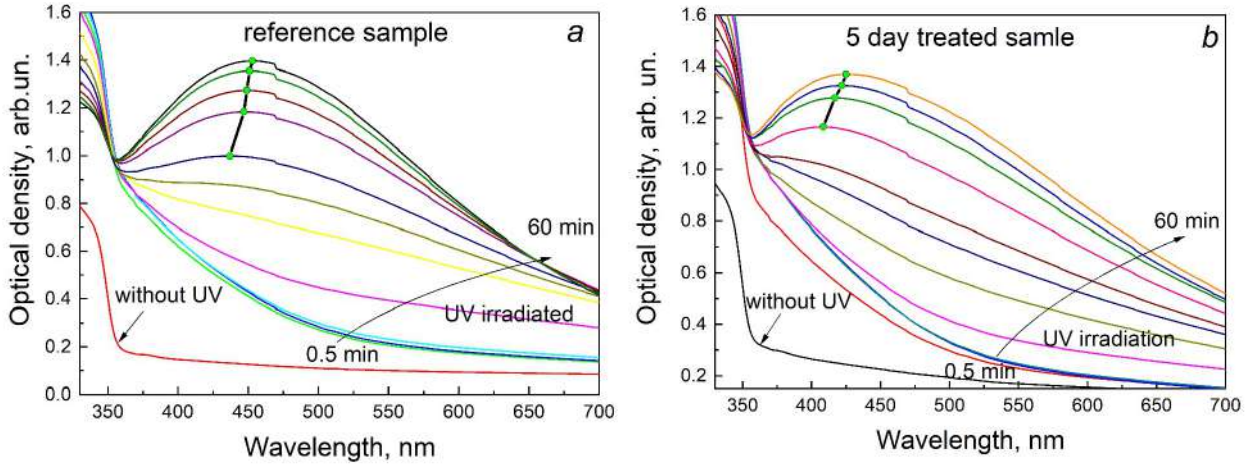

Fig. 1. OD spectra for the reference sample (a) and the pre-treated during 5 days (b) one at different UV radiation doses. The curves labeled ‘without UV’ are obtained for the solutions containing ZnO NPs, silver nitrate and sulfur before UV irradiation.

Moreover, increasing the UV dose leads to a long-wavelength displacement of this peak. These processes are characteristic for all studied samples. But the energy positions of the observed peak at low and maximum doses of weak magnetic field treatment do not match. It was found that within 30 days the final position of the maximum of plasmon absorption of the Ag, which were formed on ZnO cores, that have been undergone magnetic field treatment, slowly shifts to the position of the latter in the reference sample. The latter

circumstance indicates a "memory effect" that lasts for a month.

Ferromagnetic-like behavior of ZnO nanostructures was observed earlier [1, 2]. Not only for nanoparticles [3] but also for nanoflowers [4] and nanoroads [5]. So, physical mechanism of observed modification based on the fact, that a ZnO nanoparticle has a non-zero magnetic moment even without external field owing to the surface states formed by dangling bonds. This is not classical ferromagnetism of course. This moment appears due to oxygen vacancies present. Photoluminescence spectra testify about a lot of them – the broad intensity band near 500 nm, which usually related to V_O, was observed. The behavior of such nanoparticle is similar to the behavior of a ferromagnet in an external magnetic field. In other words, a ZnO nanoparticle will orient itself so to arrange its magnetic moment along the induction of the external field. Longer exposure of particle ensembles in the magnetic field will obviously orient more particles' magnetic moments. This can explain the observed shift of the plasmon absorption maximum, which was proportional to the duration of the magnetic field exposure of the solutions of ZnO nanoparticles in ethanol. The long-term effect observed during 30 days is most likely related to the thermal disordering of the system of "magnetized" ZnO nanoparticles, i.e. due to the thermal motion of atoms and molecules, the studied nanoparticles returned to their initial non-magnetized state.

The shift of SPR peak due to magnetic field influent was observer earlier [6, 7]. Authors relates observed features with the changes of refractive index of studied NPs due to the magnetization. Thus, we have tended to assume that in our case due to magnetization of ZnO NPs the refractive index of the near-surface region of ZnO has changed or/and the shape of ZnO/Ag nanocomposites may be changed due to this too. And all of these result in observed changes in LSPR of ZnO/Ag nanocomposites. The modeling with MiePlot 4.16 Software confirms principal possibility of this assumption

Regardless of the physical reasons and mechanisms of the observed phenomenon, MF pre-treatment may be used as an effective tool for manipulation of plasmon properties of silver-based nanoparticles, which is perspective for creation of new-generation sensor systems.

Abstract: This work introduces the sequential deposition method for Ag-NPs on a silicon ripple substrate. This method enables the formation of nearly spherical NPs and prevents LSPR anisotropy. The concept is validated through detailed FDTD simulations, experiments, and SERS analysis, demonstrating its effectiveness in enhancing signal uniformity and intensity.

Surface-Enhanced Raman Spectroscopy (SERS) is a highly effective technique for detecting trace amounts of various molecules, finding applications in diagnostics, food safety, forensics, and more [1,2]. For SERS applications, optically isotropic arrays of metal nanoparticles (NPs) are crucial for achieving strong near-field coupling. One way to create such arrays involves low-energy ion beam sputtering (a bottom-up approach), which leads to the formation of regular ripple structures on the surface. These ripple patterns can be tailored by adjusting parameters like ion beam energy, incidence angle, and ion fluence [3], followed by the growth of metal NPs. However, the asymmetric ridges of these ripple patterns often lead to uniaxial growth [4], causing atoms to preferentially align along the ripples and resulting in elongated NP formation over time. In this study, silicon ripples with a typical wavelength of ~30 nm are used as a template as seen in Fig. 1(i). While these types of arrays (Fig. 1(ii)) often result in optically anisotropic substrates and their anisotropic SERS responses. For the first time, we employ the method of sequential deposition of silver (Ag)-NPs to produce isotropic SERS substrates as illustrated in Fig. 1(iii). This sequential deposition provides significant flexibility in fine-tuning the sphericity of the NPs while minimizing the anisotropy present in the sample.

At first, we performed the FDTD simulation to optimize the size and gap of our NP arrays to get optimized field enhancement. The key findings of the simulations are as follows: (i) As the gap (along the ripple 'd') increases, plasmonic coupling weakens, leading to a decrease in electric field enhancement. (ii) The interplay between the gap and aspect ratio significantly influences the shift in the Localized Surface Plasmon Resonance (LSPR) peak and field enhancement. (iii) Notably, when the aspect ratio satisfies 'a = b,' nearly spherical NPs form, ensuring uniform field enhancement along and across the ripple, as shown in Fig. 1(iv)-(vi).

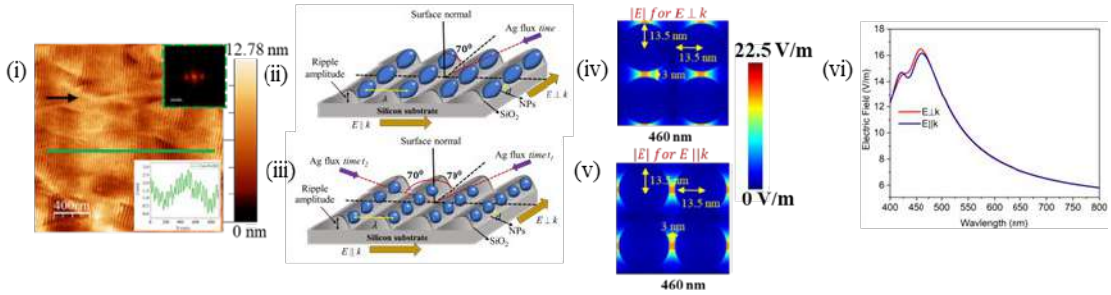

Fig.1 (i) AFM image of ripple pattern on silicon substrate with periodicity of ~ 30 nm. (ii) Schematic illustration of ripple formation on a silicon ripple, from single side deposition of Ag-NPs at an oblique angle of 70, and (iii)

Sequential deposition method for time t_1 and t_2. Electric field distribution for a particular frequency around the NPs using FDTD simulation for, (iv) E⊥k (v) E||k. (vi) Electric field vs wavelength spectra obtained for 'a'= 'b' with 'd' = 3 nm [5].

Four this study four samples were prepared: Ag-NPs deposited continuously for 60 min perpendicular to the ripple pattern (Ag_60_in) from one side and 60 min opposite to it (Ag_60_opp). Both these led to ellipsoidal NPs due to uniaxial growth (Fig. 2(i) and (iii)), causing elongation along the ripple. To avoid this uniaxial growth the novel concept of sequential deposition is employed where the Ag-NPs deposited 30 min from the direction beam and rotated the sample to deposit further 30 min from the opposite side (Ag_30+30_in) and vice versa (Ag_30+30_opp) as shown in Fig. 2(ii) and (iv). This resulted in nearly spherical NPs, with the aspect ratio decreasing from 1.69 (Ag_60_opp) to 1.24 (Ag_30+30_in). To investigate the LSPR anisotropy in the sample, reflection spectra measurements were carried out using the ellipsometry. For sample Ag_30+30_opp the shift in LSPR is decreases by 54 nm as shown in Fig. 3(i) leads to anisotropy minimization as compare to 209 nm for 60 min case. Furthermore, the effectiveness of this approach in SERS applications was validated using Crystal Violet (CV) dye at a concentration of 10^{-6} M. This sample exhibited the highest intensity while minimizing intensity variations across the substrate, rendering it nearly isotropic (Fig. 3(ii)).

This study demonstrates that the sequential deposition of Ag-NPs on silicon ripples facilitates the formation of low-aspect-ratio (almost spherical) NPs without requiring annealing, which would otherwise increase interparticle gaps via the Ostwald ripening process. The minimized LSPR shift and uniform SERS enhancement across the sample confirm the isotropic nature of the deposited NPs while preserving their regularity.

Abstract: This paper focuses on the surface plasmon polaritons potential at noble metals interface for enhancing chiroptical sensing of dilute chiral drug solutions. Circular dichroism is amplified by plasmonic resonances in a nano-scale drug volumes, showing relevant results for sensitive analysis of solvated reparixin, enabling advanced chiroptical sensor development.

Chiral sensing plays a key role in the pharmaceutics because the specific enantiomeric form of drugs affects their functionality and toxicity [1]. In this study, we explore the potential of surface plasmon polaritons at noble metal interfaces for surface-enhanced chiroptical sensing of dilute chiral drug solutions with nanoliter volumes. Such techniques are compatible with real-time analysis, lab-on-a-chip integration and wider nanomedicine applications. Here we focus on isotropic assemblies of reparixin (adopted as an inhibitor of the CXCR2 function, attenuating inflammatory responses for the treatment of hospitalized patients with COVID-19 pneumonia) solvated in water with dilute number molecular density $n_{mol} = n_{mol}^{(R)} + n_{mol}^{(S)} \approx 10^{-2}\text{nm}^{-3}$, where the number densities of R and S enantiomers are represented by $n_{mol}^{(R,S)}$. Our results are based on quantum chemical calculations adopting a hybrid computational approach that integrates Molecular Dynamics, time-dependent Density Functional Theory, and the Perturbed Matrix Method. [2]. The interactions between radiation and matter are analyzed from first principles using the density matrix formalism. The macroscopic optical parameters, such as dielectric permittivity, magnetic permeability, and chiral parameters of the dilute drug solution, are determined by perturbatively solving the density matrix equations within the dipole approximation. We evaluated the plasmon-enhanced circular dichroism differential absorption (CDDA) [3] in both the Otto and Kretschmann configurations.We attain a CDDA enhancement by a factor of ≈ 20 for silver metal substrate in the Otto configuration. In turn, by measuring the CDDA we can retrieve the enantiomeric imbalance in the drug solution. Our findings are relevant for the development of innovative chiroptical sensors capable of measuring the enantiomeric imbalance of nl volume chiral drug solutions.

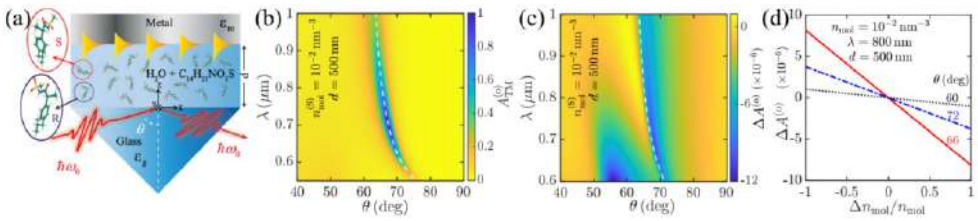

Fig. 1 (a) Schematic representation of plasmon-enhanced CD in the Otto configuration. The considered chiral sample is a solution of S and R reparixin enantiomers dissolved in water with molecular density n_{mol}. [(b) and (c)] Dependence of (b) TM absorbance $A_{TM}^{(o)}(\theta, \lambda)$ (for TM linear polarization excitation) and (c) CDDA $\Delta A^{(o)}(\theta, \lambda) = A_R(\theta, \lambda) - A_L(\theta, \lambda)$ (for circular polarization excitations) over the vacuum wavelength λ and the angle of incidence θ of the impinging radiation .The plots refer to a pure S reparixin enantiomer dissolved in water. (d) Dependence of CDDA over the enantiomeric number density imbalance $\Delta n_{mol} = n_{mol}^{(S)} - n_{mol}^{(R)}$ for several distinct incidence angles θ and fixed excitation vacuum wavelength λ = 800 nm. The dashed white curves in [(b) and (c)] indicate the SPP dispersion relation.

Multiphysics Calculation of Plasmonic Photothermal Effects in Gold Nanorod Dimers: Influence of Size Mismatch

T. Zhou[1], M. V. Balois-Oguchi[1], and K. Kajikawa[1*]
[1]School of Engineering, Institute of Science Tokyo, Japan
kajikawa@ee.e.titech.ac.jp

Abstract

This study investigates the optical and photothermal behavior of gold nanorod dimers using finite element method. Our findings highlight the anti-correlation between near-field enhancement and photothermal efficiency resulting from size mismatch in gold nanorod dimers, providing valuable insights for optimizing the nanostructure design in plasmonic applications.

1 Introduction

Over the last decades, gold nanoparticles (GNPs) have greatly attracted interest in nanoscience due to their remarkable localized surface plasmonic resonance. The collective oscillation of free electrons in metals leads to intense light absorption and scattering as well as impressive near-field enhancement, which triggered many applications, such as biosensing, surface-enhanced Raman spectroscopy (SERS) and plasmon-enhanced second harmonic generation (SHG) [1]. Moreover, losses in the metal and the associated energy conversion from light to heat should also be a concern. On one hand, GNPs, serving as nanoscale heat sources, exhibit great potential in nanomedicine, such as plasmonic photothermal therapy, drug delivery and photothermal imaging. On the other hand, study of the heat transfer inside and around GNPs can help better understand the origin of the experimental observations in photonic applications [2].

In our research, the plasmonic optical and associated thermal responses of gold nanorod dimers (GNDs) in water under laser illumination are simultaneously investigated by employing multi-physics modeling via the finite element method (FEM). Our results highlight the anti-correlation between the light-to-heat energy conversion efficiency and local field enhancement when breaking the length asymmetry in GNDs.

2 Simulation Model

Computational models of GNDs were built and calculated using the FEM simulation software COMSOL Multiphysics (COMSOL). The study primarily focuses on gold nanorod monomers and dimers in water, as shown in Figure 1a. Each nanorod is 20 nm in diameter, and the total length is 41 nm. In the dimer structures, the interparticle gap is fixed at 1 nm, while the shorter rod length varies from 5 nm to 20 nm. The laser spot size is sufficiently large to ensure homogeneous illumination of the nanoparticles.

3 Results and Discussion

Figure 1b illustrates the absorption efficiency as a function of wavelength. The single nanorod (41 nm) exhibits the highest absorption peak at approximately 660 nm. For hetero-dimers, as the length of the shorter rod L_2 increases and the longer rod L_1 decreases, the absorption peak exhibits a blue shift and damped intensity. When the two rods in GNDs are of equal length

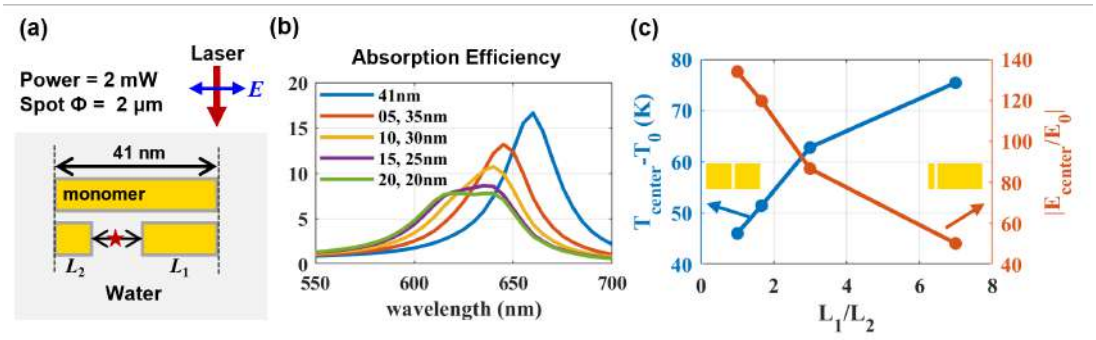

Figure 1: (a). Schematic of the gold nanorod monomer and dimers. The red star marks the gap center. (b). Absorption efficiency spectra of monomer and dimers with 1 nm gap. (c). Comparison of temperature rise (blue curve, left axis) and the local electric field enhancement (orange curve, right axis) at the gap center of GNDs excited by light of the LSPR wavelengths (i.e., peak wavelengths in (b)) as a function of length ratio.

(20, 20 nm), the absorption peak is the lowest, accompanied by a further blue shift and spectral broadening. The absorbed laser energy is converted into heat within the gold nanorods and subsequently dissipates into the surrounding water until thermal equilibrium is reached. The left axis of figure 1c presents the steady-state temperature at the gap center (marked by red star in figure 1a) between nanorods. Interestingly, the electromagnetic field enhancement at the same position (right axis of figure 1c) exhibits an inverse correlation with the temperature rise.

The anti-correlation in our findings can find its origin in the asymmetric energy distribution caused by size mismatch [3]. When the electron oscillation in each individual perfectly matches that of the other, the charges of equal magnitude and opposite sign on the facing faces can 'lock' electromagnetic energy within the gap. In contrast, length mismatch slows down the overall oscillation and drives the electromagnetic energy from one side to the other, so that the photons that cannot be 'locked' in the gap are absorbed and converted into heat within the metal .

Although the absorption and scattering are closely related to hot spots in GNPs, in techniques such as SERS and SHG, when we only concern the local field and temperature of certain hot spots, the extinction properties might mislead the design of GNPs. According to our findings, we propose gold nanorod homodimers as candidates for near-field optical applications, while size-mismached heterodimers can serve as nanoheat sources and highly sensitive biosensors.

Abstract: We create self-organized, re-writable, laser-induced periodic surface structures in single-crystalline vanadium dioxide. We discover anisotropic features from canalized surface plasmon polaritons that can only propagate along one crystal axis. All nanostructures remain mostly single-crystalline and preserve the material's sharp metal-to-insulator transition, enabling femtosecond switching by temperature or light.

Vanadium dioxide (VO_2) is a strongly correlated material with a first-order phase transition that changes the crystal structure from monoclinic to rutile at a temperature of $T_{trans} \approx 68^\circ$ C. At the same temperature, the material also switches from insulator to metal and its resistivity decreases by a factor of $>10^3$. The material is therefore a highly promising candidate for controllable and switchable nanophotonic devices and metamaterials. However, the fabrication of nanostructures of VO_2 is currently limited in size and quantity.

Here we investigate whether laser-induced periodic surface structures (LIPSS) can be induced in VO_2. Similar structures on other materials have found various applications in optics, structural coloring, friction reduction, dewetting or antibacterial surfaces, among many others [1]. We use large single crystals of VO_2 grown via liquid-flow crystallization [2] and hit their optically flat surface with ultrashort (300 fs) pulses of linearly polarized laser light with a center wavelength of 1030 nm. At high fluences this allows to produce periodic patterns orthogonal to the laser polarization (see Fig. 1a-d), that can be overwritten by exposure to laser light of other polarizations (Fig. 1e).

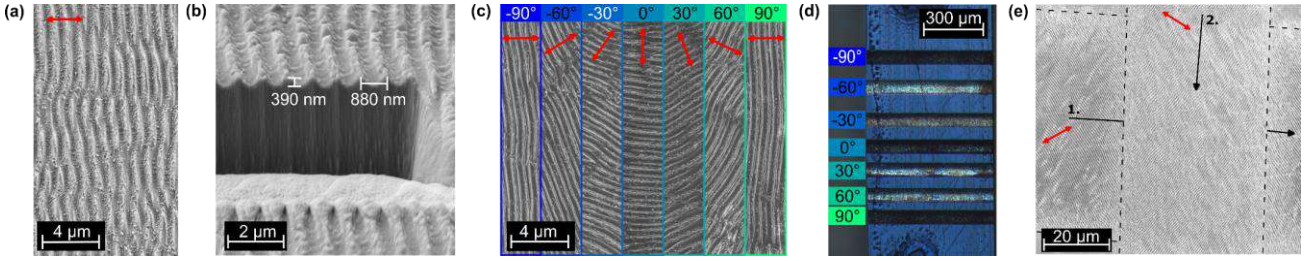

Fig. 1. Laser-induced surface structures on a VO_2 single crystal. (a) SEM image of the written structures in VO_2, writing fluence 400 mJ/cm^2 **(b)** SEM image of a cut with a focused ion beam through one of the structures. The grooves have a depth of ~390 nm and a periodicity of ~880 nm. **(c)** SEM images of the grooves for different laser polarizations (red). The grooves show a perpendicular orientation to the polarization of the incident light. **(d)** Cross-polarized light microscopy image of the structures for different laser polarizations. The wavelength-dependency of the optical response is evident by the different colors of the individual experiments. **(e)** Re-writing of LIPSS. A first laser (1) writes with ~30° polarization and then a second laser (2) writes at ~150°. The SEM image shows the results.

However, at lower fluences, another feature appears; a subharmonic pattern, that is oriented independently of the laser polarization.

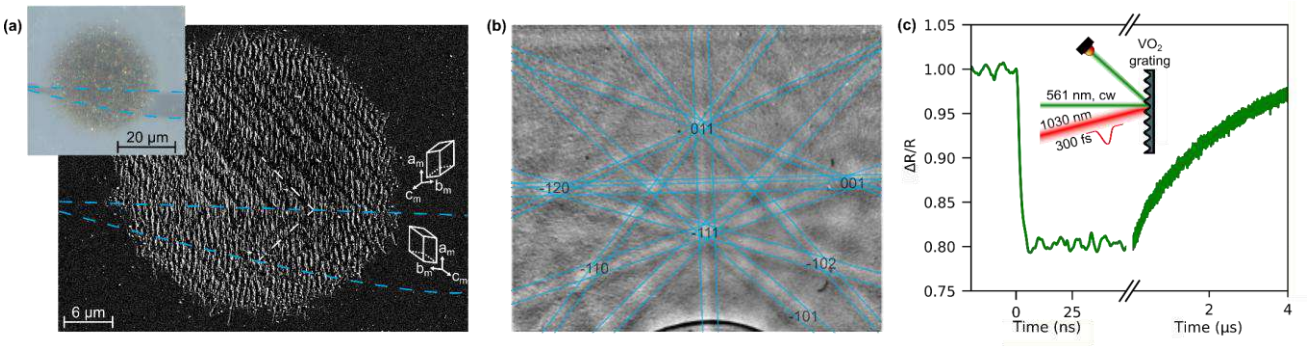

Fig. 2. Canalized light couples the ripple formation to the crystal structure. (a) Subharmonic structures with different directions (dashed white lines). The microscope image taken with crossed polarizers (inset) confirms that the different patterns belong to different crystal orientations (separated by dashed blue lines). **(b)** Electron back-scatter diffraction analysis proves the single-crystallinity of written structure and further confirms this coupling. **(c)** We pump our regular periodic surface structure with an ultrafast laser and observe the time-dependent refracted intensity of a green continuous wave laser with a fast diode. We see that the grating switches with approx. 2 ns, limited by the speed of the diode.

The low-temperature phase of VO_2 has a lower symmetry than the high-temperature phase. Therefore, some of our crystals exhibit rich domain structures that can be distinguished using polarized optical microscopy (insets in Fig. 3a). We now write the subharmonic structure on a domain boundary and see that the structures orient differently dependent on the orientation of the low temperature phase (Fig. 3a). Electron backscatter diffraction (Fig. 3b) identifies this orientation as orthogonal to the c_m-axis of the monoclinic low temperature phase. This points to the mechanism behind this crystal-coupled feature. In the low temperature phase, the dielectric constant of VO_2 is highly anisotropic [3] allowing the formation of surface plasmon polaritons only in the direction along cm, which leads to the formation of the anisotropic feature. At higher fluences, the material transforms into the nearly isotropic metallic state, where the patterns become dependent on the laser polarization.

Figure 2c shows how our written structures can be used as an ultrafast switchable diffraction grating. The single-crystallinity of the material is maintained during the nanostructuring process and allows for sharp hysteresis and femtosecond modulation of the refracted light.

Our results show that laser-induced surface structures in single-crystalline and anisotropic media can be generated with a large variety of geometries by utilizing and optimizing the transient femtosecond properties of photo-doped materials. The tools of femtosecond laser science in combination with correlated solid-state materials can therefore be used to create laser-induced nanostructures at unprecedented complexity. In turn, measurements of fabricated structures can provide insight into the underlying optical dynamics of surface plasmon polaritons or canalized light, time-frozen into the solid material. For applications, single-crystalline laser-induced surface structures with adjustable periodicity along polarization-controlled or crystallographic directions may therefore become a useful tool for producing active metamaterials on macroscopic scales.

Abstract: Nanophotonic structures have been extensively used for realizing custom tailored flat optical elements. Amongst the various investigated structures, anisotropic gold nanoparticles have been a popular choice for different optical applications due to their aspect ratio dependent resonance. In this study, we demonstrate ultra-wide tunability via thermally driven shape change in highly anisotropic gold nano bipyramids. Using localized patterned heating of bipyramid substrates, we fabricate various patterns using these substrates with a tunable optical response (both reflectivity and transmission). Correlative microscopy, including in-situ TEM and in-situ optical spectroscopy with an integrated heating platform, is used to track the real-time changes in the optical response due to heating. Numerical modelling is also carried out to understand the far-field response and the underlying changes in the near-field of the bipyramid assemblies. These tunable substrates can potentially be used for designer ultra-thin optical filters for various applications.

1. Introduction

Anisotropic plasmonic nanoparticles are crucial components in making substrates for different applications [1, 2, 3]. The shape anisotropy and the size of the particles enables us to tune the resonance wavelength through a large spectral range. However, once the structures are prepared, it is quite difficult to tune or modify the resonance unless the structures are integrated with an active tuning medium [3]. Note that tunability of the resonance is beneficial for achieving the best performance from these structures when employed for a specific application. Amongst all the anisotropic particles, gold bipyramids and gold nanorods have emerged as the most popular candidates in terms of their spectral tunability right from the UV to the mid-IR range. From a near-field enhancement perspective, gold bipyramids typically exhibit a higher net near-field enhancement due to its smaller radius of curvature as compared to nanorods. In this study, we have developed thermally tunable plasmonic substrates based on self-assembled anisotropic gold bipyramids. *In-situ* reflection studies on substrates coated with anisotropic AuNPs give us a better understanding of shape change with a change in temperature [4]. This study opens a scope of easily controlling the fabrication of tunable substrates and optical filters for different applications [5]. By heating the substrates locally, we can prepare substrates with different LSPRs at different locations. This helps us to develop patterns or circuits with different LSPRs on the same substrate.

2. Methods

2.1. Synthesis of gold bipyramids

The synthesis of gold nano bipyramid (AuNBP) particles was carried out using a two-step seed-mediated growth method. A modified version of the method used by Li *et al.* [3] was employed for the synthesis. Briefly, in the first step, very small penta-twined nanoparticles (~5 nm) were synthesized by the rapid addition of NaBH4 to a

solution of $HAuCl_4$ and CTAB/CTAC. In the second step, this seed was injected into a growth solution (mention growth solution here) and stirred for 2 hours to achieve penta-twined AuNBP particles.

2.2 Self-assembled AuNBP substrates

Clean glass coverslips were functionalized by immersing them in a polyelectrolyte (PE) solution. In this method, the clean glass coverslip was first dipped in 1M NaCl solution for one minute and then transferred to 1M Poly-allylamine hydrochloride (PAH) solution for 10 minutes. The glass coverslips were then transferred to 1M NaCl solution for one minute, followed by 10 minutes in 1M Poly-4-styrene sulfonic acid (PSS) solution. This process was repeated in a cycle until five alternate layers of PSS and PAH were coated with PSS as the top layer. PSS was negatively charged and helped fix the positively charged AuNBPs on the glass coverslip surface. The AuNBP particles were purified and mixed with 1 M NaCl for a higher concentration of particles on the substrate surface. The PE-coated glass coverslips were then immersed in the AuNBPs solution and kept undisturbed for 4 hours. After 4 hrs, the substrate was gently washed with DI water and kept for drying at room temperature.

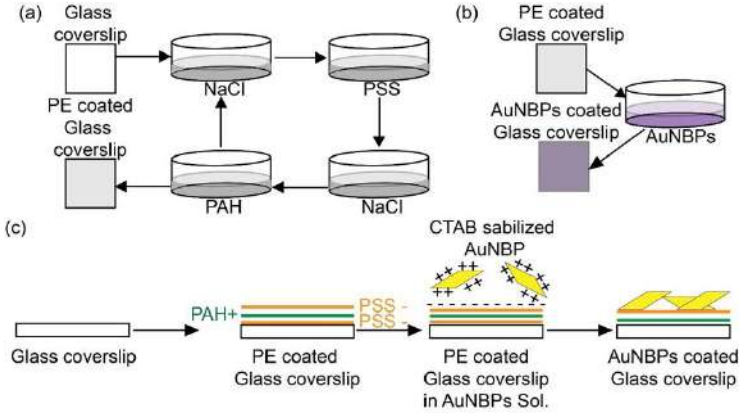

Figure 1. Schematics of substrate preparation. **(a)** Functionalization of glass coverslips by dipping in PE solutions of different surface charges. **(b)** Coating of these surface functionalized substrates in AuNBP solution. **(c)** Surface charge distribution and immobilization of AuNBPs on the surface.

3. Results and discussion

The synthesized AuNBP particles exhibit a resonance at around 800 nm. On heating the substrates to temperatures ranging from 200ºC to 400ºC, the substrate exhibit a strong color change from gray to purple and correspondingly, the resonance wavelength changes from around 800 nm to 550 nm. This is due to the change in the particle shape from anisotropic bipyramids to near-hemispherical nanoparticles. Subsequently, we patterned the self-assembled substrate through localized heating. The AuNBP substrate is placed over to copper plates which are placed on the heating stage. On heating, the substrate in contact with the copper strip exhibits a larger change in color due to larger temperature assisted shape change.

A major color change was observed at the area which was in contact with the copper plate figure 2(b). A significant shift of spectrum is observed on performing scanning of the substrate, showing a clear spectral difference between the region of contact and the surroundings, as shown in Figure 2(c). Figure 2(e) shows the collected spectrum from the contact region and two other regions near and far from the area of contact, as marked in Figure 2(b). figure 2(d) shows the corresponding SEM image of the marked region. The area 2 which was in contact with copper plate shows most particles turned spherical whereas area 1 which is far from the area of contact shows long bipyramid shaped particles. Figure 2(f) shows the particle aspect ratio distribution of

the three points, and we see that the aspect ratio at point 2 is nearly 1 whereas that of point 1 is about 1.5. This data proves the shape change is related to the color change, and it can be done locally.

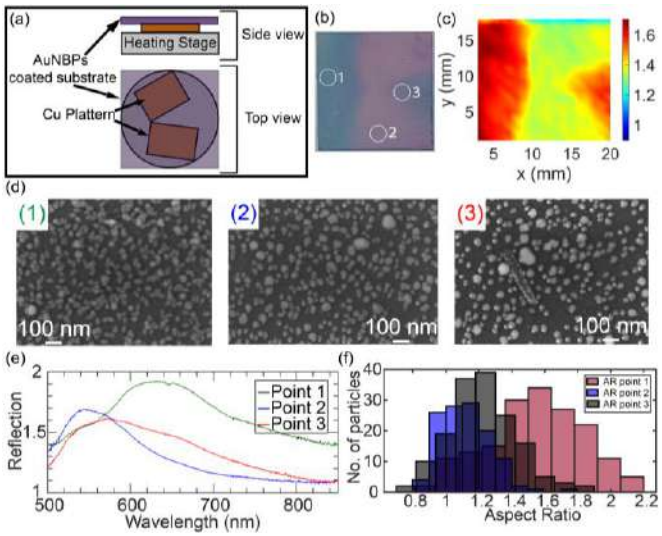

Figure 2 (a) Schematics of heating AuNBP substrates for developing patterns. (b) Shows the substrate with the pattern. (c) Spectral mapping of the substrate showing change in spectra in heated and unheated area. (d) SEM image of different points on the substrate which are exposed to different heating temperatures. (e) Shows the spectrum at the corresponding points. (f) Shows the particle aspect ratio distribution at these corresponding points.

Conclusions

In the current *in-situ* study, thermally driven resonance tuning in AuNBP substrates provides us with an facile approach for tuning the optical response of these structures. The heating temperature, holding time and nature of heating affect the shape change associated resonance shifts. This resonance shift is very large upto the tune of 300 nm when operating in the visible spectral domain. The *in-situ* studies enables us to track the realtime changes in the absorbance spectrum and lets us tailor these process more accurately. NThis setup helps gain a thorough understanding of the effect of rate heating required to achieve the desired change. We observe that the major changes occur during the heating cycle at 200ºC and 300ºC. Using simple parterning technique, we are able to realize patterns in the self-assembled gold-bypyramid samples. In future, this study can assist in the development of substrates with desired optical responses and structures.

Thermal radiation forces on nanostructures with reduced symmetry

J. R. Deop-Ruano[1*], A. Manjavacas[1]

[1]Instituto de Química-Física "Blas Cabrera" (IQF-CSIC), Spain
[*]corresponding author: juan.deop@csic.es

Abstract: The fluctuations of the electromagnetic field produce a drag force on nanostructures moving with respect to a thermal radiation bath. We show that nanostructures with the appropriate symmetry properties are subject to a lateral force that significantly modifies their trajectory and a propulsion force that opposes the drag.

Fluctuations in the electromagnetic field, of both thermal and quantum origin, generate forces that play a crucial role in the motion of material structures. A key example is thermal radiation drag, which causes objects to decelerate as they move through a thermal radiation bath [1-2]. This effect arises from the Doppler shift of the thermal radiation bath in the frame comoving with the object: photons propagating with and against the trajectory experience redshift and blueshift, respectively, leading to different absorption rates.

The counterintuitive nature of the thermal radiation drag and its potential applications have led to increasing interest in recent years. However, prior studies have predominantly examined isotropic and homogeneous objects, simplifying the analysis but overlooking effects related to structural asymmetry.

In this study, we demonstrate that nanostructures with anisotropic optical properties experience both a lateral force and a torque when moving through a thermal radiation bath, as depicted in Figure 1(a) [3]. Remarkably, for highly anisotropic structures, the lateral force can be comparable in magnitude to the drag force, as shown in Figure 1(b). This leads to a strong modification of the trajectory, which tends to align with the direction of maximum polarizability. Interestingly, we find notable similarities between the motion of these nanostructures in a thermal radiation bath and the behavior of a wing in a viscous fluid.

Although anisotropy enables control over the trajectory of the nanostructure, its motion remains constrained by thermal drag. To overcome this limitation, we propose a bilayer structure composed of an absorbing and a reflecting material, which spontaneously accelerates when placed in a thermal environment with a different temperature [4]. This self-propulsion mechanism, powered by stored thermal energy, effectively acts as a thermal engine.

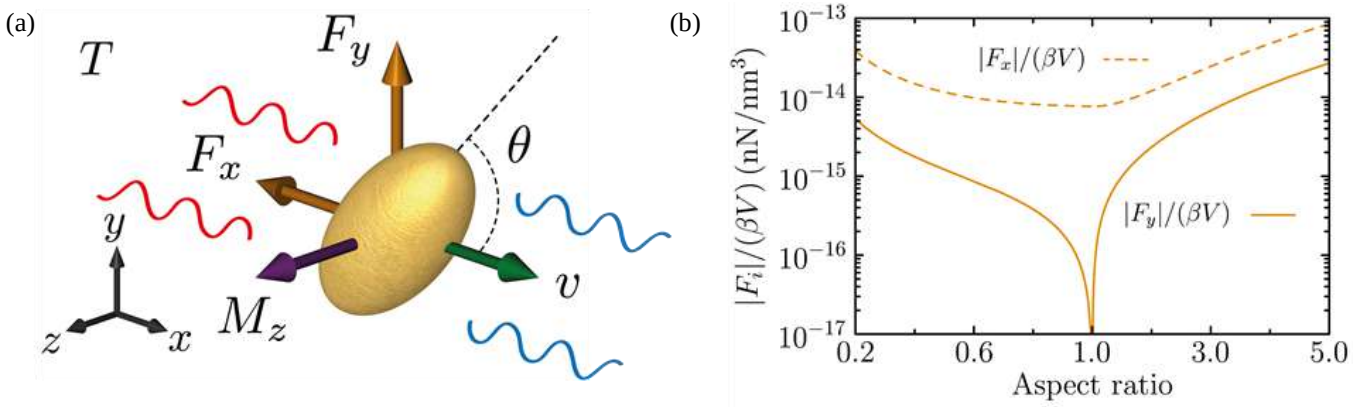

Figure 1. (a) Schematics of the system and (b) components of the force as a function of the aspect ratio.

Fourier Modal Method for Calculating Two-Dimensional Periodic Photonic Crystals with Chiral Inclusions

Ilia Smagin[1], **Sergey Dyakov**[1]
1. Skolkovo Institute of Science and Technology, Bolshoy Boulevard, 30, bld. 1, Moscow 121205, Russia

One of the main methods of theoretical investigation of resonances in layered periodic structures in nanophotonics is the Fourier Modal Method (FMM) in the form of a scattering matrix, based on the Fourier decomposition of electric and magnetic fields in layers homogeneous along the z axis. As far as we know, there are no publications in the literature that present a generalization of the Fourier modal method for the case of chiral substances in the most general anisotropic case. This work proposes to solve this scientific problem. In solving it, we will use an existing approach to take into account the cross coupling coefficients of local induction vectors and fields vectors, which consists in introducing a macroscopic chirality coefficient of a substance, by analogy with macroscopic permittivity and magnetic susceptibility.

It is necessary to increase light-chiral matter interaction for chiral molecules detection which is exactly what is achieved on the resonant responses. Scientific significance and novelty will be the Fourier-modal method generalization taking into account the factorization rules for mathematically correct Fourier transform of the material equation with chiral coefficients in the most general anisotropic case.

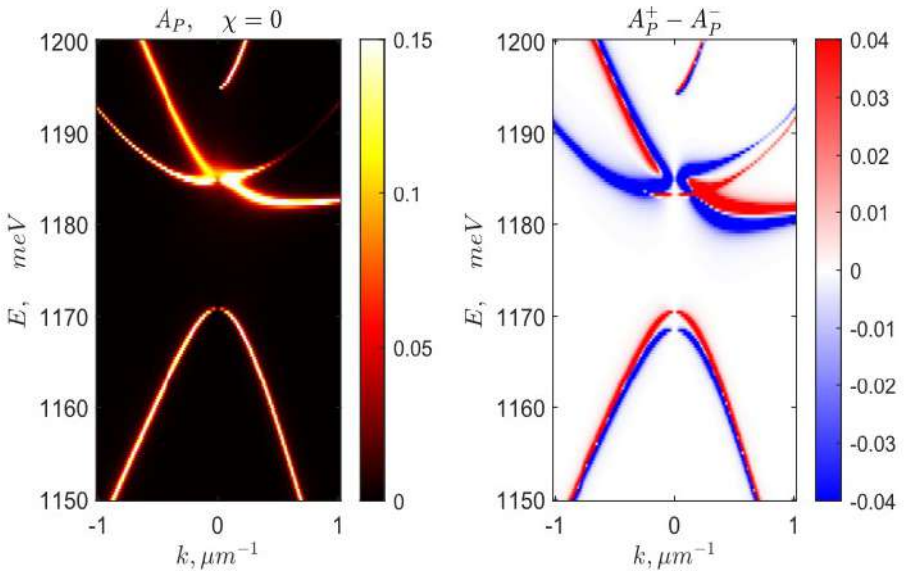

Fig. 1 Absorption spectrum in abstance of chirality (left) and the difference between spectra with different chiral coefficients sign (right).

As an example, using the FMM we got the absorption spectra demonstrated on the fig. 1. On the left panel the absorption spectrum above the light cone in the reciprocal space demonstrated for the case for which all the material is non-chiral, i.e. the chiral coefficient $\chi = \xi^* = 0$, while on the right panel the difference between the "+" and "-" chiral signs that chiral material has takes place. Namely, on the right side we have demonstrated the difference of the absorption spectra for $\chi_+ = \xi_+^* = \in 0.02i$ and $\chi_\in = \xi_\in^* = 0.02i$. On the abscissa axis the projection of the k-vector ($\mu k^{\in 1}$) in the main optical directions $M \in \Gamma \in X$ takes place while the ordinate axis indicates the wave energy in meV. In the presence of the non-zero chiral coefficients modes slightly change its energy position, which demonstrated on the right panel with red and blue colors.

Interaction between Ag nanoparticles and excitons in organic light emtting diode: plasmonic enhancement and quenching

A. T. Diallo, N. Khiri, M. Chakaroun and A. Boudrioua

Laboratoire de Physique des Lasers, CNRS(UMR7538), Université Sorbonne Paris Nord 93430 Villetaneuse, France.

Abstract: We report the effect of the distance between of Ag nanoparticles and the emitting layer of an OLED. A figure of merit is suggested, which includes LSPR, electrical and optical effects of nanoparticles.

Organic light-emitting diodes (OLEDs) are now widely available and increasingly used due to their low cost and great flexibility in design. Incorporating metallic nanoparticles (NPs) into OLED heterostructures presents a promising way to, significantly, enhance both optical and electrical performance. This improvement is, mainly, attributed to Localized Surface Plasmon Resonances (LSPR) [1], which have spurred ambitious developments and applications. However, the ability of plasmonic resonances to boost fluorescence strongly depends on the distance between the NPs and the emitter [2]. Moreover, these nanoparticles can enhance the local electric field at the excitation wavelength, thereby increasing the excitation rate. In addition, their scattering cross-section and antenna radiation pattern contribute to a more efficient out-coupling of the emitted light [3, 4]. Nevertheless, the mechanisms behind this enhancement remain not fully understood. One major challenge with metals is the inherent conductivity losses that may lead to emission quenching [3].

In this work, we present the investigation of the effects of metallic Ag-NPs randomly dispersed in a standard guest-host OLED by thermal evaporation during the fabrication process. We mainly study the interaction between the Ag-NP layer and excitons by varying the position of the Ag-NPs within the OLED stack. At each NP position, we compare the OLED performance with that of a reference device without NPs, and we provide an overall analysis of the variations in electroluminescence efficiency as a function of Ag-NP positioning relative to the exciton distribution in the emitting layer.

The typical OLED stack used in our experiments consists of the following layers: ITO/M-MTDATA as a 30 nm-thick hole injection layer (HIL), a 15 nm-thick NPD hole transport layer (HTL), a 30 nm-thick Alq_3 emitting layer (EML) doped with 1.5 wt% DCM to achieve red emission peaking at 620 nm, a 5 nm-thick BCP hole blocking layer (HBL), a 30 nm-thick Bphen electron transport layer (ETL), a 1 nm-thick LiF layer, and a 100 nm-thick Aluminum (Al) cathode. For the plasmonic devices, Ag-NPs with sizes ranging from 8 to 20 nm were evaporated and randomly dispersed within the OLED heterostructure during fabrication. The position of these NPs was varied using the NPB/Alq_3:DCM interface as a reference (see Figure 1).

Afterward, we analyzed the variations in electroluminescence efficiency as a function of the Ag-NP positioning relative to the exciton distribution within the EML. The experimental results (Figure 1) illustrate the interplay between enhancement and quenching effects induced by the Ag-NPs and their overall impact on the optical and electrical properties of the OLED. Two distinct physical phenomena must be considered, one near the cathode and the other near the anode (blue and green lines in Fig. 1), as well as the correlation between near-field and far-field effects. Specifically, figure 1 reveals two competing effects: on the one hand the LSPR amplification for large distances between the Ag-NPs and the emissive sites and on the other hand, the quenching effect by metallic NPs for short distances between the Ag-NPs and the emissive sites. On the anode side, for distances of 45nm and 30nm, the effect of the LSPR-exciton coupling is at the origin of the improvement in the overall

efficiency of the device. Regarding OLEDs with a distance less than or equal to 15 nm, the fall in efficiency can be attributed to the quenching of excitons by NPs. On the cathode side, the behavior of the NPs-OLED is quite different: the quenching phenomena is observed up to distance of 45nm. Besides, it should be indicated that the recombination area of excitons is mainly close to the NPB/Alq3: DCM interface.

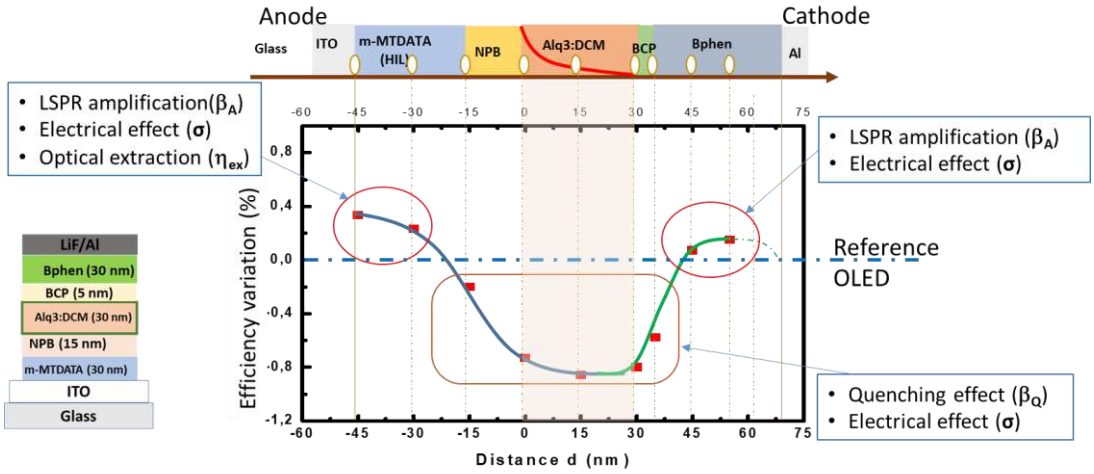

Figure 1 Experimental results of the efficiency variation vs Ag NPs-EML distance. Left and above: Typical OLED structure and the position of Ag NPs studied.

Nevertheless, other phenomena such as the influence of Ag-NPs on the charge carrier injection and transport (electrical effect) and their scattering effect, which influence the optical extraction, should be also taken into account in order to thoroughly understand the effect of metallic nanoparticles on the OLED structure performance. Eventually, our study enables us to suggest a figure of merit giving the total yield enhancement as following:

$$\eta = \sigma \beta_A \beta_Q \eta_{ex}$$

where σ accounts for NPs electrical effects, β_A and β_Q are LSPR amplification and plasmonic quenching, respectively and η_{ex} is related to NPs optical extraction effect.

The weight of each parameter will be analyzed and discussed. These experimental results allow us to assess the balance between amplification and quenching effects induced by the Ag-NPs, which is of a great interest in order to develop new generation of highly efficient OLED-based devices.

Enhanced Light Harvesting and Photothermal Conversion with Anisotropic Gold Nanoparticles

R. Miao,[1*] M. Bissoli, [1] and V. Amendola[1*]

[1] Department of Chemical Sciences, University of Padova, Italy
[*]corresponding author: runpeng.miao@phd.unipd.it

Abstract: Gold nanoparticles (Au NPs) face challenges in broadband light harvesting due to limited spectral coverage and low photothermal efficiency. This study compares spherical Au NPs with anisotropic Au nanostructures, including nanospheres and nanocorals, for enhanced absorption. Their optical and photothermal properties are tested in photo-thermoelectric generators for efficient energy conversion.

The increasing global energy demand and the urgent need to mitigate climate change necessitate innovative approaches to harness solar energy effectively. This study investigates the optical properties of anisotropic Au NPs and their potential applications in solar light harvesting and photo-thermoelectric conversion. The research focuses on synthesizing three distinct types of Au NPs—nanospheres (NSs), aggregated nanospheres (ANSs), and nanocorals (NCs)—and evaluating their performance in converting solar energy into usable forms.[1]

Firstly, the synthesis of Au NPs was achieved through laser ablation in liquid (LAL) using a Q-switched Nd:YAG laser, as shown in Figure 1(A). The process involved varying the concentration of hydrogen peroxide in the solvent to produce different nanoparticle morphologies, as shown in Figure 1 (B-D). Secondly, the optical properties of the synthesized nanoparticles were characterized using transmission electron microscopy (TEM) and numerical simulations based on the discrete dipole approximation (DDA) method. The study also included photothermal experiments to assess the efficiency of light-to-heat conversion across the ultraviolet (UV), visible (Vis), and near-infrared (NIR) regions of the solar spectrum.

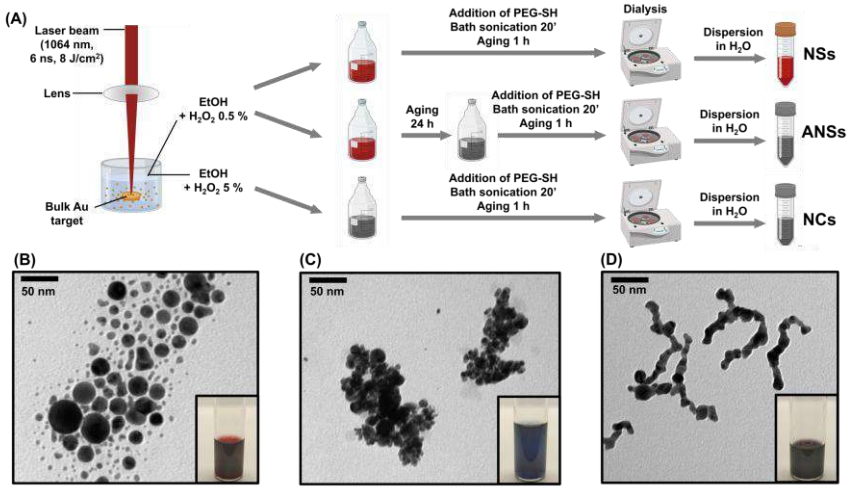

Figure 1 (A) Sketch of the synthesis workflow leading to the three types of Au NPs. (B) B–D) Representative TEM images of final Au NSs (B), ANSs (C), and NCs (D).

Furthermore, the results demonstrated that the optical properties of the Au NPs are significantly influenced by their morphology. The absorbance spectra indicated that the ANSs and NCs exhibited enhanced light absorption capabilities, particularly in the NIR region, compared to the NSs, which was shown in Figure 2 (A). This is crucial for maximizing solar energy capture, as more than half of the solar emission occurs at wavelengths longer than 700 nm.[2] The study also highlighted the importance of optimizing the absorptivity on

the hot side of photo-thermoelectric generators (TEGs) to enhance energy conversion efficiency. The findings suggest that the use of plasmonic materials, such as the Au NPs studied, could provide significant advantages in terms of device simplicity and scalability.

At last, the radar graph analysis revealed that the NCs achieved superior performance metrics, including a photothermal voltage of 0.244 V under Vis-NIR irradiation, which is 95% of the theoretical maximum. This performance is attributed to the synergistic effects of their unique structural features, which facilitate both light absorption and photothermal conversion. In contrast, while the ANSs showed higher absorbance in the visible range, their overall efficiency in energy conversion was lower than that of the NCs.

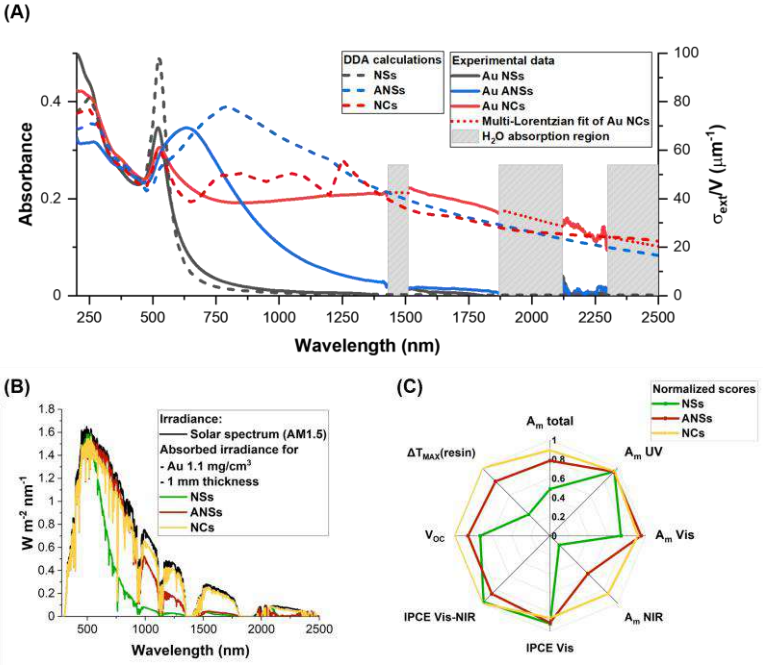

Figure 2 (A) Comparison of experimental absorption spectra and the volume-weighted average of calculated σ_{ext}/V for NSs, ANSs and NCs. (B) Comparative analysis of solar spectrum irradiance and absorbed spectral irradiance of the three Au NPs samples. (C) Radar graph for the comparative assessment of NSs, ANSs and NCs: solar-weighted absorption coefficient (A_m) for different spectral intervals (UV; Vis; NIR); IPCE under Vis and Vis-NIR irradiation; maximum VOC and temperature increase in resin (ΔT) reached under Vis-NIR irradiation at 1.02 ±0.01 $W \cdot cm^{-2}$.

In conclusion, this research underscores the potential of anisotropic gold nanoparticles as effective materials for solar light harvesting and photothermal applications. The ability of NCs to achieve high photothermal conversion efficiency positions them as promising candidates for future developments in sustainable energy technologies. The study contributes to the growing body of knowledge on nanomaterials for energy applications and highlights the need for further exploration of their properties and optimization strategies.

Abstract: Crystals of DNA-functionalized nanoparticle (DNA-NP) superlattices offer high design flexibility and excellent biocompatibility, making them promising for reliable *in-vivo* SERS sensing applications. In this study, we successfully fabricated superlattices consisting of Au-Ag core-shell nanostructures with precise control of their nano-gap distances, showing highly reproducible SERS effect.

Single crystals of DNA-functionalized gold nanoparticle superlattices are composed of periodic structures of gold nanoparticles linked by sequence-designed synthetic DNA molecules[1]. Due to their high degree of design freedom and well-defined periodic structure of plasmonic nanoparticles, they exhibit distinct optical properties such as Mie Resonance[2], Nonlinear optical effects[3], and Surface Enhanced Raman Scattering (SERS).

Recently, Raman-based vibrational imaging of biological cells and tissues has attracted considerable attention[4]. However, due to the inherently small scattering cross-section of Raman scattering, the scattered signals are typically weak, limiting sensitivity and temporal resolution. SERS is a powerful technique that can significantly improve the sensitivity of Raman scattering and enhance the temporal resolution[5]. DNA-functionalized gold nanoparticle (DNA-AuNP) crystals are promising optical SERS probes in biological sensing owing to their unique optical properties, reproducible structure, and excellent biocompatibility.

In this study, we fabricated high-quality DNA-AuNP single crystals and further processed these crystals to serve as optical SERS probes.

AuNPs were functionalized with thiol-modified DNA molecules. Single crystals of superlattices were fabricated through a self-assembly method, aiming for high-quality periodic structure. However, in the aqueous environment, inter-surface distances between nanoparticles within the DNA-AuNP crystal are relatively long, insufficient for the conditions required for strong near-field enhancement. To overcome this limitation, we subsequently induced the formation of core-shell structures on nanoparticles through Ag^+ ion reduction, concurrently contracting the DNA linkages between nanoparticles within the superlattice. Reduction of Ag^+ ions was carried out by adding L-sodium ascorbate, polyvinylpyrrolidone, and a low concentration of $AgNO_3$, each selected for controlled Ag shell formation. After washing the core-shelled nanoparticle crystals with $NaClO_4$ solution, additional higher concentration $AgNO_3$ was added for contracting of DNA[6]. Crystallinity of DNA-AuNP superlattice was verified by synchrotron-based small-angle X-ray scattering (SAXS) and it was confirmed that the crystal structure was maintained even after reduction. SEM analysis also confirmed the successful formation of periodic structures with nano-scale gaps and short-range order (Figure 1a).

To evaluate the SERS effect of the crystals, we performed Raman spectroscopy measurements. The crystals were washed again with $NaClO_4$ solution to remove residual $AgNO_3$, then mixed with Rhodamine B (Rh B) as the model analyte. Raman spectroscopy measurements were conducted in an aqueous environment, resulting in

consistent detection of Rh B at concentrations of 10 μM, 1 μM, and even 100 nM (Figure 1b). These results indicate that SERS enhancement within the crystal structure enabled highly sensitive molecular detection.

Boundary Element Method (BEM) simulations[7] were also conducted to elucidate the near-field properties. A three-dimensional nanoparticle array model, derived from SAXS analysis, was irradiated with a 532 nm plane wave which is same as that used in the Raman spectroscopic measurements, to assess electric field enhancement within the crystal. The simulations revealed strong electric field enhancement due to the periodic, nano-gapped structure of the superlattice. (Figure 1c).

In conclusion, we successfully fabricated DNA-functionalized nanoparticle superlattices maintaining short-range order, detected molecules at low concentrations in solution, and confirmed near-field enhancement inside crystals. Future research will focus on further characterizing their physical properties and exploring their applications in intracellular sensing.

Frozen Plasmons on Uniformly Moving Surface

Abstract: We revisited the problem of a dielectric medium moving uniformly along its surface, focusing on the dispersion relation of its surface modes. We discovered a mode with no group velocity, a frozen mode. Moreover, the surface motion induces a lateral force on a nearby source, maximised by frozen modes.

In our research we studied the reflection of light on a dielectric medium moving parallel to its surface at a fixed speed. Interesting phenomena linked to phase velocity of light have been discovered when the problem is studied through quantum mechanics [1]. However, we approached it from a classical standpoint mixing electromagnetism and special relativity, which revealed interesting features connected to the group velocity of light.

We started by deriving the reflection coefficients of a dielectric medium moving in the plane spanned by its surface. Starting from the s and p polarisation components of an arbitrary incident field we reconstruct the electric and magnetic fields before boosting them with Lorentz transformation. Then, in the rest frame of the surface, we reflect the fields and boost them back into the original frame. In general, we observe a mixing of polarisation in the reflected fields, which has been observed in [2], unless the motion of the surface is along the plane of incidence of the light. The motion of the surface modifies the dependence of the reflection coefficients on the wavevector transverse components, creating an asymmetry between the directions. This asymmetry has a direct impact on the dispersion relation of the surface and causes it to tilt, creating novel ways to excite surface plasmon polaritons (SPP) on the surface (Fig. 1).

It is now possible to excite more than one SPP along a given direction. For example, the negative frequency branch, curves up into the positive frequency domain [1]. Also, the positive branch curves down on one side, creating a maximum frequency point past which certain modes can no longer be excited. This maximum has a derivative equal to zero (see Fig. 1a) which means that there exists a mode with no group velocity, a frozen mode which was our main subject of study.

Another consequence of the asymmetry in the dispersion relation is the asymmetry induced in the emission of SPPs, which carry energy and momentum. This imbalance in momentum between the directions implies that a nearby source will experience a lateral optical force. Thus, we derived the expression of the force and showed that even if the source has no preferred direction of emission it will experience a force due to the motion of the surface. Furthermore, we found that it is possible to maximize the force by exciting the frozen modes mentioned before (Fig. 1b). In fact, studying other quantities such as the torque, the power emitted and the density of state we observed the same effect of enhancement at the frozen modes specifically.

The fields were also calculated and observed in the frame of the surface, from whose point of view the source is moving. From the point of view of the stationary surface, the frozen mode

corresponds to the situation in which the source is moving along the surface precisely at the group velocity of the surface plasmons, such that the source moves together with the envelope of the plasmons which it emits. Furthermore, it helped us understand other modes where the source moves faster than its plasmons, allowing us to fully interpret the dispersion relation and all the possible SPPs.

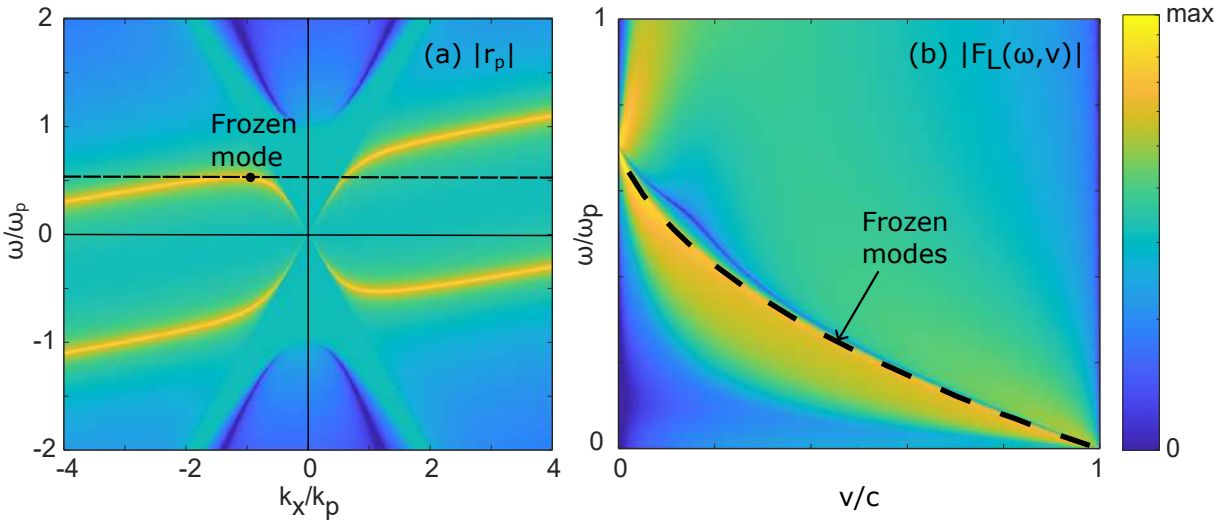

Figure 1: (a) Dispersion relation of the moving dielectric surface represented by the yellow lines, using a lossless Drude model for the relative permittivity of the surface. (b) Plot of the lateral force as a function of frequency (ω) and speed (v/c) with the frozen mode frequencies represented by the black curve.

Abstract: We demonstrate all-optical creation and low-power readout of stable single-atom features in plasmonic nanogaps. These deterministically “written” picocavities exhibit week-long ambient stability in darkness, enabling applications in single-atom devices and catalysis.

The ever-stronger push for miniaturization has resulted in substantial interest towards observing and controlling the dynamics of matter at the level of single atoms. Devices that incorporate single-atom electronic components and memory are highly sought-after in nanoelectronics, while in catalysis single atoms on metal surfaces are key for interactions with molecules. Usually, atomic scale studies require disruptive electron beam techniques. Here, we show all-optical control over single gold atom dynamics through “writing”, “reading” and “storing” them within a plasmonic nanoarchitecture in ambient conditions [1].

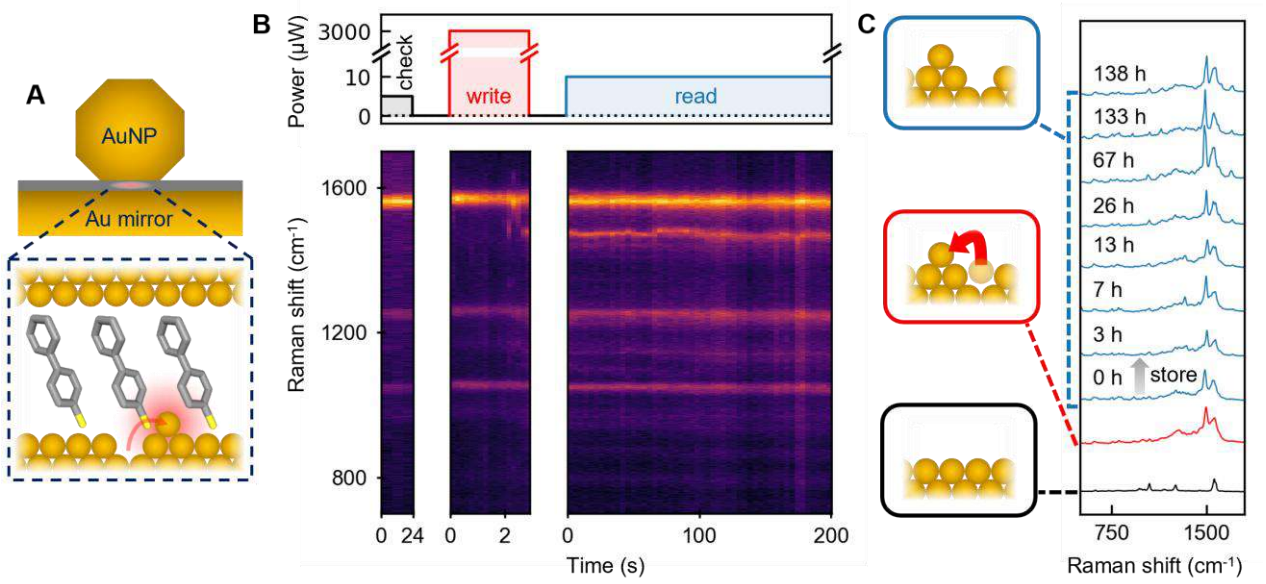

Fig. 1. (**A**) Top: nanoparticle-on-mirror (NPoM) structure, confining light to a nanogap filled with a biphenyl-4-thiol (BPT) monolayer (grey). Bottom: NPoM nanogap interior, where a gold adatom confines light to a picocavity (red) that perturbs one BPT molecule. (**B**) 633 nm laser irradiation power over the course of a typical *write-read* experiment with corresponding Raman time scans. (**C**) 633 nm excitation SERS spectra resulting from a *write-read* experiment on a picocavity over the course of a week, with increasing periods of dark storage between read spectra. Insets are inferred structure configurations corresponding to the spectra.

We use a nanoparticle-on-mirror (NPoM) architecture to plasmonically confine light within a ~1 nm gap between a gold mirror and gold nanoparticle. The nanogap is supported by a self-assembled monolayer of biphenyl-4-thiol (BPT) molecules, whose Raman spectra are visible due to the >108 enhancement in the gap. Illuminating the NPoM results in spontaneous new transient narrowband features termed “picocavities” [2,3].

These are found to be single gold adatoms lifting out of the gold surface, further confining light to sub-nm3 scales (Fig. 1A). Within this volume, the confinement is enough to discern Raman scattering of single BPT molecules next to the gold atom.

The adatoms preferentially form and decay at higher light powers, which we utilise for a write-read protocol. The NPoM is illuminated at ~mW 633 nm laser powers, allowing <10 s picocavity creation. Raman spectra are measured and automatically checked for adatom formation in real time. On strong peak appearance (adatom writing), laser powers are dropped to μW levels, at which it can be repeatedly read (Fig. 1B). This experiment is replicated on >1000 NPoMs at different write and read powers. Here 3 mW is found to be the optimal write power, while >75% of the adatoms survive for 200 s at <10 μW reads. Moreover, experiments where the same picocavity is read intermittently with extended dark periods in-between show picocavity stability for up to a week in ambient conditions (Fig. 1C). This shows the remarkable robustness of the adatom in ambient conditions.

Our study enables room-temperature, real-time optical manipulation of single atoms with week-long stability. These findings advance the integration of plasmonics into nanoelectronic devices and single-atom catalysis applications.

Abstract: We propose an optical coupler with total internal reflected propagative modes to enhance signal detection in smart eyewear eye-tracking systems. Supporting surface lattice resonances, the metasurface is tuned to near-infrared wavelengths via geometric control of dielectric meta-atoms. Fabricated using electron-beam lithography, it achieves >80% visible transparency while enhancing infrared scattering at the lens.

Smart eyewear development requires careful integration to ensure the final device is both comfortable and functional, offering a lightweight and easy-to-wear solution. A key feature in these devices is eye-tracking technology, which detects and follows the user's gaze. This typically involves using infrared light to illuminate the eye and measuring the reflected light with photodetectors, enabling precise eye movement tracking [1]. The main challenges when embedding such systems into eyewear is minimizing form factor, reducing power consumption and computational load, all while maintaining high performances. In response to this, a recent proposal from a smart eyewear research team suggests a novel eye-tracking method that integrates photodetectors into the frame itself, positioned near the lens edge [2]. To enhance the photodetector signals, we suggest utilizing a metasurface (MS) with non-local properties, which can be applied to the lens. This metasurface enables surface lattice resonances (SLRs), created by the interaction of Rayleigh anomalies with meta-atom resonances, allowing for fine-tuned control of in-plane scattering efficiency [3].

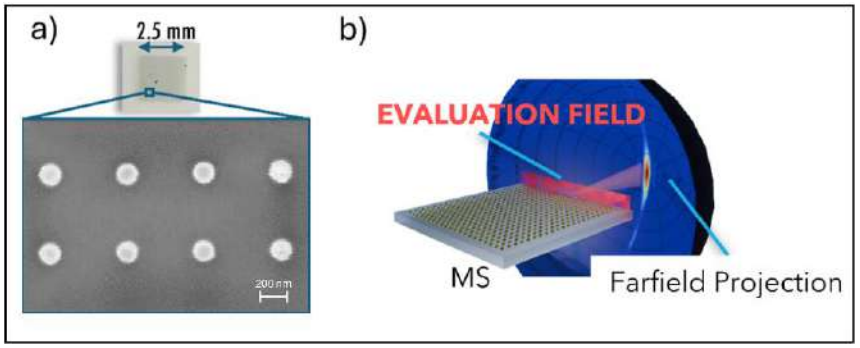

Figure 1: (a) Upper: Metasurface prototype consisting of meta-atoms arranged on a silicon oxide substrate. Lower: Scanning electron microscope (SEM) image of a portion of the metasurface. (b) Schematic representation of the in-plane scattering emitted from the metasurface.

By manipulating the geometric properties of the meta-atoms—such as their spacing, diameter, and height—we can control the scattering spectrum, aligning it with the near-infrared (NIR) LED's emission range used to illuminate the eye. This precise tuning ensures that the metasurface remains transparent to over 80% in the visible spectrum, enabling it to be applied directly on the lens without interfering with the user's see-through vision. In choosing materials, we focused on optical properties and considered two potential options: metallic and dielectric platforms. While metals like gold can facilitate plasmonic resonances, their optical losses in the visible spectrum might reduce overall transparency and the quality factor of the resonances. High-index dielectric materials, such as silicon, however, efficiently support resonances while minimizing visible spectrum losses, making them an ideal choice for photonic devices [4]. The metasurfaces were fabricated using electron-beam lithography (EBL), with material deposition and lift-off processes to finalize the structure. The optical performance of the device was evaluated using a specialized setup to measure both the transparency of the metasurface and the intensity of scattered infrared radiation at the lens surface.

This work was carried out in the Smart Eyewear Lab, a Joint Research Center between EssilorLuxottica and Politecnico di Milano.

Abstract: We report complementary hBN metasurface hosting embedded nanocavities. Comprehensive optical characterization reveals visible-regime high-Q resonances due to the quasi-bound states in the continuum, which produce a spatially uniform electric fields. The cavity field enables single-molecule surface-enhanced Raman spectroscopy, which we here consider for ATTO 610-doped ethanol. Results demonstrate strong absorption–emission enhancement and signal levels exceeding those of conventional plasmonic platforms.

This study is devoted to the design of a complementary all-dielectric metasurface formed hexagonal Boron Nitride (hBN) film, including cylindrical cavities. The optical response sustains high-Q resonances in the visible regime and uniform electric field inside the cavities due to the quasi-bound states in continuum [1, 2]. We investigate the single-molecule SERS process by considering a single ATTO 610 molecule in ethanol solvent inside the cavity. The schematic of the hBN metasurface with a single molecule inside a cavity is shown in Fig.1(a). The SERS intensity enhancement of a single molecule is investigated with equation (1) [3]:

$$I_{SERS} = |\frac{E(\mathbf{r},\omega)}{E_0(\mathbf{r},\omega)}|^2 \times F_p, \tag{1}$$

where $E(\mathbf{r},\omega)$, and $E_0(\mathbf{r},\omega)$ are electric fields in the molecule's position in hBN metasurface and free space, respectively. The F_p is the Purcell factor of a molecule inside the hBN cavity metasurface, defined as:

$$F = \frac{3}{4\pi^2}(\frac{\lambda}{n})^3 \frac{Q}{V_{\text{eff}}}, \tag{2}$$

where λ is the free-space resonant wavelength, n is the refractive index of the medium, Q is the quality factor of the resonance and V_{eff} is the effective mode volume. The effective mode volume can be calculated by:

$$V_{\text{eff}} = \frac{\int_{\text{V}} \varepsilon(\mathbf{r}) \left|\mathbf{E}(\mathbf{r})\right|^2 \mathrm{d}V}{\max\left[\varepsilon(\mathbf{r}) \left|\mathbf{E}(\mathbf{r})\right|^2\right]} \tag{3}$$

The SERS signal intensity in the logarithmic scale is shown as a function of the cavity diameter in Fig.1(b), demonstrating strong SERS intensity enhancement in larger volume compared to traditional plasmonic cavities. The SERS signal intensity enhancement in the hBN cavity with a diameter of 40 nm with respect to free space is around 10 orders of magnitude.

In summary, hBN metasurfaces offer exceptional potential for SERS spectroscopy, enabling both single-molecule detection and enhanced sensitivity of multi-molecule detection in coherent media.

The authors acknowledge the support from the National Science Centre, Poland (Project No. 2020/39/I/ST3/00526).

Abstract

Infrared absorption spectroscopy, in transmission and reflectance modes, Raman scattering spectroscopy, X-ray rocking curve imaging analytics were used to characterize optical and structural properties of *n*-type and *p*-type bulk germanium crystals doped above the Mott transition. Such materials are being considered for mid-infrared technology as a counterpart to silicon-based devices.

1. Introduction

Heavily doped (HD) semiconductors are indispensable materials for realization of electronic and optoelectronic devices in particular because their properties bridge dielectric and metallic matter [1]. However, there is a lack of a comprehensive theoretical background that adequately explains all experimentally observed optical features, especially when the latter result from spectrally overlapping strong light-matter interaction. This upsurges the importance of empirical data on these materials and its direct analysis.

Germanium (Ge) crystals offers high mobility of charge carriers and possess low lattice absorption in the mid-infrared wavelength range that makes it one of the key materials for optoelectronic applications and sensing. Most of present research on HD Ge is focused on engineering approaches for a substitutional one-electron donor doped thin (typically not above 1 μm) films deposited on various substrates. Complex techniques using epitaxial and ion implantation methods were explored to overcome the natural limits of doping [2,3]. Note that many mid-infrared applications would require a thickness of a high-quality homogeneous material that exceeds the light wavelength. Such requirements can be addressed mainly by doped bulk crystals, which therefore remain the universal platform for multi-vector semiconductor technology.

We report on the characterization of optical and structural properties of *n*-type and *p*-type Ge crystals doped with single-electron substitutional impurities above the Mott transition, up to about the equilibrium solubility limit [4-6].

2. Crystal growth and characterization

All crystals were grown by the Czochralski (Cz) method or its modified variant, the so called “mini-Cz”, with the doping from the gas phase [4]. Concentration of the free charge carriers was estimated from calibrated resistivity measurements. The *p*-Ge crystals have large concentration of charge carriers than *n*-Ge; *p*-Ge ingots exhibit an axial doping gradient.

For the heavily doped (HD) *p*-Ge:Ga crystal (gallium concentration up to ~ 2×10^{20} cm^{-3}) [5] sections along this gradient (i.e. in the growth direction, Fig. 1a) were investigated. For a HD *n*-Ge:Sb (antimony concentration up to ~ 1.6×10^{18} cm^{-3}) and a HD *n*-Ge:P (phosphorus concentration up to ~ 2×10^{17} cm^{-3}), only sections perpendicular to the growth axis were measured.

The structural properties were analyzed using X-ray rocking curve imaging on the crystal sections along the growth axis. The 2D maps (intensities) of the rocking curves indicate an increased defect density at Ga concentrations above 10^{20} cm^{-3}, when HD Ge:Ga become multicrystalline.

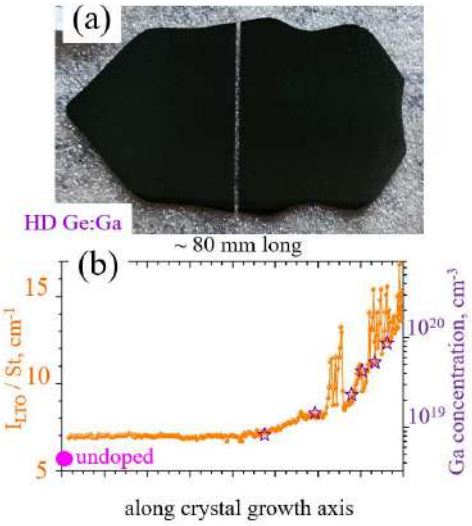

Figure 1. (a) A section along the HD Ge:Ga crystal growth (acceptor gradient) axis, the Ga concentration increases from the left to the right end; (b) Raman signal integrated absorption under the Ge LTO line over the LTO frequency, used to show the evolution of the LTO mode along the crystal growth axis; right axis – for the Ga concentration, the values marked as stars were obtained from calibrated resistivity measurements.

Raman spectra were recorded in the backscattering geometry using a WITEC 300 Alpha microscope providing a spatial resolution of 1.5 μm and a 532 nm laser. The spectra as it has been shown provide supplementary information on the concentration gradient as well as local lattice distortion (the latter – in the region of the ultra-high doping limit).

The first-order zone-centered LTO optical phonon exhibits a red shift in the energy and asymmetric line broadening. The large local deviations from the mean LTO frequency value (Fig. 1b) are most likely caused by strong structural changes, such as dislocation clusters towards the highly doped ingot end, which were observed using energy dispersive Laue spectroscopy [5].

The second-order Raman spectra show a strong increase in the scattering rates of the sum-phonon bands, expressed in line broadening, the intensity decrease of most of second-order bands and the appearance of defect-induced bands.

3. Infrared absorption spectroscopy

Infrared absorption spectra were collected with a Bruker Fourier-Transform spectrometer in transmission mode (normal incidence on the sample surface) and in reflection mode (biconic mode, 13° – 13°).

Transmission spectra of HD Ge crystals do not return useful information in the mid-infrared range for crystals doped above the Mott transition. This is apparently due to the strong free carrier absorption, which affects the spectra up to the bandgap absorption for *p*-Ge (Fig. 2).

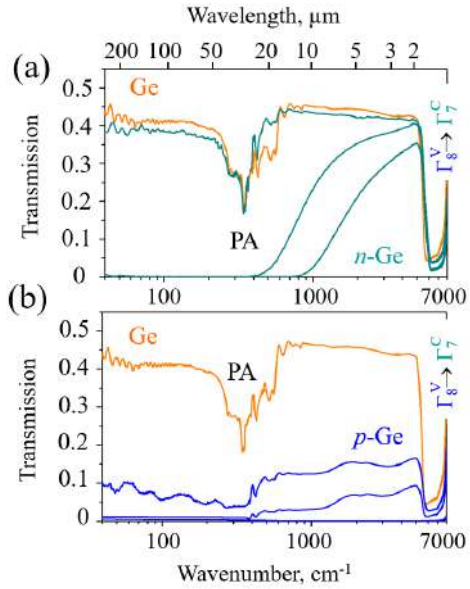

Figure 2. Transmission spectra of Ge samples doped below and above the Mott transitions, compared with the spectra of undoped Ge (residual acceptors below 10^{13} cm^{-3}). (a) Sb doped *n*-Ge, donor densities are $9.\times10^{14}$ cm^{-3}, 5.7×10^{17} cm^{-3}, 1.6×10^{18} cm^{-3}; (b) Ga doped *p*-Ge, acceptor densities are 1.1×10^{16} cm^{-3}, ~5×10^{18} cm^{-3}, ~5×10^{19} cm^{-3}. Interband transitions contributing to the integral absorption are shown. PA stays for multi-phonon absorption bands.

The samples doped below the Mott transitions exhibit non-vanishing transmission with the characteristic features of multi-phonon absorption (PA) bands (Fig. 2).

Infrared reflectance spectra of HD Ge reveal the impact of various optical processes contributing to infrared absorption: intraband absorption by free electrons ($e \rightarrow e$), including features associated with intervalley scattering in the conduction band of *n*-type Ge; intrasubband heavy and light holes ($hh \rightarrow hh$ and $lh \rightarrow lh$) and intersubband absorption by heavy-to-light hole transitions ($hh \rightarrow lh$) in *p*-Ge. Additionally, common for the both materials, interband absorption (dominating by) direct $\Gamma_8^{VB} \rightarrow \Gamma_7^{CB}$ transitions between the valence and conduction bands is clearly observed in the high-frequency region of the mid-infrared reflectance spectra. The frequency shift in the latter transition type illustrates the doping-induced bandgap narrowing [7] in a HD Ge.

4. Conclusions

Complementary (transmission and reflection) infrared absorption spectroscopy provides detailed information about optical properties of heavily doped germanium bulk crystals. At charge carrier densities above the Mott transition, mid-infrared transmission vanishes, while reflectance spectra indicate the transition between strong reflection and absorption regions.

Raman microscopy can be used to evaluate the local quality of HD Ge crystals, which is affected by local (dopant) and distributed (lattice) defects.

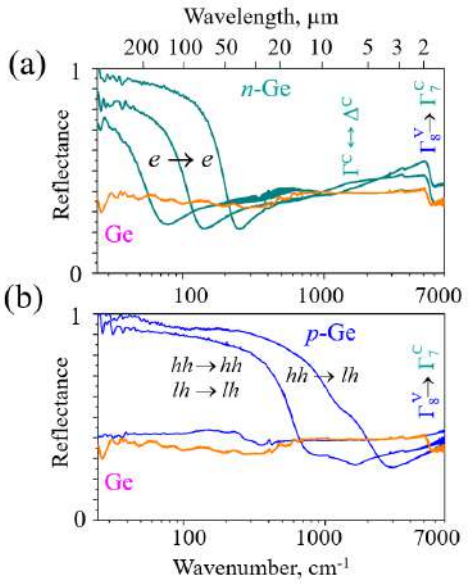

Figure 3. Reflectance spectra of HD Ge samples compared with the spectra of undoped Ge. (a) Sb doped HD *n*-Ge, donor densities are 1.4×10^{17} cm^{-3}, 5.7×10^{17} cm^{-3}, 1.6×10^{18} cm^{-3}. (b) Ga doped HD *p*-Ge, acceptor densities are 1.1×10^{16} cm^{-3}, ~5×10^{18} cm^{-3}, ~5×10^{19} cm^{-3}. Intrasubband $e \rightarrow e$, $hh \rightarrow hh$, $lh \rightarrow lh$, intersubband $hh \rightarrow lh$, interband $\Gamma_8 \rightarrow \Gamma_7$ as well as $\Gamma \rightarrow \Delta$ intervalley scattering transitions contributing to the integral absorption are shown.

Abstract:

Nonlocal metasurfaces are very promising solutions for advanced Augmented Reality (AR)-devices, but major challenges are still to be faced. This poster summarizes all the activities we have performed to achieve advanced nonlocal metasurfaces for this application, focusing on the theoretical studies and simulations, but also with experimental validations on structures fabricated at our facilities.

Suppressing photobleaching of j-aggregates via strong light-matter coupling

Abstract

Here, we experimentally investigate the suppression of photobleaching of cyanine dye j-aggregates when it is strongly coupled to propagating surface plasmons on planar silver film. The experimental technique involves the novelty of probing only the strongly coupled molecules for bleaching suppression in the Kretschmann configuration with no background from uncoupled molecules.

1. Introduction

Surface plasmon polaritons (SPPs) are spatially confined electromagnetic field modes at a metal-dielectric interface capable of generating intense near-field optical forces on ultrafast time scales[1]. When an organic emitter interacts with surface plasmon polariton (SPP) fields, it can form a hybrid system with new energy eigenstates called polaritonic states. This strong coupling is evidenced by an anti-crossing behavior in the dispersion relation, known as Rabi splitting[2,3]. It has been shown that chemical reactivity, charge, and exciton transport[4] can be modified under strong coupling conditions. The photobleaching effect is one such fundamental chemical property appearing in many organic molecules, suppressing the fluorescence of dye molecules and leading to irreversible photodamage. It limits the applications of organic electronic devices such as organic solar cells, electroluminescent devices, organic dye lasers, and molecular fluorescence[5]. Photobleaching occurs through photodynamic interactions, where dye molecules in an excited triplet state interact with atmospheric oxygen, which is also in its triplet state, via a charge transfer mechanism generating reactive oxygen species, which in turn chemically degrade the fluorophores[6,7]. Since polaritonic states are coherent hybrids of plasmons and excitons they have extremely short lifetimes (~ 10fs) far faster than typical intersystem crossing rates (10^{-8} to 10^{-3} seconds). This prevents efficient triplet state population, making polaritonic states highly effective in suppressing photobleaching reactions[8,9]. Recent studies have demonstrated that photobleaching of Rhodamine 6G molecules is significantly suppressed when the molecules are strongly coupled to surface plasmon polaritons (SPPs) on a 50 nm planar silver film using the Kretschmann configuration (KC). This suppression is evidenced by fluorescence intensity and lifetime measurements[10,11]. However, spectroscopic measurements involve the background of uncoupled molecules in the system. Here, we showed the experimental novelty in exciting and probing only the strongly coupled molecules with no background from uncoupled molecules. Time-dependent bleaching measurements were performed to obtain the bleaching curve from the reflectance spectrum in the Kretschmann configuration. The results demonstrated reduced photobleaching in strongly coupled j-aggregated molecules compared to the photobleaching observed when the sample was directly exposed to laser light.

2. Materials and Experimental Method

The commercially purchased water-soluble Cyanine dye 5,6-Dichloro-2-[[5,6-dichloro-1ethyl-3-(4sufobutyl) benzimidazole-2-ylidene] propenyl]-1-ethyl-3-(4-sulfobutyl) benzimidazolium hydroxide, inner salt, sodium salt (TDBC). A dye solution with Polyvinyl Alcohol (PVA) as a matrix was prepared by dissolving 1 mg of dye in 1 mL of a mixed solvent of Ethanol and PVA in a 4:1 ratio. The concentration of PVA was 25mg/ml in deionized water. The absorption spectrum of the dye in ethanol solvent exhibits a broad absorption peak at 525 nm. However, when spin-coated on a glass substrate, the spectrum shows an intense, narrow, red-shifted absorption band at 587 nm, indicating the formation of j-aggregates in the film form. The monomer and j-aggregate spectrum of the TDBC dye is shown in Figure 1.

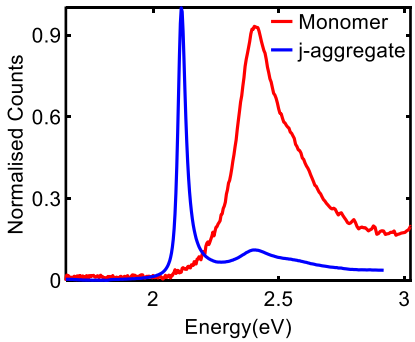

Figure 1: Absorption spectrum of TDBC monomer and j-aggregate.

The schematic diagram of the experimental setup is shown in Figure 2. It consists of a Tungsten-Halogen broadband source for reflectance measurements and a Supercontinuum pulsed laser source with wavelength selective filter for exposing the sample in the Kretschmann configuration. The spot size and beam path of the two sources have been made precisely coincided with the help of mirrors, beam splitter

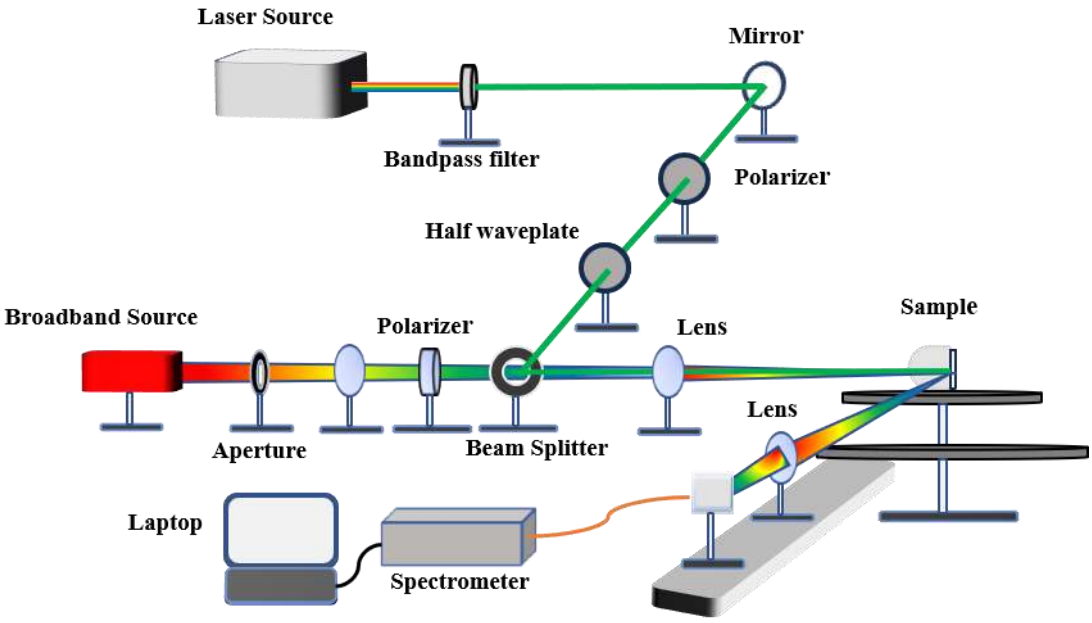

Figure 2: Schematic diagram of the experimental setup.

and lenses before they fell on the sample. This arrangement exposes the sample with a laser for a certain period and collects the reflectance spectrum from the same spot for the bleaching signature in the Kretschmann configuration. Polarizers have been introduced in the two paths to make both beams horizontally polarized. Since both exposing the dye and taking reflectance measurements are done in the Kretschmann configuration, the hallmark of bleaching is from the coupled molecules.

3. Results and Discussion

The angle-resolved reflection measurements were done to check for the signature of strong coupling through dispersion relation. The sample consists of a 50nm silver film spin-coated with the TDBC dye solution on it at 2000 rpm. The silver film was placed on the hemicylindrical prism, with index-matching oil.

3.1. Measuring the dispersion relation

To obtain the dispersion relation the angle-resolved reflection spectrum was fitted with the Fano line-shape function[12]–[14]. Figure 3a shows the Fano-fitted reflectivity spectrum at an angle of 46.5 degrees. Figure 3b shows the obtained dispersion relation, with the fitted parameter as resonance data points of upper and lower polaritonic branches. The expression for the Fano line shape function is given as

$$R(w,\phi) = \sum_{i=1}^{2} \left| a_i + \frac{b_i * e^{i*\phi_i} * \Gamma_{radi}}{w - w_{0i} + i * \Gamma_{radi}} \right|^2 \qquad (1)$$

Where a_1, b_1, ϕ_1, and a_2, b_2, ϕ_2, are the complex value parameters. The resonance positions of the upper and lower polaritonic branches obtained by Fano fitting the angle-resolved reflection spectrum is being used in getting the dispersion relation.

The dispersion relation shows the anti-crossing behavior at the j-aggregate absorption wavelength.

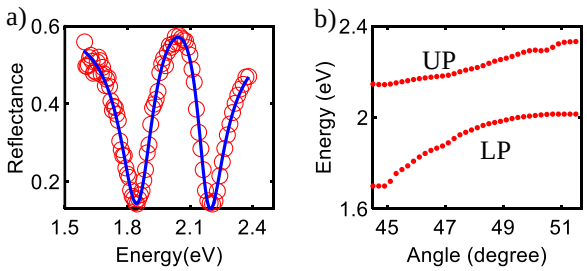

Figure 3: a) Reflection data (red circle) at 46.5degree angle fitted with Fano line-shape function (blue line). b) Dispersion relation showing the upper and lower polaritonic branches.

3.2. Modeling the dispersion relation

When molecular aggregates undergo strong coupling with surface plasmons, they form hybrid polaritonic states that exhibit ultrafast decay dynamics on the timescale of a few femtoseconds. The strength of the strong interaction or Rabi splitting energy between the hybrid states is given as[15]

$$\hbar\Omega_R = 2 * d * \sqrt{\frac{\hbar * w_c * N}{2 * \varepsilon_0 * V}} \qquad (2)$$

where d is the dipole moment of the oscillator, V is the mode volume, and N is the number of molecules or oscillators. The linear optical behavior of this hybrid structure can be effectively described using a coupled harmonic oscillator model, where the exciton and surface plasmon polaritons (SPPs) are represented as complex Lorentzian oscillators[16]. According to the model, the UP and LP hybrid mode frequencies are given by:

$$w_{UP/LP} = \frac{w_x + w_{spp}}{2} \pm 0.5 * \sqrt{(w_x - w_{spp})^2 + 4 * \Omega_R^2} \quad (3)$$

Where w_x and w_{spp} represents the complex frequency of the exciton and SPP. Figure 4a shows the contour plot of the angle-resolved reflection measurement done on the silver film without coating the TDBC dye. It shows the plasmon resonance varying from 1.6 eV to 2.4 eV. Whereas, Figure 4b shows the contour plot of the angle-resolved measurement for the coupled system. It shows the formation of a hybrid system with upper and lower polaritonic branches. The coupled oscillator model fitting of the dispersion relation gives the Rabi splitting energy around 365±6 meV.

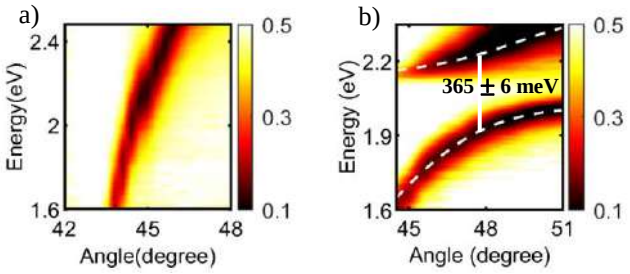

Figure 4: Contour plot of the angle-resolved reflection measurement a) On 50nm silver film without TDBC coating b) With TDBC coating.

For time-dependent bleaching information of the dye, the reflectance spectrum of the coupled system was recorded at a particular angle. The angle was chosen so the exposing laser wavelength can outcoupled through SPR in the Kretschmann configuration. The reflectance spectrum was recorded using a broadband source at different time intervals of laser exposure. Figure 5 shows the reflectance spectrum of the coupled system for various time intervals of laser exposure of wavelength 580nm in the Kretschmann configuration.

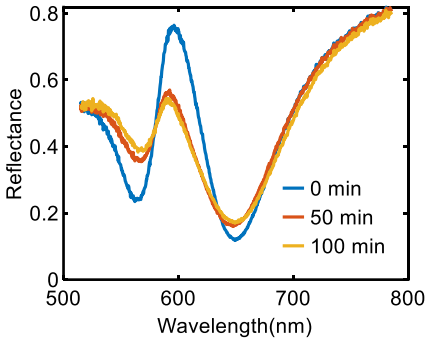

Figure 5: Reflectance spectrum at different time intervals of laser exposure of 580nm wavelength in Kretschmann configuration.

The bleaching of the dye reduces the number of active molecules participating in the coupling, which in turn decreases the Rabi splitting energy. As a result, the energy gap between the lower and upper polaritonic branches is reduced. It introduces inhomogeneous broadening due to variations in the dye's transition energies and partial photodamage. This broadens the polaritonic states. Here, we investigate the bleaching of the dye under strong coupling with SPPs in the Kretschmann configuration, analyzing its dependence on the exposure laser wavelength. The reflectance spectrum at different time intervals of laser exposure, for various exposure wavelengths, was fitted with a Fano profile to determine the resonance positions of the lower and upper polaritons. The results indicate that when the exposure wavelength is closer to the excitonic absorption, the polaritonic branches shift towards each other more significantly compared to when the exposure wavelength is farther from the excitonic absorption. This suggests that dye bleaching is more pronounced when the system exhibits excitonic-like behavior and is suppressed when it becomes plasmonic-like, farther from the excitonic absorption band. Table 1 shows the shifting of the resonances of the lower and upper polaritonic branches, as a function of bleaching time for different laser wavelength exposure.

Table 1: Resonances of Lower Polariton (LP) and Upper Polariton (UP) at different times for different laser wavelength exposures.

Time → Exposing laser wavelength ↓	0 (min)		100 (min)		Difference (0^{th}-100^{th})	
	LP (nm)	UP (nm)	LP (nm)	UP (nm)	LP (nm)	UP (nm)
580	649	563	645	570	4	7
550	661	564	659	568	2	4
520	607	508	606	511	1	3

The difference reflectance plots were obtained by subtracting the peak points of the reflectance spectrum at the 0th minute from those at various time intervals. This was done for different laser exposure wavelengths to analyze the changes over time. It presents the bleaching percentage for all laser exposure wavelengths in the Kretschmann configuration, along with direct dye bleaching at 590 nm exposure.

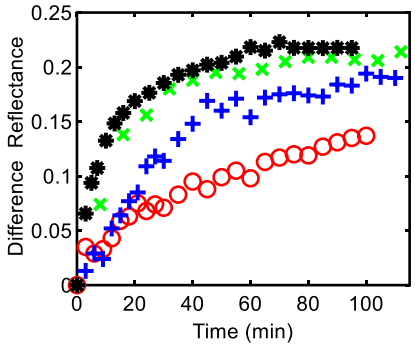

Figure 6: Bleaching curves for different laser wavelengths of exposure 1) 520nm (red circles) in KC 2) 550nm (blue plus) in KC 3) 580nm (green cross) in KC 4) 590nm (black asterisk) direct bleaching.

Table 2 summarizes the percentage of bleaching observed under different laser wavelengths for 50 minutes of exposure, comparing the Kretschmann configuration and direct bleaching. This comparison illustrates the suppression of bleaching under strong coupling conditions achieved in the Kretschmann setup. A bleaching of 20.39% was observed in

the J-aggregate dye upon direct exposure to a 590 nm laser for 50 minutes.

Table 2: Percentage bleaching suppressed for different exposing laser wavelengths.

Exposing laser Wavelength	%Bleaching data for 50^{th} minute	%Bleaching suppressed (Direct-KC)
520nm in KC	9.90	10.49
550nm in KC	16.0	4.39
580nm in KC	19.50	0.89

4. Conclusions

In this work, we investigated the photobleaching behavior of j-aggregating cyanine dye molecules under strong light-matter coupling with propagating surface plasmons supported by planar 50nm silver film. Using angle-resolved reflectance measurements in the Kretschmann configuration, we tracked bleaching dynamics by repeatedly probing the same spot during controlled laser exposure. Our results reveal that exposure at wavelengths far detuned from the excitonic absorption of the dye leads to significantly suppressed photobleaching compared to near-resonant excitation. This behavior contrasts with the direct bleaching observed under 590nm laser exposure in the non-Kretschmann configuration, where the excitation is near the excitonic absorption peak. Notably, the suppression of photobleaching is more effective when the polaritonic mode is plasmon like (off-resonance) than when it is more exciton-like (near resonance) indicating the role of photonic character in mitigating dye degradation. The observed suppression is attributed to the rapid relaxation dynamics of polaritonic states formed under strong coupling. This inhibits population of the triplet state and thus reduce the generation of reactive oxygen species responsible for fluorophore degradation. These results suggest that plasmon-exciton coupling can be an effective strategy to enhance photostability in dye-based optical systems.

Abstract: Rare-earth perovskite nickelates, ReNiO3, are characterized by a large number of structural and physical properties, presenting a sharp metal-to-insulator transition, MIT. During the MIT, a rapid change of optical and electrical properties occurs. Here we will show how to tune the MIT and shift it around room temperature.

Correlated transition metal oxides (TMOs) are a class of materials that have attracted significant attention from the scientific community due to their remarkable electronic, magnetic, structural and optical properties. Within the TMOs, the family of the rare-earth perovskite nickelates, described by the general formula $RNiO_3$, with R a trivalent rare-earth (R = La, Pr, Nd, Sm, ..., Lu), is particularly interesting. These materials exhibit a wide range of structural and physical properties, forming a rich phase diagram [1]. With the exception of $LaNiO_3$, a remarkable phenomenon of nickelates is their sharp metal-to-insulator transition (MIT), during which rapid changes in optical and electrical properties occur. These changes could be leveraged in combination with nanostructures to endow new temperature-dependent functioalities to devices [2]. However, effectively exploiting these properties requires precise control of the MIT, adjusting its transition temperature and sharpness. Nowadays, the most studied materials for this purpose are part of the vanadium oxides family [3]. Unfortunately, their chemical inflexibility makes tuning their MIT temperature challenging.

In this work, we present our results on the growth of nickelates thin films by Pulsed Laser Deposition (PLD). We show how we were able to shift their MIT to room temperature by using a combination of Sm and Nd cations in $Sm_{1-x}Nd_xNiO_3$. In addition, we demonstrate the possibility to further modulate the MIT temperature and sharpness by changing the applied strain, i.e. using different crystalline substrates. Fourier-transform infrared spectroscopy, FTIR, reveals a significant change in optical reflectance during the transition, see Fig. 1. This pronounced temperature-driven infrared reflectance could enable various applications, including infrared camouflage. Our findings contribute to optimizing the properties of nickelates, facilitating their integration into next-generation nanostructured devices.

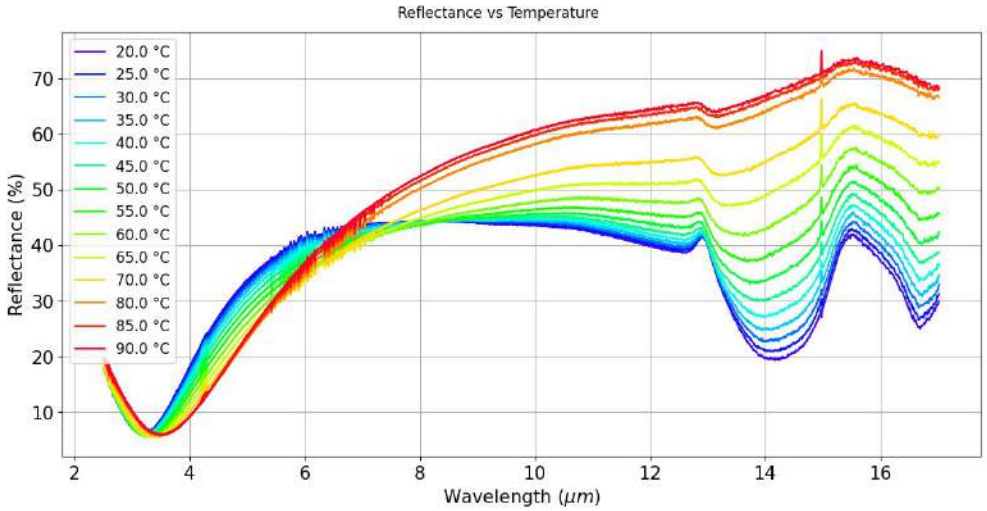

Fig. 1: Measured infrared reflectance for a $Sm_{0.85}Nd_{0.15}NiO_3$ grown on $LaAlO_3$ substrate. The measurement was performed while heating up. A significant increase in reflectance occurs above 8 um wavelengths. A decrease in reflectance is instead observed in the 4-6 um wavelength region

Abstract: The non-Hermitian skin effect (NHSE) characterized by the tendency of bulk states to concentrate toward the boundary is one of the most important and widespread phenomena within non-Hermitian Hamiltonian systems. Due to their topological origin, skin modes are usually robust and difficult to regulate. In our work, we engineered magnetic-field-like on-site and randomlike on-site potentials, and we found nonmonotonic and monotonic suppression patterns on skin modes. These suppression patterns represent characteristic transitions as the on-site potential shifts from order to disorder. Relying solely on on-site potential energy engineering, we develop a general strategy to control suppression of skin modes. By integrating with the scaling theory, we have extended the concept of controllable suppression of NHSEs to higher-dimensional systems.

Through potential energy engineering, we elucidated how a magnetic field affects skin modes that previously were emphasized for either suppression or enhancement. Though their topological origin, we developed a general strategy to control the suppression of skin modes, achieving both the robustness and controllable adjustability of skin modes. Finally, the concept of controllable suppression of skin modes was generalized to higher dimensions, addressing an important scenario often overlooked in higher dimensions. Moreover, this work only considered the most original Anderson localization and did not distinguish between strong and weak localization as well as weak antilocalization, and the richer connotation between the suppression of skin modes and localization, which need to be explored further.

Abstract: We present a comprehensive study on the design of a dielectric TiO_2-based nanostructured metasurface into a novel perovskite solar cell with the aim of optimizing the power generation in indoor environments. An absorption improvement, and a consequent increment of the solar cell efficiency, with respect to the planar case, are obtained. Our findings highlight the potential of dielectric metasurfaces for next-generation photovoltaic devices.

Renewable energy is a must in a world with limited fossil fuels, and a strong impact on climate conditions. In this sense, solar energy is one of the most powerful alternatives, with currently 2 TW of energy installed, and a projection of 8 TW in 2030, according to the Global Solar Council [1]. Although silicon is the prevalent material worldwide, some alternatives appeared in recent years, such as organic or multi-junction cells, among others [2]. But there are still scenarios where power supply with these devices is far from the ideal case, like those indoors. In this context, Perovskite Solar Cells (PSC), known for their high absorption in the visible range and spectral tunability with material selection [3], may be a good choice [4]. Moreover, their efficiency can be further improved through metasurface engineering. High refractive index (HRI) dielectric nanostructures (e.g. Si, Ge, AlAs) are a good alternative to plasmonic nanostructures, due to their low ohmic losses in the visible and near-infrared spectral regions [5]. These HRI nanostructures have demonstrated the ability to perform a variety of functions such as phase tuners, directional filters, gratings, mirrors, etc. [6, 7]

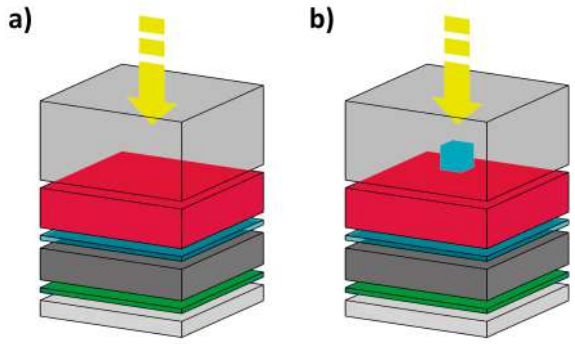

Figure 1: (a) Planar PSC reference composition. From top to bottom: silica (SiO_2), indium tin oxide (ITO) anode contact, poly(3,4-ethylenedioxythiophene) polystyrene sulfonate (PEDOT:PSS) as the Hole Transport Layer (HTL), FASI as active layer, fullerene (C_{60}) as Electron Transport Layer (ETL), and silver (Ag) as cathode. **(b)** Metasurfaced PSC with embedded dielectric on top of the ITO layer.

In this work, a novel formamidinium tin iodide ($FASnI_3$, or FASI) PSC was studied, intended to be used under indoor environments. The optical absorption in the photosensitive layer has been analyzed using the finite-difference time-domain (FDTD) method. The planar case (Fig. 1a) is taken as the reference starting point [8].

We investigated enhancement of absorption by embedding a dielectric metasurface into the former PSC (Fig. 1b), varying its geometry, location and material composition. By doing so, we disclosed which topologies were preferred to maximize the interaction of the field with the active layer, to provide light handling towards it and consequently increase the absorption. The factor chosen to discriminate against different structures was the optical efficiency (η), defined as in equation (1), in the range between 400 nm and 750 nm. In this equation, Abs(λ) is the spectral-dependent

absorption in the active layer, and $\mathrm{Irr}(\lambda)$ is the incident light irradiance, which corresponds to the LED luminaire in Figure 2. Using this irradiance as reference ensures that our optimization effort is effective for this indoor enhancement purpose.

$$\eta = \frac{\int_{\lambda_0}^{\lambda_f} \mathrm{Abs}(\lambda)\mathrm{Irr}(\lambda)\mathrm{d}\lambda}{\int_{\lambda_0}^{\lambda_f} \mathrm{Irr}(\lambda)\mathrm{d}\lambda} \tag{1}$$

In this contribution, we explored the case of a periodic array made of squared-base prismatic TiO_2 nanostructures (Fig. 1b) located on the ITO layer with a side base of 80 nm, demonstrating its feasibility to enhance efficiency for indoor environments by a 1.1 factor regarding the planar case, as shown in Fig. 2.

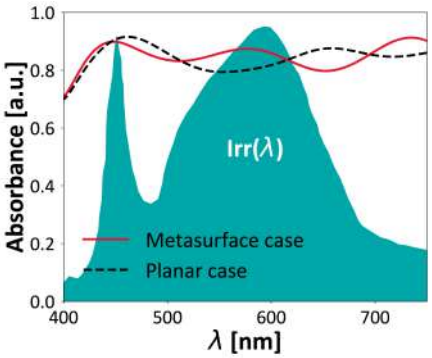

Figure 2: Absorbance spectra for the best case (red line) against the planar structure one (black dotted line). The LED luminaire is shown shaded in green for comparison.

Abstract: Recent advances in the monodispersity and ligand engineering of perovskite quantum dot dispersions have allowed the realization of high optical quality films amenable for integration in optical cavities. Rational and precise design of these resonators yields the formation of exciton-polaritons in quantum dot solids, opening new routes in optoelectronics.

Lead halide perovskite quantum dots (QDs) exhibit significant promise for optoelectronic applications, largely due to their bright and spectrally tunable photoemission characteristics. A recent breakthrough synthesis employing zwitterionic ligands has enabled the production of highly concentrated QD dispersions [1]. These dispersions can be processed into uniform films of controlled thickness that are free from scattering and display distinct excitonic transitions. The integration of these QD films into high-quality optical cavities has allowed for the first demonstration of strong coupling between confined photons and bound electron-hole pairs within a QD solid. [2] The resulting formation of hybridized exciton-polariton states leads to a fundamental reorganization of the system's optical properties. For instance, strongly coupled systems can absorb and emit light in spectral ranges where the uncoupled components show minimal optical activity [3]. This capability opens up opportunities for utilizing this interaction in various domains, including lasing, photodetection, catalysis, and chemistry.

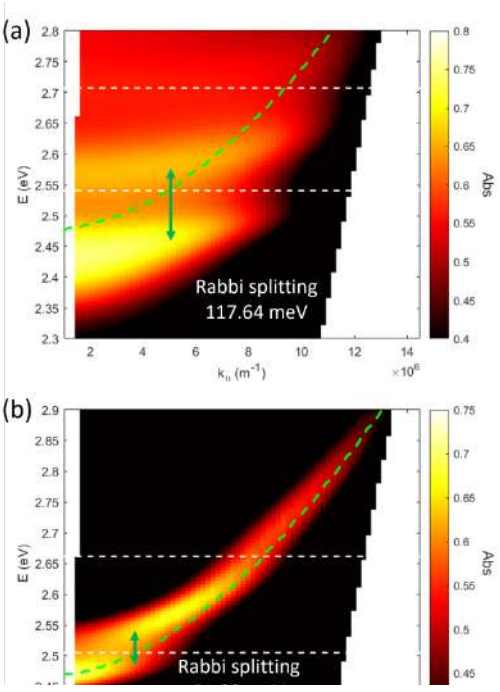

Figure 1 – Exciton-polariton energy dispersion relation for QD cavities capped with (a) PEA and (b) lecithin ligands

In this talk, we show that the coupling strength between QD excitons and cavity photons can be precisely controlled by adjusting the volume density of QDs within the film. To achieve this, we constructed two different optical resonators using QD films. These films were prepared from colloidal dispersions of CsPbBr3 QDs of similar size (approximately 6 nm in diameter), which were capped with two distinct zwitterionic ligands: C8C12-PEA [4] and lecithin [1]. The type of ligand used influences the spacing between particles in the QD solid. This

difference in spacing provides a way to manipulate the QD density in the film, and thus, the strength of the light-matter coupling. Figure 1 visually supports this, displaying the room-temperature absorption energy dispersion maps obtained from the two systems investigated. It is readily apparent that strong light-matter coupling was achieved in both cases, but with markedly different strengths. Our findings underscore the potential of employing ligand engineering as a tool to modulate coupling strength in QD polariton systems [5].
